## REPORT OF THE SAITHE (COALFISH) WORKING GROUP

Copenhagen, 23 - 29 April 1985

This document is a report of a working Group of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council. Therefore, it should not be quoted without consultation with the General Secretary.

| R Cook | U.K. |
| T Jakobsen | Norway |
| B W Jones | U.K. |
| A Kristiansen | Faroes |
| B Mesnil(Chairman) | France |
| K Nedreaas | Norway |
| J B Perodou | France |
| H H Reinsch | Federal Republic of Germany |

Mr. K. Hoydal attended the meeting as ICES Statistician.

### 1.2 Terms of Reference

At the 72 nd Council Meting it was decided (C.Res. 1984/2:4:12) that the Saithe (Coalfish) Working Group should meet at ICES Headquarters from 23-29 April 1985 to assess catch options for 1986 and 1987 for the saithe stocks and for cod and haddock in Faroese waters inside safe biological limits.

In addition it was decided (C.Res.1984/4:13) that, as other North Sea stock Assessment Working Groups, the Group should:

1) provide quarterly catch at age and mean weight at age data as input for the Multispecies VPA for the period 1974 to 1984 and, as far as possible, for earlier years back to 1963 for the North Sea stocks,
2) evaluate the evidence of natural mortality for the oldest age groups,
3) assess the effects of applying the estimates of total natural mortality calculated by the Multispecies Working Group,
4) provide advice to the Multispecies Working Group on the geographical distribution of saithe by age group and quarter, and on the proportions of these which would be predators on North Sea prey species.

### 1.3 Landings of Saithe in the North East Atlantic

Historical record of catches from the saithe stocks dealt with by the Working Group are given in Table 1.1

## 2 NORTH-EAST ARCTIC SAITHE (Sub-areas I and II)

### 2.1 Landings (Table 2.1, Fiqure 2.1.A)

The provisional estimate of landings in 1984 is 150,315 tonnes which is 8,000 tonnes less than in 1983.

### 2.2 Age Composition (Table 2.2)

The age composition from Norwegian landings in 1983 was revised. There was an increase in the numbers for all age groups older than 5 years, which was caused mostly by redistribution of the trawl catches according to log-book data. Provisional age compositions for 1984 were available from the Federal Republic of Germany and

Norway, accounting for $99 \%$ of the landings.

### 2.3 Weight at Age (Table 2.3)

For 1960-79, a fixed set of weights at age are used both for catch and stock. For 1980-84, the annual weights at age in the catch for each year are used for catch and stock weights.

The weight at age data used in the yield per recruit and were derived by averaging the weights at age for the years 1982-84.

### 2.4 Fishing Mortality and Stock Size Estimate from VPA

### 2.4.1 Estimates of fishing mortality

The assessment of the 1984 Working Group was based on the assumption that fishing mortalities had been stable from 1980 to 1983. The background for this was the development in catches by different gear categories in recent years, (Figure 2.2) and a separable VPA which showed indication of a change in the exploitation pattern since 1980. The reported catches in 1984 were 24,000 tonnes in excess of the catches predicted by the 1984 Working Group . The prediction for 1984 split on gears showed that most of the difference was in the trawl catches, where the age groups 3 and especially 4 had been caught in much larger numbers than predicted. This is in good accordance with the distribution of the trawl catch by area and season which shows that the main increase had occurred in summer in the southern part of the area. Judging by the catch data and the discrepancies with the prediction, there seems to have been an increase rather than a shift in the effort by the trawlers. To account for this in the VPA, fishing mortality on age 3 and 4 in 1984 was increased substantially compared to the recent years.

Effort and cpue for the Norwegian trawlers (Table 2.6) have so far been of little use to the assessment. Data for 1984 were not available at the time of the working Group meeting. The level of fishing mortalities on the other age groups were therefore kept approximately at the 1980-82 level.

There is evidence of lower fishing mortalities on the oldest age groups after 1980 (Table 2.4). A level of less than 0.2 is indicated, but in view of the large year to year variation in the level of these values in the past, fishing mortality at age 14 for 1981-84 was reduced only from 0.35 to 0.30 .

### 2.4.2 Spawning stock biomass and recruitment

Estimates of spawning stock biomass are given in Table 2.5 and Figure 2.1.B. There is a decline from 1970 onwards, to 143,000 tonnes in 1981, the lowest observed spawning biomass in the time series. The values in recent years are somewhat higher than the 1984 Working Group estimates, and the main reason for this is the revision of the 1983 catch at age data.

Estimates of stock numbers at each age are given in Table 2.5, and recruitment at age 1 is plotted in Figure 2.1.B. The 1978 year class is as large as those in 1973 and 1966-68, however the more recent year classes, from 1979-81, are amongst the lowest in the period reported.

### 2.5 Yield per Recruit

The $Y / R$ curve is given in Figure 2.2.C. It was calculated using the 1984 exploitation pattern and the 1982-84 average weight at age data (Table 2.7.). Current exploitation ( $\bar{F}_{3-8}$ unweighted) at $F$ $=0.59$ is in excess of $\mathrm{F}_{\max }=0.30$ and $\mathrm{F}_{\mathrm{O-1}}=0.18$.

## 2. 6 Catch Predictions

The data used for catch predictions are given in Table 2.7. It was decided to use recruitment approaching the recent low level ( $\mathrm{R}_{1}=$ $200 \times 10^{6}$ ) rather than the long-term average $\left(R_{1}=318 \times 10^{6}\right)$. The predicted catches for 1986 will to a large extent depend on the size of the year classes 1982-84 and possibly represent low estimates.

Any major changes in the exploitation will most likely be caused by the Norwegian trawlers. Effort on North-East Arctic saithe may be reduced if catch rates are higher in the North Sea or if they are given higher quotas on Arctic cod and haddock. However, such changes appear to be of less importance than recruitment for the prediction. In view of this, and lacking information indicating future changes in the exploitation, the 1984 fishing mortalities were used as basis for the prediction.

Predicted catches and stock biomasses for 1985 and for a range of exploitation levels in 1986 are given in Table 2.8. Predicted yield in 1986 and the spawning stock biomass for 1987 are shown in Figure 2.1.D. Assuming that exploitation continues at the 1984 level, catches in 1985 and 1986 are predicted to be 128,000 tonnes and 126,000 tonnes, respectively. The spawning stock will decline to a level of less than 100,000 tonnes in 1987, unless fishing in 1986 is reduced.

### 2.7 Comments on the Assessment

The problems concerning the assessment of North-East Arctic saithe are lack of recruitment estimates, useful effort data, and other fishing independent data, and inadequate sampling, especially of the older fish. Last year's log-books from trawlers will normally not be available at the time of the meeting. The log-books are used to reallocate catches to fishing areas and the changes from the preliminary statistics may be substantial. The current tendency of variation in the trawl fishery represents a source of
error in the predictions.

## 3 NORTH SEA SAITHE (Sub-area IV and Division IIIa)

### 3.1 Landings (Table 3.1)

Landings of saithe from the North sea in recent years have been in the range 120,000-175,000 tonnes. Revised figures for 1983 indicate that the official landings were 157,000 tonnes, slightly lower than that estimated at the 1984 Working Group meeting. The Working Group estimate of landings for 1983 is 165,500 tonnes, however, and this figure has been used in assessments.

Provisional landings reported for 1984 including industrial bycatch amount to $172,000 \mathrm{t}$. The working Group estimate for the same year is higher at 200,000 tonnes and has been used in the assessment.

### 3.2 Age Composition (Table 3.1.1)

Age compositions for 1983 were revised in line with updated national data. For 1984 age composition data were available for $99 \%$ of landings from the following countries: Denmark, England, France, Federal Republic of Germany, Norway, and Scotland.

The total international age composition was obtained by summing the human consumption compositions, raising this sum to total human consumption landings and then adding the industrial bycatch.

### 3.3 Weight at Age (Table 3.2)

Weight at age data were provided by all countries providing age composition data. Catch at age or weight at age were adjusted to eliminate SOP discrepancies as appropriate.

As noted in earlier reports weights at age prior to 1979 are unreliable and are simply average values.

Weight at age used in predictions are mean values for the years 1982-84.
3.4 Fishing Mortality and Stock Estimates from VPA
3.4.1 Estimates of fishing mortality

Trial runs of VPA using last year's input Fs indicated that the exploitation pattern changed after 1979 when the Norwegian fleet effort increased substantially (see Table 3.5). The VPA was therefore tuned by setting the input Fs to the mean value for the period 1980-1982. These values can be seen in Table 3.3. where the value for age group 1 has been adjusted to give recruitment at age 1 in 1984 of about 260 million fish which corresponds to mean recruitment for the years 1974-1982.

A cpue index of spawning stock biomass was available from French data. This index (Table 3.6) is plotted against spawning stock biomass from VPA (Fig. 3.2) and suggests the VPA value is too low. To overcome this would require lower input Fs. There is however no independent evidence to support such a change and the total international effort in French units (Table 3.5) is little changed from recent years. Partial fishing mortality for France plotted against effective French effort (Table 3.5 and Fig. 3.3) shows the input Fs are consistent with effort data.

The exploitation pattern chosen as input for 1984 generates an exploitation pattern for 1983 which is noticeably different for older fish. This change is probably due to the Norwegian catch in 1984 which unlike 1983 was taken predominantly in the latter part of the year and therefore took proportionately more young fish.

### 3.4.2 Spawning stock biomass and recruitment

Spawning stock biomass and recruitment are given in Table 3.4 and are plotted in Fig. 3.1B. Recruitment has been increasing following the 1978 year class. The value for the 1982 year class may be too high but indications from the Norwegian industrial bycatch suggest that the 1982 year class is above average. The results of Norwegian acoustic surveys in 1984 and 1985 suggest that the 1981 year class is also above average (Smedstad, unpublished data).

Spawning stock biomass has been in the region of 150-250 thousand tonnes in recent years and appears likely to increase due to improved recruitment in recent years.

### 3.5 Yield per Recruit

Input data for yield per recruit are shown in Table 3.7. The analysis in this report indicates that present fishing mortality rate is in excess of both $F_{\max }$ and $F_{0.1}$ (Table $3.8,3.9$ and $F i g$. 3.1C).

Yield per recruit analysis as applied to the North Sea stock has a history of being unreliable primarily due to the uncertainty of the position of current $F$ in relation to $F_{\max }$. In 1982 for example the assessment suggested that $F$ was in excess of $F_{\text {max }}$. The 1983 and 1984 assessments imply that for the same years $F$ was approximately equal to $F_{\text {max }}$. This change was partly responsible for the large change in the TAC between 1983 and 1984. The present assessment now implies that $F$ is once again above $F_{\text {max }}$ despite the
fact that there has been no major change in the level of exploitation as far as can be ascertained from effort data and mean $F$. It seems unlikely therefore, that the present analysis is capable of showing whether or not the stock is overfished in terms of yield per recruit.

### 3.6 Catch Predictions

Input data for catch predictions are given in Table 3.7. The input exploitation pattern is that for for the period 1980-1982. Assuming no change in fishing mortality rate in 1985 the predicted catches for 1985 will be 259 thousand tonnes which is above the agreed TAC of 200,000 tonnes. Table 3.8 shows the effect of this catch on the management options in 1986. Table 3.9 makes the equivalent predictions based on the catch in 1985 being restricted to the TAC figure. The effect on yields and SSB for these two predictions are given in Fig 3.1.D.

### 3.7 Quarterly Age Composition Data

There was insufficient time at the meeting to construct a catch at age matrix on a quarterly basis as requested by the Multispecies Working Group. It was agreed that national data would be sent to the Marine Laboratory, Aberdeen for processing along with other roundfish species, on the same basis described in the 1985 Roundfish Working Group report. The summary below shows the availability of data. It should be noted that for the earliex years the age composition data become increasingly unreliable and a large proportion of the catch was not sampled.

ENGLAND: Data are available for all quarters though the level of age sampling is rather too low to split the annual catches down to a quarterly level in some years.

FRANCE: Data are available by quarter from 1976 or 1977 onwards.

FEDERAL REPUBLIC of GERMANY: Catch data are available by quarter from 1974 onwards. No weight at age data are available by quarter.

NORWAY: Quarterly data are available from 1980 onwards and can be split down to fleet level though it is felt that the sample size is rather too small to do this adequately. It is possible to split catches prior to 1980 roughly by quarter by assuming seasonality in the catches by certain sub-fleets.

SCOTLAND: Data are available from 1972 onwards by quarter(or month) and can be disaggregated down to fleet level.

DENMARK and USSR: These countries have both taken large catches from the North Sea during the period in question. It is not known if quarterly data can be obtained from these nations.

## 3. 8 Geographical distribution by age group of North Sea Saithe

O-group saithe are found pelagically in the North sea in spring and early summer. The distribution is mainly north of $58^{\circ} \mathrm{N}$ and normally the highest concentrations are found along the eastern part of the North Sea plateau. On the Norwegian west coast 0 -group saithe are found in shallow waters from May and by the end of June most of the year class seems to have reached the coast. The pattern appears to be the same on the British side of the North Sea. After June, O-group saithe are normally not found in large concentrations outside the coastal areas, but exceptional years (e.g. 1967) are known.

The saithe stay on the Norwegian west coast, for 2-3 years. Purseseine catches which are taken mostly at depths of $50-100 \mathrm{~m}$, are usually dominated by $2-3$ year old fish. Migration across the Norwegian deep mostly takes place when the fish is three years old. This is reflected in the saithe by-catches from the industrial trawl fishery, where 3 year old fish usually are much
more numerous than 2 year olds.

Immature saithe, mostly 3 and 4 year old fish, tend to be concentrated along the eastern side of the North sea plateau between $57^{\circ} 30^{\prime} N$ and $61^{\circ} N$, and east of $2^{\circ} \mathrm{E}$. Concentrations are also found in the shetland area, but the fish there are usually somewhat larger. Immature saithe are also found more or less regularly all over the North sea north of $57^{\circ} \mathrm{N}$, but usually not further south.

The saithe in the North Sea mostly reach maturity when they are 5 years old. The spawning grounds are found near the edge of the shelf at about 200 m depth and extends more or less continuously from west of Shetland to the Viking Bank. There appears to be a northeastward spawning migration along the Shelf west of Shetland which may continue east and southeast as far as the Viking Bank. There may also be a spawning migration from the south in the eastern part of the North Sea. The behaviour of the mature fish outside the spawning season appears to be variable. The concentrations are probably less dense and there are no grounds where they occur regularly before towards the end of the year.

## 4 ICELANDIC SAITHE

Landings of saithe from Division Va amounted to about 63,000 tonnes in 1984, $96 \%$ of which being taken by Icelandic vessels (Table 4.1).

Age composition of Icelandic landings was communicated to the Working Group by telex and was used to update the datafiles (Tables 4.2-4.4).

In the absence of a representative from the country which is primarily concerned with monitoring and fishing this stock the Working Group was lacking the essential background information required for a reasonable assessment of the stock and fisheries. They were not in a position to discuss the trial assessment
carried out at the Icelandic Institute and thus felt unable to endorse it.

## 5 WEST OF SCOTLAND SAITHE (Sub-area VI)

### 5.1 Landings

Landings of saithe from Sub-area VI are given in Table 5.1 and are shown in Figure 5.4.

With a peak of 36,000 tonnes in the period 1974-76 the catches decreased. to 20,000 tonnes in 1979, and then remained more stable around this value. Landings in 1984 are estimated to be 20,300 tonnes.

### 5.2 Age Composition (Table 5.2)

Age compositions for 1984 were provided by England, Scotland and France and they account for $93 \%$ of the total landings. Minor corrections were made to the catch at age data for 1982 and 1983.

### 5.3 Weight at Age (Table 5.3)

Weight at age data for 1984 were provided by England, France and Scotland. The estimated mean weights at age for 1984 shown in Table 5.3 are similar to previous years.

### 5.4 Effort and Cpue Data

Catch and effort data for the French fleet were used as in previous years to compute an index of effective catch per unit effort, by fitting a multiplicative model correcting for area and
month effects. This index is given in Table 5.6 and was used to derive an estimate of total international effort. In spite of a slight increase in 1983, the series shows a pronounced decreasing trend which is supported by information on the fleets given in the Appendix.

Another abundance index, computed in the same way, was fitted to the French catch and effort data in the first quarter of each year, when the fleet directs its effort towards adult saithe. This index (Table 5.6) should thus indicate the relative levels of spawning stock biomasses, although the value for 1975 is questionable.

## 5. 5 Fishing Mortality Estimates

As already mentioned in previous reports, he general level of fishing mortality for this stock has decreased to such a degree that VPA estimates do not demonstrate any convergence and are thus highly dependent on input values.

To account for the decreasing trend in effort, input values for 1984 should be set still lower than the recent level, implying a further loss of reliability of the VPA results. Attempts to define a set of acceptable input values proved unconclusive.

Trial runs were made using SVPA with $S$ terminal = 0.4. (Fig. 5.1). Table 5.7 shows the log-catch-ratio residual table for the run which gave values of $F(I)$ which best reflected the trend in French effort data. The residuals for ages $10 / 11$ and $11 / 12$ in the years 1983/84 are particularly large and suggest problems in the data.

The problem was further complicated this year due to sampling or ageing deficiences on age groups 11 and 12, and it was not considered possible to correct for this adequately.

Consequently, it was preferred not to rely on an analical assessment and the VPA results (Tables 5.4-5.5) are given for indication only.

### 5.6 Yield per Recruit

Because of failure of the VPA to produce satisfactory estimates of $F$ at age in relation with M values, and in the absence of any evidence on changes in the exploitation pattern, it has been felt useless to recalculate a yield-per-recruit curve. Reference is thus made to last year's report.

### 5.7 Catch Predictions

Since no reliable estimate of stock size at age is available for 1984, the usual catch forecast could not be computed.

Referring to the time sexies shown in Figure 5.4 (corrected from last year's report) for the last decade, when data are considered of acceptable reliance, it can be seen that since 1978 landings have fluctuated in the range $20,000-27,000$ tonnes, and that recruitment is at comparatively high levels. Spawning stock biomass shows a slow decreasing trend in spite of a continuously decreasing fishing effort. This effect is partly due to the high sensitivity of a non-converging VPA to uncertain input terminal Fs, and partly to variable mixture with North Sea spawners, as explained in the next section.

Further indications are given in the time series plots of effort and CPUE based on French data (Fig. 5.2) which show that the reduction of fishing effort has occured along with a pronounced increase of catch rates which were stable at high levels in the last three years.

All the available evidence suggest that this stock is not in any immediate danger.

In order to derive an estimate of status-quo catches, use was made of available CPUE data which are plotted vs. fishing effort in Figure 5.3. Assuming a linear relationship in the range of observed fishing efforts, one arrives at the regression equation: $Y=0.12 \mathrm{x} \mathbf{f}+4.07$. If fishing effort is to remain at the 1984 level, which is likely to occur for the fleets presently engaged in this fishery, landings may be expected to amount to 20,000 tonnes. Using the equation fitted to the data, one may simulate the effects of slight variations of the fishing effort which should produce results in the range $18,000-20,000$ tonnes.

### 5.8 Comments on the Assessment

If fishing pressure is to remain at the present low level in the near future, assessment of the West of scotland saithe stock is likely to be subject to the acute problem encountered this year and alrea dy expected last year, namely that the usual analytical approach fails to provide reliable estimates of fishing mortalities and stock numbers at age. As a consequence, alternative methods should be used in order to try and forecast status-quo catches.

The absence of fishery independent data, particularly of abundance index at age time series, makes the use of some of the short-cut methods recommended by the Methodology Working Group of lesser interest, since they would imply mere averages. Solutions might be found in a more refined treatment of CPUEs by age group or over discrete ranges of age groups.

Another question arises from fishery indications that the adult concentrations of saithe along the shelf edge to the northwest of the British Isles are found in continuity from the west of Hebrides up to the northwest of Shetland, well apart the IVa-VIa limit, and no quantitative evidence is available on the relative
contribution of these spawners to the recruitment in the North Sea and in the West of Scotland respectively.

If there is evidence that the West of Scotland and North Sea spawning areas are not clearly separated then or assessment purposes, both stocks might thus be combined, which might eliminate some of the problems with VPA. There is no doubt however that for management purposes they should remain as separate units with, for example, regional TACs set.

## 6 DEMERSAL FISHERIES ON THE FAROE PLATEAU IN 1984

### 6.1 Introduction

ACFM concluded on the basis of last year's assessment (Coop.Res.Report 131) that....there is no doubt that the effort .... has increased since 1977, especially by virtue of the increased number of single boat and pair trawlers. In addition, technical improvements and improved knowledge of the grounds by new skippers are assumed to have increased the fishing power of the trawling fleets...... ....Despite diffculties in splitting the effort between the three species (cod, haddock and saithe) it is evident that a major built up of overall fishing effort, especially in the trawl fisheries has taken place in the demersal fisheries at the Faroes.

### 6.2 Trends in 1984

Because of problems in connection with a change in computerisation of logbook data, no effort estimates for the larger vessels (trawlers with more than 400 HP and other vessels above 100 GRT) were available to the Working Group.

The following qualitative evidence about changes in 1984 is based on the analyses of the Faroese Board of Fisheries. Two new trawlers have entered the fishery in 1984 (class >2000 HP). In 1985 an expected number of 5 will enter (class 1000-1999). The two trawlers entering in 1984 have mainly been exploiting the deep waters (redfish, blue ling), whereas the 5 entering in 1985 are expected to fish for saithe and to a lesser extent for cod and haddock. Because of a cut-back in the quotas in Icelandic waters 5 trawlers in the $>1000 \mathrm{HP}$ class have been fishing in Faroe waters throughout the year in 1984, and thus increased the fishing pressure on the demersal stocks, especially saithe. Table 6.1 gives a review of the development in recent years and a more general description of the fishery at the faroes is given in the Appendix.

Evidence from the fishery seems to indicate that the demersal trawl effort has been more directed towards saithe in 1984, compared with 1983.

It should be noticed, that the trawlers (and all other gears in principle) have been discouraged from fishing fish below certain size limits. For saithe this has been achieved by a system of closing areas with high percentages of young fish in the catches on short notice and by refusing to accept fish below 60 cm at the fish factories.

### 6.3 Further Analysis of the Detailed Effort Data for 1973-1983

The analysis of the detailed FISKHAG effort data bank has been continued. An attempt to correct for directivity was made by including an area factor. This attempt seems, however, not to have solved the problem. Previously, corrections for seasonality have been introduced. On the basis of statistical analysis of data disaggregated on 22 fleet units, the data were grouped in

| long line boats | $<100$ GRT |
| :--- | :--- |
| long line ships | $>100 \mathrm{GRT}$ |
| Trawlers | $<400 \mathrm{HP}$ |
| Trawlers | $400-999$ |
| Trawlers | $>1000$ |
| Pairtrawlers |  |

The variance of que estimates from gill-net and handine is very high, and this is also the case of the cpue estimates from the open boats and these series have not been treated any further. The pairtrawler series covers only 4 years and is therefor of limited use at present. The cpue was estimated from the multiplicative model:

```
ln(cpue) is a function of rectangle
    vessel class
    season
    + error term
```

In Figure 6.1 some of the annual cpue indexes are plotted. These values have been backtransformed by the following equation.

```
exp(model + mean square divided by 2)
```

are plotted against year.

Effort estimates can then be derived by dividing the catch by this cpue estimates. Table 6.2 summarises the cpue estimates for the main species exploited by different vessel categories.

It should be noted in Fig. 6.1 that there is an increase in haddock cpue for the trawlers in 1983. This is probably an indication of the change in directivity in 1983.

### 6.4 The Use of Effort Data to Tune VPAs of Cod and Haddock

As no effort data were available for most of the larger vesselgroups for 1984, it was decided to base an evaluation of the trend in effort on the long line ( $<100$ GRT) only. This can be used for cod and haddock, but as this gear does not catch saithe, there is no way to use the 1984 data for saithe.

The long line data were used in the following way: Paxtial Fs for long line were calculated (Table 6.3 and 6.4 ) and the average $F$ for ages 3-8 for the converged part of the VPA was regressed against the effort estimates derived from the model. A VPA was run, which brought the 1981, 1982, 1983 and 1984 points close to the line.

The results for cod and haddock are shown in Figures 6.2 and 6.3. and are the basis for the VPA finally accepted. It should be noted that the residuals are quite high and this probably precludes straightforward predictions based on the effort data.

7 FAROE SAITHE (Division Vb)

### 7.1 Landings (Table 7.1, Figure 7.1A)

Preliminary reports indicate that the landings in 1984 were 54,417 tonnes which represents an increase of $39 \%$ above the 1983 landings of 39,178 tonnes and continues the trend of increasing landings since 1980. The 1980 year class is very abundant and has dominated the landings in 1984 accounting for $39 \%$ of the landed weight.

### 7.2 Age Composition (Table 7.2)

Age composition data for 1983 from Faroes, France, Federal Republic of Germany, and Norway were updated and new data for 1984 were available for Faroes and the Federal Republic of Germany.

## 7. 3 Weight at Age (Table 7.3)

Average weight-at-age data for fish in the catch were provided for 1983 and 1984, and these data were corrected for SOP discrepancies. Catch weight-at-age data were also used for stock weight at age for determining stock biomass. Weight-at-age data used in the catch predictions have been obtained by averaging the values for the years 1982-84.

### 7.4 Fishing Mortality and Stock Values from VPA

### 7.4.1 Estimates of Fishing Mortality

Recent developments in the Faroese fisheries have been described in Section 6. No fishing effort data were available for 1984 for the fleets which fish for saithe and therefore it was not possible to attempt any of the effort based VPA tuning methods. As mentioned in section 6 there has been a trend of increasing fishing effort on saithe by the Faroese fleets due partly to an overall increase in fleet size and partly to a greater proportion of the available effort being directed towards saithe. In addition a reduction in fishing opportunities at Iceland has resulted in some diversion of effort from that area to Faroe.

In addition to an overal'l tren'd of increasing effort there appears to. have been some concentration of fishing in 1984 on the very abundant 1980 year class resulting "in a changed exploitation pattern in that year. The alternative explanation of the large
catches of 4 -year-olds in 1984 would be that the 1980 year class is far larger than any other year class on record : using an average $F$ value of 0.17 on age-group 4 in 1984 would give a year class strength at age 1 of 145 millions compared to an average abundance of 37 millions. The alternative of increased fishing mortality on age-group 4 is considered to be the more likely one.

The VPA input $F$ values for 1984 have therefore been chosen to reflect these changes which are believed to have taken place in the fishery. These values and the back-calculated values for earlier years are given in Table 7.4 and Figure 7.1A.

### 7.4.2 Spawning Stock Biomass and Recruitment (Table 7.5 and Fiqure 7.1B)

After a succession of abundant year classes (1966-69) the subsequent year classes up to that of 1976 followed a declining trend. More recently the 1978 and 1980 year classes have been very abundant although the size of the 1980 year class cannot yet be accurately determined.

Spawning stock biomass increased following the trend of increasing recruitment in the $1960^{\prime}$ s reaching a peak level in the mid-1970's. Subsequently spawning stock biomass declined until 1982 after which the declining trend has halted with the recruitment of the 1978 and 1980 to the spawning stock. It should be noted that the recent abundant year classes are making less of a contribution to the spawning stock than those of comparable size in the 1960's due to the higher levels of fishing mortality now prevailing.

### 7.5 Equilibrium Yield

Data used in the calculation of equilibrium yield are given in Table 7.6. The exploitation pattern used is based on the average for the years 1980-82 but the $F$ value for the three-year-olds has been reduced to take into account recent restrictions placed on
the landing of this age-group. This exploitation pattern differs from that used in the catch prediction (see below).

The curves of equilibrium yield and equilibrium spawning stock biomass for average recruitment at age 1 of 37 million are given in Figure 7.1C. The current fishing mortality level is assessed to be $F_{(4-8)}=0.4$ which is close to the value of $F_{\max }=0.42$. The value of $\mathrm{F}_{(0.1)}$ is 0.19 .

### 7.6 Catch Prediction

Input data for the catch prediction are given in Table 7.7. Year classes 1982 and later are assumed to be of average abundance (= 37 million for the years 1963-81).

The exploitation pattern in 1984 appears to have been distorted from the average pattern in recent years due to a concentration of fishing on the very abundant 1980 year class. It seems likely that this situation may continue, though probably to a lesser extent, into the prediction period. The exploitation pattern used for the prediction for 1985 and 1986 has been derived as follows: an average exploitation pattern for the years $1980-82$ was calculated, the $F$ on age-group 5 was increased from 0.19 to 0.3 to allow for some concentration of fishing on the 1980 year class, the resultant $F$ array was then raised to give $F_{(4-8)}=0.4$, and the $F$ on age-group 3 was reduced to 0.03 in view of the restrictions on landings of this age group.

Results of the catch predictions are given in Table 7.8 and Figure 7.1D. For unchanged average fishing mortality in 1985 landings are expected to be 45,000 tonnes, and in 198644,000 tonnes. Spawning stock biomass is expected to increase in 1985 when the 1980 yearclass recruits to the spawning stock but in 1986-87 will decline again to just below the 1984 level.

## 8 FAROE COD

### 8.1 Faroe Plateau Cod

### 8.1.1 Landings (Table 8.1)

Preliminary catch figures indicate a total catch in 1984 of 37,318 tonnes from the Faroe Plateau stock. This is a decrease of 822 tonnes or $2.2 \%$ compared to 1983. Non-Faroese landings of cod from the Faroe Plateau were less than $1 \%$ of the total landings. The total landings in 1960-84 are shown graphically in Figure 8.1.A.

### 8.1.2 Age Compositions (Table 8.3)

Age compositions were provided only for the Faroese landings. The Norwegian and United Kingdom (England) catch at age was estimated using the age composition in the larger Faroese long liners' landing. The Federal Republic of Germany data were distributed according to the age composition of catches by large Faroese trawlers (more than 1,000 HP).

### 8.1.3 Weight at Age (Table 8.4)

Weight at age date for 1984 were provided by Faroes. They gave a sop discrepancy of $2 \%$. The weight at age data for 1983 used in past year's report were revised in accordance with new information provided by Faroes. These gave a sop discrepancy for 1983 of $3 \%$ compared to $10 \%$ by the data used in last year's report. For the predictions the average weight at age data for the period 1981 1984 were used.
8.2 Results of VPA (Tables 8.5 og 8.6$)$

### 8.2.1 Fishing mortality

The fishing mortality for 1984 was estimated using the effort data for Faroese long liners. The procedure is described in Section 6.3. Fs for ages 1 and 2 were scaled to reflect the general increase in effort. Fishing mortalities as calculated from VPA are given in Table 8.5, together with input values for 1984 and for the oldest age group in each year. The trend in fishing mortality is shown graphically in Figure 8.1.A.

### 8.2.2 Spawning stock biomass and recruitment

Estimates of spawning stock biomass (age groups 4 to $10+$ ) are given in Table 8.6 and shown graphically in Figure 8.1.B. The estimated number of recruits at age 1 for the year classes 1961-82 are given in Figure 8.1.B. The 1982 and earlier year classes were taken a calculated by the VPA. As no reliable information on the abundance of the 1983 and 1984 year classes is available these have been assumed to be equal to the average calculated for year classes 1961-81 (22.7 million at age 1). The current assessment confirm that the 1978 year class is above average and also that the 1981 and 1982 are above average.

## 8.3 yield per Recruit

Curves of yield per recruit and spawning biomass per 1 year old recruit are plotted in Figure 8.1.C, using the data given in Table 8.7. The estimated fishing mortality in $1984\left(F_{(3-8)}=0.58\right)$ is larger than $F_{\max }=0.34$ and $F_{0.1}=0.16$.

### 8.4 Catch Predictions

Data used in the catch predictions are given in Table 8.7, and the results are given in Table 8.8 and plotted graphically in Figure 8.1.D. If fishing mortality is maintained at the 1984 level $\left.\left(F_{3-8}\right)=0.58\right)$, landings of 35,000 tonnes are predicted in 1985 and of 33,000 tonnes in 1986.

### 8.5 Faroe Bank Cod (Table 8.2)

The landings of cod from the Faroe Bank are presented in Table 8.2. No attempt was made to assess this stock.

## 9 FAROE HADDOCK

The assessment was made for the stock of haddock for the total Faroe area (Division Vb).

### 9.1 Landings (Tables 9.1 and 9.2, Figure 9.1.A)

The total landings in Divisions Vb1 (Faroe Plateau) and Vb2 (Faroe Bank) were in 1984 12,400 tonnes. This is a decrease of 494 tonnes or $3.7 \%$ compared to 1983. The landings were almost exclusively by Faroese vessels.

### 9.2 Age Compositions (Table 9.3)

Age compositions data for the Faroese landings from the Faroe Plateau were provided. These were used to calculate the age composition for the total landings of Faroese vessels from the Faroe Plateau and Faroe Bank combined. The Norwegian and United Kingdom (Scotland) catch at age was estimated using the age composition in the larger Faroese long liners' landings. Because of minor updates to the 1982 and 1983 catch data there were also

```
minor revisions of the }1982\mathrm{ and 1983 catch at age arrays.
```

### 9.3 Weight at Age (Table 9.4)

Weight at age data for 1984 were provided by Faroes. They gave a SOP discrepancy of $6 \%$. In the predictions the average weight at age data for 1981 - 1984 were used.

## 9. 4 Results of VPA

### 9.4.1 Fishing mortality

The fishing mortality for 1984 was estimated in the same way as for cod in the Faroe area, using the effort data for Faroese long liners (See Section 6.3).

Estimates of fishing mortality in each year calculated by the VPA are given in Table 9.5, together with the input values for 1984 and for the oldest age in each year. The trend in fishing mortalities is shown graphically in Figure 9.1.C.

### 9.4.2 Spawning stock biomass and recruitment

Spawning stock biomass (Table 9.6, Figure 9.1.B) was relatively stable at about 60,000 tonnes up to 1974. Subsequently, the spawning stock benefitted from recruitment of the abundant 1972 and 1973 year classes, which increased the spawning stock to about 110,000 tonnes. By 1981, the spawning stock had returned to a lower level. The estimated numbers of recruits at age 1 are given in Table 9.6 and Figure 9.1.B.

### 9.5 Yield per Recruit

The yield per recruit curve given in Figure 9.1.C has been calculated using the exploitation pattern assumed for 1984 and the mean weight at age for the years 1981-84. The present level of $F_{(3-8) u}=0.31$ is higher than $F_{0.1}=0.2$.

It should be noted that the continuing depressed catch levels for this stock at present not is due to an excessive fishing mortality level, as judged from the $Y / R$ curve, but is caused by the very low recruitment levels which have persisted since 1977. There are, however, signs that the 1982 year class is back to normal.

### 9.6 Catch Predictions

Catch predictions were made using a recruitment level of 37.2 million 1 year old fish (average of year classes 1966-80) for the year classes 1983-86. The stock estimate at 1 January 1985 for year classes 1982 and earlier was taken from the VPA. The input data are given in Table 9.7. The exploitation pattern assumed for 1985 and 1986 is based on the 1984 exploitation pattern. The results are given in Table 9.8 and Figure 9.1.C. If fishing mortality is maintained at the 1984 level $\left(F_{(3-8)}=0.31\right)$, landings of 12,000 tonnes are predicted in 1985 and of 14,000 tonnes in 1986.

## 10 OTHER ITEMS

## 10. 1 The Problem of Single Nation Stocks

As a result of the introduction of exclusive fishing zones, some stocks dealt with at the Saithe Working Group are now exploited almost entirely by the coastal state and may be regarded as single nation stocks. The scope for broader scientific involvement in the
assessment of these stocks has as a consequence been much reduced because the source data required for the assessment and local knowledge of the fisheries reside in the hands of scientists from the coastal state. Working Group members from countries with this type of stock therefore find themselves somewhat isolated at the meeting in having to undertake the major share of the assessments for these stocks. Equally members from countries which no longer fish these stocks have little to contribute either in terms of data or knowledge of the present state of the fishery. When there is no Working Group member from the coastal state of a single nation stock the Working Group has had difficulty in carrying out the assessment.

The Working Group discussed the problems outlined above and expressed the view that:

1) because data for the assessment of single nation stocks come from a single fisheries institute, data could be presented to the Working Group at a more advanced stage of analysis or working papers could be circulated in advance of the meeting. This would keep the working Group better informed and would afford more time for effective scientific discussion.
2) the catch prediction methods as applied to single nation stocks may not be adequate. In particular, since the TAC approach to fishery management is not normally applied to these stocks the traditional catch option prediction is perhaps redundant. The Working Group felt that because these single nation stocks are essentially part of a multispecies demersal fishery and given the inherent advantages of having single nation exploitation it is perhaps time to consider more sophisticated assessment techniques appropriate for multispecies management, particularly the technical interaction between subfleets.

As a result of the discussions of the problems of single nation stocks questions were raised as to the suitability of the grouping of the present stocks into a single working Group. It may be more appropriate for example to assess the North sea and West of Scotland stocks within the North Sea Roundfish Working Group and the North-East Arctic Stock within the Arctic Working Group. This would would leave the Faroese and Icelandic stocks which could be dealt with in a new working Group forum. If such a redistribution was adopted, it should be borne in mind that the broader scientific discussion of single-nation stocks would be reduced.

The meeting noted the somewhat anomalous situation that the Icelandic saithe stock is assessed in isolation from cod and haddock. Perhaps it would be desirable to consider assessing all the Icelandic demersal stocks together where they form part of the same multispecies fishery.

### 10.2 Sugqestions for Assessment Proqrams

For a number of stocks the need has been expressed for computing partial $\mathrm{F}^{\prime}$ s at age for those fleets for which effort data are available. If fleet catch age compositions could be stored in the ICES database then a program to calculate the partial $F^{\prime}$ s is viewed as a first priority.

Due to marked seasonal variations in the level of effort aimed at saithe and in the variation in the age composition of the catchable stock for some saithe fisheries, computation of fishing mortalities at age on a quarterly basis, for example, may prove desirable especially in cases when management bodies may wish to consider seasonal regulations. As for the partial F's this implies that the corresponding data are available, and also that quarterly parameters can be handled separately in, for example, prediction programs.

The software should enable basic national data to be stored in the database in a disaggregated form (e.g. by fleets and quarters). Programs would be required to process and aggregate the basic data with provision to store the processed data in separate files. The basic data as supplied should not be overwritten with any processed data.

The working Group would also welcome software allowing for multispecies and technical interactions which would be of particular interest for the assessment of the Faroese stocks.

Availability of general purpose software (spreadsheets, wordprocessing, statistical analysis and graphics) is appreciated, although with infrequent use it is difficult to become familiar with their specific commands and to use them efficiently.

If standard figures for printing in the reports are to be prepared by computer graphics provision should be made for the assessment programs to output data files which could be directly accessed by the graphics software thus avoiding manual transcription and repunching of the data.

Table 1.1 Summary of total landings of SAITHE from the main fishing areas (in tonnes, whole weight). This table is based on the biological data supplied to the Working Group and used in the assessments. These figures differ to some extent from the official Bulletin Statistique data which are used for Tables 4.1, 5.1, 6.1, 7.1 and 9.1.
(IV + IIIa includes industrial fishery by-catch by Denmark and Norway).

| Year | Fishing Area |  |  |  |  | Total |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | I + II | IV+IIIa | Va | Vb | VI |  |

## APPENDIX

## REVIEW OF FLEETS FISHING FOR SAITHE IN THE NORTHEAST ATLANTIC

In most countries demersal fisheries are aimed at mixed groundfish species and, depending on the seasons or grounds fished, the different components of each national fleet may have quite different fishing patterns.

In this review, an attempt is made to describe in broad terms the characteristics and behaviour of those fleets which, regularly or occasionally, direct their effort towards saithe in the North East Atlantic.

This information is intended to provide a concrete basis for discussions when effort data are used in assessments, and for estimating the likely trends in effort in predictions.
** ENGLAND and WALES:

In the years preceding the extension of national fisheries jurisdiction, annual landings of saithe in England and Wales were generally in the range $30000-40000$ tonnes. The greater part of the catch was taken by vessels fishing in distant-water areas (IIa, $V a, V b)$ with $a$ lesser quantity coming from middle-water grounds (IVa, VIa). There was very little directed fishing for saithe, and saithe were generally taken as part of a multispecies trawl fishery with cod and haddock as the principal objectives.

The extension of national jurisdiction had the effect of reducing access to many of the distant-water fishing grounds and landings from these areas fell from 26000 tonnes in 1973 to less than 1,000 tonnes by 1980. To a limited extent up to 1978 the reduction in distant-water landings was offset by increasing landings from middle waters. However, since 1978 there has been a decline in the middle-water fleet resulting in a progressive decline in saithe
landings. By 1984 total saithe landings were 2700 tonnes of which 300 tonnes came from distant-water grounds.

During the last decade the vessels typically working grounds at Faroe, West of Scotland and northern Noxth Sea have been sidetrawlers of about 40 m in length and about 350 tons GRT. The vessels working the distant-water grounds were the larger side- of freezer stern-trawlers of up to 70 m in length and 1500 tons GRT.

## ** FAROES:

The Faroes fishery on demersal stocks at Faroes has increased from $21 \%$ of the total demersal landings in 1974 to $93 \%$ in 1984, with cod, saithe and haddock being the main species caught. In recent years however, redfish and blue ling have been of increased importance. All demersal fish caught at Faroes by local vessels are landed fresh. In 1984, $98.5 \%$ were landed at Faroes while the rest, mainly redfish, were landed in Federal Republic of Germany and United Kingdom.

The Faroese fleet fishing at Faroes is normally grouped into categories according to the engine power and gears used:

- Deep-waters trawlers: Vessels in this category (590 GRT, 2200 HP) have entered the fleet in the last $2-4$ years. They were two in 1982, 6 in 1984-85. They fish mainly for saithe, redfish and blue ling in deep waters with an annual effort of about 285 days at sea. They landed about 14,000 tonnes in 1984.
- Trawlers > 1000 HP, type I: These vessels (360 GRT, 1,600 HP) caught about 11,700 tonnes in 1984, with saithe accounting for $58 \%$ and redfish for $17 \%$. They were 4 in 1982, 5 in 1984-85. Up to 1983 they were allowed to fish a quota in Icelandic waters but since 1984 they are fishing all year round in Faroese waters. Thus, they have contributed to the increase in the effort exerted on saithe and redfish at Faroes (300 days at sea).
- Trawlers > 1000 HP , type II: The number $f$ vessels in this class ( 310 GRT, 1100 HP ), which represent a great part of the Faroese home water fishing fleet, has increased from 17 in 1982 to 26 in 1985. They caught about 23,000 tonnes in 1984 (260 days at sea), with saithe accounting for $69 \%$ and cod for $17 \%$. 12 of them operate as pair-trawlers with catch rates similar to single trawlers.
- Trawlers 700-999 HP and 400-699 HP: In the former group (11 in 1982, 16 in 1985) all vessels operated as single trawlers in 1984, and all of the latter group (10 in 1982, 20 in 1985) as pair-trawlers. Despite this, the catch compositions of both groups were almost identical with $48 \%$ of saithe, $35 \%$ of cod and $10-13 \%$ of haddock, and landings of about 13,000 tonnes and 16,000 tonnes respectively (260 and 225 days at sea).
- Trawlers < $400 \mathrm{HP}:$ These vessels (4 in 1982, 6 in 1984-85, 50 GRT, 250 HP ) are fishing mainly for cod (50\%), saithe (19\%) and flatfish (15\%). Trawling within the 12 mile limit is generally banned. These vessels however are licensed to operate during summer in some limited areas in order to utilize such stocks as lemon sole, plaice and angler.
- Longliners > 110 GRT: Most vessels in this category of about 20 units ( 225 GRT, 540 HP , crew of 15 men ) are licensed to fish a limited quota at Iceland during one part of the year. Cod ( $27 \%$ ) and tusk ( $23 \%$ ) are the main species caught and saithe accounted for about $12 \%$ in 1984 out of total landings of 19,500 tonnes ( 245 days at sea).
- Longliners 60-110 GRT: Some of the 14 vessels in this category also are licensed to fish at Iceland, mainly for saithe using automatic handline (crew of 5). They also practise this fishery at Faroes but also operate partly as longliners. In 1984 they landed about 5,600 tonnes with saithe accounting for $40 \%$ and cod for $36 \%$.

[^6]The material presented in this section is based mainly on preliminary statistics for 1984, and includes catches from outside the Faroese waters. The grouping of vessels is according to that used by the Faroese Board of Fisheries, which monitors the economic results of the fishery. The catch compositions obviously can vary depending on the relative abundance of the species, as was the case for the good results on cod and saithe in 1983 and 1984. It is felt however that the figures given provide a fair description of the fleet components.

## ** FRANCE:

French fisheries for saithe are carried out in the North Sea and to the west of the British Isles by the deep-sea trawlers from the Boulogne area and from Brittany.

The vessels landing regularly in Boulogne belong to 3 categories:

- The largest trawlers (50-60 m, most of them $54 \mathrm{~m}, 550-750$ GRT, 1800-2000 HP, hold capacity of 400-550 cu.m or 180-200 tonnes of boxed fish) have been in rather steady number (1820) from 1971 to 1980, but their characteristics have changed in the meantime as side-trawlers were progressively replaced by stern-trawlers. Their number eventually decreased to 16 in 1983 and no new vessel in this category is expected.
- An intermediate class includes stern-trawlers of 45-50 m, 450-500 GRT, 1 500-1 800 HP , with hold capacity of about 500 cu.m. Like the larger ones, their crews are of 22 men (the
catch is sorted, graded and boxed at sea). There were 8-10 of these vessels from 1972 to 1976,7 from 1977 to 1979 and 5 by now. Two new vessels are expected, with equipment for freezing the fish at sea thus allowing longer trips.
- In the last 10 years, 4-5 vessels of about 43 m , 350-400 GRT, 1 200-1 500 HP , with hold capacity of $300 \mathrm{cu} . \mathrm{m}$ and crews of 18 men have at times participated in the saithe fishery, especially in summer, but their regular target is mixed gadoid species in the central and southern North sea.

By union's agreement, the normal trip duration is 12 days including sailing time which, to and from saithe fishing grounds, can amount to 4-5 days, each trip is followed by 3 days ashore. This results in potentially $22-24$ trips over 11 months (about 250 days at sea per year). In recent years, landing limitations have been fixed by Producers' Organisations further restricting the effort directed towards saithe.

For these vessels, fishing for saithe has not been a long tradition: landings in Boulogne suddenly increased in 1964 from less than 20000 tonnes to a steady production of $30,000-40,000$ tonnes a year, and were in the past predominantly in the first 4 months. At present, the typical pattern is to search for (pre-) spawning concentrations along the shelf edge to the west of northern Scotland (in Division VIa) during the first quarter. These concentrations are fished while they move to the northwest of Shetland (in Division IVa) till May, when the large fish disperse in deep waters. In summer the fleets return to 'inner' North Sea (Bressay Bank) for mixed gadoid fisheries and, at times, fisheries for young saithe in the ling Bank area when large concentrations can be found. In some years, due to restricted access to Canadian waters and Barents Sea, some long distance freezers joined the wet fish vessels in this summer fishery.

Vessels registered in Brittany (Lorient, Concarneau and Douarnenez) make a major part of the catches of West of Scotland saithe; they can be grouped into 2 classes:

- The large stern trawlers (40-60 m, 250-600 GRT, 1,800-2,000 HP) are very similar to those from Boulogne and have the same fishing pattern for saithe: they fish mainly from January to May on grounds to the west-northwest of Hebrides and Shetlands, on adult saithe concentrations. They make about 18 trips a year ( 240 days at sea on average, sailing time included). In Lorient, a specific scheme by which vessels ( 8 in 1981-1982, 6 in 1983) exchange their crews (16 men) in rotation allows longer time at sea (310 days on average). Fishing effort by these vessels has decreased as many have been laid up. In Lorient, their number decreased from 39 in 1974 to 31 in 1978, 26 in 1981 and 21 in 1983; they were 10 in Concarneau in 1978 but in 1983 all the vessels over 40 m had been decommissioned.
- The fleet of medium trawlers fishing to the west and southwest of the British Isles showed different evolutions in each of the 3 harbours. In Lorient, a fleet of old side trawlers has virtually disappeared and only 4 vessels (33-36 m, 450-800 HP) remained in 1983 as compared to 14 in 1974. In the other two harbours, a similar change happened but there, new types of modern stern-trawlers were built to maintain the fishing potential: 9 vessels (36-38m, 200-300 GRT, 1 100-1 400 HP ) in Douarnenez and 16 vessels (30-39 m, most of them 34 m long and 800 HP ) in Concarneau.

In fact, this class of vessels never had saithe as a main target and used to fish for mixed groundfish species on the shelf area to the south of Division VIa and in the Irish Sea. Although large saithe apparently can still be found in these areas in late spring, the fleet has totally redirected its effort towards closer grounds and more valuable species than traditional gadoids, and has been redesigned accordingly.

In summary, fishing effort on saithe by French trawlers has decreased significantly during the last decade, especially to the west of Scotland. This trend is likely to continue as the fleet is faced with 2 main constraints: - a larger distance to the fishing grounds as compared to other European fleets, - market problems and loss of profitability by the deep-sea fleet which is heavily dependent on gadoid species, hampering the purchase of new vessels fitted to the type of fishery considered here.
** FEDERAL REPUBLIC OF GERMANY:

The German fleet is fishing for saithe mainly in the North Sea. Additional catches are made off the Norwegian coasts (IIa) and to the West of Scotland (VIa). Small amounts are caught in faroese waters where saithe is a by-catch in the fishery for redfish and blue ling.

The German fishery for saithe and other demersal species started as far back as the beginning of the German deep-sea fishery, at the end of the 19 th century. At that time the main fishing grounds were off Norway and Iceland, in the central and northern North Sea and, occasionally, off the Hebrides.

Until the introduction of quotas and the closing of the Icelandic waters for foreign trawlers, the major part of saithe catches came from waters off Norway and Iceland. Afterwards, they came predominantly from the North Sea.

As of January 1st, 1985, the German fleet fishing for saithe consisted of the following categories, all using bottom trawls:

[^7]- 4 of the 7 wetfish-trawlers (800-999 GRT) are older than 20 years, and the other 3 were built in 1977-1978. These vessels also fish mainly for cod and redfish in Greenland waters. In winter and spring they fish for saithe and other demersal species in Norwegian waters (mainly NW Norway), starting in January, up to the exhaustion of their catch quotas (generally by May- June). Occasionally they fish in the North Sea, to the west of Scotland and off the Faroes. In the North sea, they fish for spawning or pre-spawning saithe in the waters around Shetland in the first quarter, then for younger saithe in summer and autumn, in the eastern part of northern and central North Sea. In 1983, their catches in Division IVa amounted to 2800 tonnes of saithe.
- In 1983, 2 large cutters (about 300 GRT) were built especially for the saithe fishery. During the spawning season they fish for adult saithe concentrated around the Shetland and off the Scottish north coast. During the rest of the year they work in the central and northern North Sea for saithe and other demersal species.

All the vessels described above are stern-trawlers. They land their catches in Bremerhaven and Cuxhaven, occasionally in Hamburg.

- More than 100 deep-sea cutters are working in the North Sea and in the Baltic. 17 of these are longer than 30 m . These large cutters and 1 lugger catch saithe and other demersal species in the central and northern North sea and in the Skagerrak, the lugger aiming more specifically at saithe than the cutters. In 1983 these vessels landed 10,600 tonnes of saithe from the North Sea.

## ** THE NETHERLANDS:

Up to the late seventies saithe was taken by a small part of the Dutch fleet in a specific saithe fishery in the northern North Sea, especially in the first quarter of the year. Since then there were only minor landings of saithe in the Netherlands and it is very unlikely that landings will increase substantially in the next future.

## ** NORWAY:

The Norwegian saithe fisheries are restricted to the North East Arctic and the North Sea. Purse seine, trawl, and gill-net account for more than 90 per cent of the landings. In the North East Arctic, landings since 1970 have been fluctuating between 120,000 and 170,000 tonnes. In the North sea there was a sudden increase from a level of about 17000 tonnes in 1976-79 to 48000 tonnes in 1980. The landings have continued to increase and were in 1984 (preliminary) 88000 tonnes.

Purse seine fishing is carried out along most of the Norwegian coast, usually not far from the coast. The purse seiners are mostly small and about $70 \%$ of the catches are taken by $17-25 \mathrm{~m}$ long vessels. There are currently about 150 vessels of this size group, but most of them are fishing for saithe only part of the year. In northern Norway, the main season is July to October. South of the Lofoten Islands, purse seining is carried out all year.

Before 1979, a large part of the Norwegian trawl catches of saithe were by small trawlers (< 250 GRT) fishing in the area between $62^{\circ}$ and $64^{\circ} \mathrm{N}$. In the North Sea, there was very little directed trawling for saithe. From 1979, quotas for cod and haddock were reduced and the larger trawlers ( $>250$ GRT) turned more of their effort towards saithe. The fleet of larger trawlers are now fishing for saithe on coastal banks along most of the Norwegian coast north of $62^{\circ} \mathrm{N}$. In the North Sea, they are fishing along the northern and eastern part of the plateau, from Shetland to the
entrance of Skagerrak.

Gill net fishing for saithe is a seasonal fishery based on the spawning migration. In the North East Arctic, most of the catches are taken at the end of the year in northern Norway and in February-March on the spawning grounds further south. In the North Sea, the season which formerly was February-March has been extended and now starts in late autumn. The fishing area is largely the same as for the trawlers, but extends to the west of Shetland and there is little fishery south of the Viking Bank.

There are no quota restrictions on the Norwegian saithe fishery in the North East Arctic. Separate quotas for purse seine and trawl have been suggested and may be introduced. There are currently 3 different minimum landing sizes: 35 cm between $62^{\circ} \mathrm{N}$ and $64^{\circ} \mathrm{N}, 37$ cm from $64^{\circ} \mathrm{N}$ to Lofoten Islands, and 40 cm further north. The basis for these regional differences is the size of the fish available for purse seine in the different areas. The minimum landing size to some extent restricts catches of 2 year old saithe. The mesh size in trawls is 135 mm and 100 mm respectively north and south of $64^{\circ} \mathrm{N}$.

In the North sea, a total quota for saithe is normally agreed by EEC and Norway. A permanent quota of 15000 tonnes on purse seine is being introduced in Norway. If necessary to avoid overfishing the Norwegian quota, trawl fishing may be stopped towards the end of the year. Minimum landing size is 32 cm ( 30 cm in Skagerrak). Minimum legal mesh size in the Norwegian economical zone is 90 mm ( 80 mm in Skagerrak).

## ** SCOTLAND :

Scotland has no directed saithe fishery at present and saithe landings represent a by-catch from a fishery directed primarily at cod, haddock and whiting. Since little fishing is carried out in the deeper water of the continental shelf edge and there is a preponderance of small inshore vessels in the Scottish fleet, most of the saithe which are caught are young and immature.

There are 4 main sub-fleets which account for the majority of Scottish demersal fish landings including saithe. These are:

- Motor trawl: Involves vessels of $80-120 \mathrm{ft}$ using heavy ground gear. The number of these vessels has declined rapidly since the 1960 s from over 100 to less than 20 at the present time. The remaining vessels are a mixture of sideand stern-trawlers. Most of them are based in Aberdeen and fish both the North Sea and the West of Scotland. The future of the fleet is uncertain but older vessels are unlikely to be replaced. Trip length is about 10 days and a crew of 10 is typical.
-- Light trawl: Involves vessels of @ $40-80 \mathrm{ft}$ using light ground gear. The number of vessels engaged in light trawling has increased over the last 10 years to approximately 350 . Vessels are distributed in most Scottish fishing ports. Trip lengths vary from 1 day for smaller vessels to 10 days for larger ones. Similarly crews vary from 3 to 10 men. This sector of the fleet is liable to increase in size.
- Seine net: The characteristics of this fleet are essentially the same as those for light trawl with the exception of the gear type. There has been a small decline in this fleet to just under 300 vessels. This decline is mainly due to the replacement of smaller vessels by fewer larger ones so that the catching capacity of the fleet has not changed. This trend seems to be continuing.
- Nephrops trawl: This fleet is similar to light trawl but generally involves smaller vessels fishing principally for Nephrops. The fleet is stable at present with approximately 300 vessels. These rarely fish for more than 2 days per trip. Crews are of 3 to 5 men.

[^5]:    * Preliminary

[^6]:    - Longliners <60 GRT: The vessels in this category represent the traditional fishery at Faroes and amount to about 125 units. They operate on daily trips to fish for $\operatorname{cod}(49 \%)$, haddock (17\%) and saithe (18\%). They landed about 17,000 tonnes in 1984.

[^7]:    - 10 freezer-trawlers (3,000-3,500 GRT) built in the years 1972-1975 have their main activities in fisheries for cod and redfish off Canada and east- and west-Greenland. They only occasionally fish for saithe in Eastern Atlantic waters.
