REPORT OF THE SAITHE (COALFISH) WORKING GROUP

Copenhagen, 29 February - 6 March 1984

This document is a report of a Working Group of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council. Therefore, it should not be quoted without consultation with the General Secretary.

x) General Secretary,
ICES,
Palægade 2-4,
DK-1261 Copenhagen K,
Denmark.

REPORT OF THE SAITHE (COALFISH) WORKING GROUP

1. PARTICIPANTS

R M Cook	United Kingdom (Scotland)
T Jakobsen	Norway
H í Jakupsstovu	Faroës
B W Jones	United Kingdom (England)
A Kristiansen	Faroës
P Lewy	Denmark
J McGlade	Canada
B Mesnil (Chairman)	France
J B Pérødou	France
H H Reinsch	Federal Republic of Germany
S A Schopka	Iceland
O Smedstad	Norway

K Hoydal attended the meeting as ICES Statistician.

2. TERMS OF REFERENCE

At the 71st Statutory Meeting of ICES it was decided (C.Res.1983/2:8:2) that the Saithe Working Group should meet at ICES headquarters from 29 February to 6 March 1984 to:

- (i) assess catch options for (a) the saithe stocks and (b) cod and haddock in Faroës waters inside safe biological limits for 1985 and, where meaningful, for 1986,
- (ii) take into account the levels of predation mortality implied by the results of the stomach sampling project,
- (iii) analyse the effect of changes in the data sets of weight at age and age at first maturity on the time series of stock and spawning stock biomass.

In addition, the Working Group was asked by ACFM to consider possible alternative methods to improve the fishing pattern for the North-East Arctic and the North Sea saithe.

3. LANDINGS OF SAITHE IN THE NORTH-EAST ATLANTIC

The estimated landings of saithe from the North-East Atlantic (Table 3.1) amounted to 462 000 tonnes in 1982 and 448 000 tonnes (provisional) in 1983. These figures indicate an increase in catches as compared to the late 1970s, but they are still much lower than the peak landings in the period 1970-76.

4. NORTH-EAST ARCTIC SAITHE (Sub-areas I and II)

4.1 Landings (Table 4.1, Figure 4.1.A)

The provisional estimate of landings in 1983 is 158 206 tonnes, which is 20 000 tonnes less than in 1982.

4.2 Age Composition (Table 4.2)

The age composition from Norwegian landings in 1982 was revised after the 1983 Working Group meeting. A new assessment was presented to the ACFM and used as a basis for the recommendations. Subsequently, only minor revisions have been made to the 1982 data. Provisional age compositions for 1983 were available from the Federal Republic of Germany and Norway, accounting for 98% of the landings.

4.3 Weight at Age (Table 4.3)

For 1960-79 the same weights at age as in previous assessments have been used. These are the same weights for each year and are used for both catch and stock. For 1980-83, annual weights at age in the catch for each year are used for catch and stock weights.

The weight at age data used in the yield per recruit and prediction calculations were derived by averaging the weights at age for the years 1981-83.

4.4 Fishing Mortality and Stock Size Estimate from VPA

4.4.1 Estimates of fishing mortality

Quota restrictions on trawlers from countries other than Norway reduced the total landings by 60 000 tonnes from 1976 to 1977, but during the period 1977-83 landings have been relatively stable. Landings by main gears in the fishery - purse-seine, trawl and gill-net - also show the same stable trend from 1977 onwards (Figure 4.2). These three gears exploit different components of the stock, the purse-seine age groups 2-5, the trawl age groups 4-8 and the gill-nets age groups 6 and older. The relatively stable fishery with each of these gears from 1977 to 1983 indicates that the total exploitation pattern may also have been relatively stable during this period.

For gill-net, no data on effort are available at present, and there is no other information about changes in the gill-net fishery in recent years.

Also for purse-seine, no data on effort are available. Account made every other year indicates no significant changes in number and size distribution of the vessels taking part in the fishery for saithe in recent years. In 1983, there were market problems which may have reduced fishing effort by purse-seiners. Fishermen in the southern part of the area claim that the maximum landing size of 35 cm has restricted their fishing in the most recent years, which could mean reduced fishing mortalities on 2, and to a lesser extent, 3 year old fish. However, the geographical distribution of both the fishing and the year classes may vary from year to year, and this can change the fishing mortality even if the total effort is constant. It is, therefore, probably not advisable to assume changes in fishing mortalities unless there is evidence of significant changes in the fishing pattern.

Although the total trawl landings from 1977-83 have been stable, Norwegian landings have made up an increasingly larger part. This may have changed the total fishing pattern for trawl, but variations in the geographical distribution of the saithe are just as likely to have caused changes in the fishing mortality. However, the data available do not provide evidence of changed exploitation pattern by trawlers in recent years.

Data on effort and catch per unit of effort are available for 11 categories of Norwegian trawlers for the period 1973-82. For 1983, data are available from the larger trawlers. The data from Division IIa are given in Table 4.6. For the side-trawlers the data for 1982 and 1983 are not included in the table because errors have been found in the 1982 data, and lack of data from smaller trawlers makes the 1983 data incomparable with earlier years. For stern-trawlers, however, only the larger vessels are of significance.

Following restrictions in quotas of cod and haddock in 1980, there was a shift in effort towards saithe by Norwegian stern trawlers which is evident from the sudden increase in cpue. A further increase in effort on saithe seems to have taken place in 1981. If the proportion of the effort directed towards saithe has been stable in 1981-83, the total effort by trawlers shows a slightly decreasing trend. The cpue for

stern-trawlers from 1981-83 follows a similar pattern as estimates of the biomass exploited by trawlers. However, the time series is too short to be of any help in estimating the level of fishing mortalities in 1983.

With little conclusive evidence of major changes in exploitation pattern and level of fishing mortalities during the period 1977-83, it seemed appropriate to run a separable VPA for this period. The log catch ratio residuals indicated that there may have been some changes in the exploitation pattern. Two ordinary VPA runs were then made, setting fishing mortalities in 1983 equal to those in 1977-79 and 1980-82, respectively. The two resulting exploitation patterns were clearly different and indicated a shift in effort towards larger fish for both purse-seiners and trawlers in the most recent years. It is not clear if this reflects a trend or a temporary change. However, the Working Group felt that fishing mortalities in 1983 were more likely to be similar to the 1980-82 pattern than suddenly being changed back to the 1977-79 pattern. It was, therefore, agreed to use 1980-82 as a basis for both the exploitation pattern and the level of fishing mortality for 1983 and in the assessment.

The result (Table 4.4) shows a higher level of fishing mortality in 1980-83 compared with 1977-79, but an improvement in the exploitation pattern.

4.4.2 Spawning stock biomass and recruitment

Estimates of spawning stock biomass are given in Table 4.5 and Figure 4.1.B. There is a decline from 1970 onwards to 102×10^3 tonnes in 1983, the lowest observed spawning biomass in the time series. This level represents 72% of the 1983 Working Group estimate.

Estimates of stock numbers at each age are given in Table 4.5, and recruitment at age 1 is plotted in Figure 4.1.B. The 1978 year class appears to be as large as those in 1973 and 1966-68, however the more recent year classes, from 1979-81, to be amongst the lowest in the period reported.

4.5 Yield per Recruit

The Y/R curve is given in Figure 4.1.C. It was calculated using the 1980-82 average exploitation pattern and the 1981-83 average weight at age data as given in Table 4.7. Current exploitation (\bar{F}_{3-8} unweighted) at $F = 0.55$ is clearly in excess of $F_{\max} = 0.30$ and $F_{0.1} = 0.17$.

4.6 Catch Predictions

The data used for catch predictions are given in Table 4.7. Average recruitment ($R_1 = 318 \times 10^6$ = average of year classes 1960-79) is assumed for the year classes 1982-85. The assessment gave very low values for the 1980 and 1981 year classes and both may be seriously underestimated. However, reports from different parts of the coast indicate that they are both clearly less than average size, and it was therefore decided to use the values from the VPA in the predictions. The 1982 year class appears to be more abundant and the 1983 year class may be very abundant.

The fishing mortality is assumed to remain at the 1983 level of $\bar{F}(3-8) = 0.55$. Predicted catches and stock biomasses for 1984 and for a range of exploitation levels in 1985 are given in Table 4.8. Predicted yield in 1985 and the spawning stock biomass for 1986 are shown in Figure 4.1.D. On the assumption that F remains unchanged from the 1983 level, the yields in 1984 and 1985 are predicted

to be 126 000 tonnes and 137 000 tonnes, respectively. Landings in 1985 corresponding to F_{max} are 85 000 tonnes. The spawning stock biomass will decrease slightly in 1985 and 1986 as the effect of the 1978 year class declines.

4.7 Comments to the Assessment

Assessments on the North-East Arctic saithe in recent years have generally given increased fishing mortalities and decreased spawning stock biomasses compared to earlier assessments. With no useful data series on effort presently available, this trend may very well continue. The current regulations do not effectively put any limit on the total fishing effort and if there is an increasing trend, this is difficult to detect if no data on effort are available. The purse-seine fishery represents a special threat to the stock because catches may not significantly decline before a recruitment failure is evident.

4.8 Improvement of the Exploitation Pattern

The exploitation pattern for North-East Arctic saithe cannot be significantly improved unless there is a reduction in the purse-seine fishery. Such a reduction can probably most effectively be obtained either by increasing the minimum landing size or by imposing quota regulations on the purse-seine fishery. There are three different minimum landing sizes in the area, and the effects of an increase are very difficult to estimate. A total quota for the purse-seine fishery will probably mean that the fishery in the north with a later peak season than in the south will be most reduced. Since the smallest fish are caught in the south, this is hardly a desirable effect. Regional quotas or quotas by vessels may solve this problem.

5. NORTH SEA SAITHE (Sub-area IV and Division IIIa)

5.1 Landings (Table 5.1)

Officially reported landings of saithe from the North Sea had declined to a relatively low level of about 120 000 tonnes in the period 1979-82 but subsequently increased to 162 000 tonnes in 1982 (revised from a preliminary estimate last year of 154 000 tonnes). The preliminary figure reported for 1983 is 163 000 tonnes, which exceeds the agreed TAC of 158 000 tonnes by 5 000 tonnes. By-catches of saithe in the industrial fisheries amounted to 5 000 tonnes in 1982 and 1 400 tonnes in 1983.

5.2 Age Composition (Table 5.2)

Provisional age compositions for 1982 used last year were updated. New data for 1983 were provided by Denmark, England, France, Federal Republic of Germany, Norway and Scotland. The landings of these countries together accounted for 163 000 tonnes out of a total of 165 000 tonnes (WG estimate of total landings). As in previous years, the reported age compositions for the human consumption fisheries were summed and then raised to the total landings of the human consumption fisheries. The age composition for the industrial by-catch was then added to give the total for the North Sea.

5.3 Weight at Age (Table 5.3)

Weight at age data were provided by all countries which provided age composition data. National data sets of either age composition or

weight at age were adjusted to eliminate sums of products discrepancies. Annual average weight at age estimates, weighted by numbers in the catch, were calculated.

Weight at age data have been reported annually only from 1979. For the earlier years a single weight at age array has been used for stock biomass calculations. SOP checks give significant discrepancies for the years prior to 1972, which could indicate that the weight at age data used may not be appropriate for these years.

Weight at age data as described above have been used to calculate annual stock biomass estimates for past years. The weight at age data used in catch and stock biomass predictions were derived by averaging the annual estimates of weight at age for the years 1981-83.

5.4 Fishing Mortality and Stock Estimates from VPA

5.4.1 Estimates of fishing mortality

Separable VPAs were made for a range of values of F (5), the fishing mortality on the reference age group 5 in 1983, and of S (14), the relative selection factor on age group 14. The analysis was performed on data for the years 1978-83 to exclude years when there were big catches made by the USSR and when there were large by-catches from the industrial fisheries. A value of $S(14) = 0.75$ was accepted as the value giving the internally most consistent selection pattern. This selection pattern and the table of log catch ratio residuals are shown in Table 5.7. There appear to be no systematic trends in the residuals, but there are some high values in the column for 1981/82 which suggest a catch data anomaly in one of these years. It was decided to use the exploitation pattern as determined by separable VPA as the basis for input F values for 1983 for the conventional VPA.

Effort and catch per unit effort data were available for French trawlers from 1974 and for Norwegian side-trawlers and stern-trawlers from 1978 and 1979 (Table 5.6). All three fleet data sets showed an increase in opue in 1983, compared with 1982, and a reduction in total fishing effort. A VPA was made using $\bar{F}(3-6) = 0.25$ to scale the exploitation pattern determined from separable VPA. The calculated F values for 1974 to 1983 were then compared with the trend in total fishing effort estimated in French units (Figure 5.2). Apart from an obvious anomaly with the values for 1975, the F and effort values correlated well ($r = 0.92$, excluding 1975). As the trend in F values closely followed the trend in estimated total effort, the trial input F values for 1983 were considered to be acceptable. The calculated F values from this analysis are given in Table 5.4, and the trend of $\bar{F}(3-6)$ with time is plotted in Figure 5.1.A.

5.4.2 Spawning stock biomass and recruitment

Stock numbers calculated from VPA are given in Table 5.5, and the estimates of year class strength at age 1 have been plotted in Figure 5.1.B. The estimate for the 1982 year class at age 1 from VPA is considered unreliable, and for prediction purposes this year class has been assumed to be of average abundance. Also the VPA gives the abundance of the 1981 year class to be equal to the big 1978 year class. The Working Group has some reservations about this estimate, and it is thought that due to sampling problems in 1983 the catch may have been incorrectly allocated between age groups 2 and 3. It has not been possible to confirm or to correct for this, but any error would not be expected to have any substantial effect on catch predictions.

Spawning stock biomass (Table 5.5, Figure 5.1.B) increased to a peak value in 1973 and then declined up to 1978. Since then spawning stock biomass has been increasing, probably as a result of the lower level of fishing mortality in recent years.

5.5 Yield per Recruit

A Y/R curve (Figure 5.1.C) was calculated using the exploitation pattern and the weight at age data given in Table 5.8. Expressed as the average fishing mortality on age groups 3-6, $F_{max} = 0.24$ and $F_{0.1} = 0.14$. The current level of F is estimated to be 0.25.

5.6 Catch Predictions

Input data used in the catch predictions are given in Table 5.8. Recruitment of the 1982 and later year classes has been assumed to be of average abundance as no pre-recruit abundance data are available.

The catch for 1984, predicted on the basis of no change in fishing mortality, is 185 000 tonnes, which is close to the TAC agreed for that year of 180 000 tonnes. For 1985, catch predictions have been made for a range of values of fishing mortality, and the results are given in Table 5.9 and are presented graphically in Figure 5.1.D.

5.7 Possibilities for Improving the Exploitation Pattern by increasing the Minimum Landing Size

The current minimum landing sizes are 32 cm in the Norwegian zone and 30 cm in the EC zone. The corresponding minimum trawl mesh sizes are 100 mm and 80 mm. Using a selection factor of 3.8, the 50% selection lengths are 38 cm and 30.4 cm. For trawlers, the minimum landing size can be related to the minimum mesh size. However, the purse-seiners, which take the majority of the smaller fish, use non-selective gear and tend to catch fish mainly in the 30-37 cm length range. A significant increase in the minimum landing size is likely to affect the viability of the purse-seine fishery.

6. ICELANDIC SAITHE (Division Va)

6.1 Landings

Landings of saithe from Division Va are given in Table 6.1 and are shown in Figure 6.1.A. Since 1977 landings have been fluctuating without trend between 50 000 and 70 000 tonnes. The 1981 catch was 59 000 tonnes, followed by an increase to 69 000 tonnes in 1982. Preliminary figures for 1983 show a decrease to 59 000 tonnes.

6.2 Age Composition

There was no need to revise the 1982 age composition used last year. Provisional age composition data for 1983 were available for landings by Iceland, which represented 97% of the total landings. These data have been used to calculate the age composition of the total landings used as input for VPA (Table 6.2).

6.3 Weight at Age (Table 6.3)

Weight at age data were available for the Icelandic catch in 1983. For the predictions, the average of the catch weight at age data for the years 1981-83 were used for both catch and stock biomass calculations.

6.4 Fishing Mortality and Stock Values from VPA

6.4.1 Estimates of fishing mortality (Table 6.5)

The Icelandic saithe fishery can generally be divided into two components, i.e., gill-net fishery during the winter season, and a trawl fishery throughout the year. The gill-net fishery, which accounts for 1/3 of the total saithe catches, exploits mainly the spawning saithe, whereas the trawl fishery is more directed towards the age groups 4-8. This fishery accounts for about 60% of the annual total landings. The saithe fished by trawlers are more or less by-catch in the fishery for cod and redfish. Depending on the availability of saithe, cod and redfish, the exploitation pattern on saithe may vary from year to year. Bearing this in mind, the Working Group decided that the use of separable VPA to estimate fishing mortalities was not an appropriate method as it assumes a constant exploitation pattern. It was, therefore, decided to use the same method as the Working Group has used in the most recent assessments, i.e., to determine an exploitation pattern from a reference period (1978-1980) and then to scale this to the estimated level of fishing mortality in 1983.

A plot for $\bar{F}(4-8)$ derived from this VPA versus effort of Icelandic trawlers diverted to saithe (Table 6.6) showed no clear relationship (Figure 6.2.2). On the other hand, there was significant correlation ($r = 0.87$) when the cpue was plotted against the biomass of 5-8 year old saithe plus a 50% proportion of the biomass of the 4 year olds (Figure 6.2.). This VPA was adopted and the calculated F values for earlier years from the VPA are given in Table 6.5, and the trend in $\bar{F}(4-9)$ with time is plotted in Figure 6.1.A.

6.4.2 Spawning stock biomass and recruitment

Spawning stock biomasses are shown in Figure 6.1.B and Table 6.4. After a decline from 1969-77, the spawning stock biomass appears to have stabilised at a level similar to that in the mid-1960s of 160 000 tonnes.

Back-calculated estimates of recruitment at age 1 are plotted in Figure 6.1.B. Recruitment has fluctuated in recent years without any clear trend. Information so far available indicates that the 1980 year class is a poor one. Therefore it has been set at the same low level as the 1978 year class (22 million at age 3) (Table 6.4). Accordingly, the F input value for this year class at age 3 was adjusted to give this result. No information is available on the strength of the year classes recruiting to the fishery except for the 1981 year class where there is some preliminary indication that this year class is at least of average size. For the catch projections, the 1981 year class was set at the same value as the long-term average ($R_3 = 49 000$), but the 1982 and 1983 year classes have been taken to be equal to average abundance of 3 year olds in the recent 1976-80 period ($R_3 = 37 000$).

6.5 Yield per Recruit

The yield per 1-year old recruit and spawning stock biomass per recruit shown in Figure 6.1.C have been calculated by using the exploitation pattern and weight at age data given in Table 6.7. Compared to the present fishing mortality, $\bar{F}(4-9) = 0.34$, the reference values $F_{max} = 0.42$ and $F_{0.1} = 0.16$.

6.6 Catch Predictions

The input data for catch projections are shown in Table 6.7. The projections are based on the 1978-80 exploitation pattern which was also used as input to the VPA.

National catch quota on saithe in 1984 is the same as the recommended TAC of 70 000 tonnes, thus $\bar{F}_{(4-6)}$ was set at a value of 0.46 in 1984. Due to a restricted cod fishery in 1984, it is expected that the enforced quota on saithe will be taken. The results of the catch options for 1985 and the spawning stock and total biomasses in 1986 are given in Table 6.8 and Figure 6.1.D.

7. WEST OF SCOTLAND SAITHE (Sub-area VI)

7.1 Landings

Officially recorded landings of saithe from Sub-area VI are shown in Table 7.1. French landings recorded in Bulletin Statistique for recent years (1980-82) have been lower than scientific estimates of landings. It was felt that the scientific estimates were more representative of true landings, and these figures were used in the assessments. Estimated landings for the years 1980 onwards have, therefore, been revised upwards by about 10%. The trends in landings are shown in Figure 7.1.A. Landings in 1983 are estimated to be 26 127 tonnes, which is a small increase over recent years.

7.2 Age Composition (Table 7.2)

Age compositions for 1983 were provided by England, France and Scotland and they accounted for 97% of the total landings. Minor changes and corrections were made to the catch at age data from 1981 onwards in line with the revised total landings.

7.3 Weight at Age

Weight at age data for 1983 were provided by England, France and Scotland. The estimated mean weights at age for 1983 shown in Table 7.3 are similar to previous years. Values of weight at age used in predictions are shown in Table 7.7 and are the means for the period 1981-83.

7.4 Fishing Mortality and Stock Values from VPA

7.4.1 Estimates of fishing mortality

Estimates at previous Working Groups have indicated that fishing mortality on the West of Scotland stock is low and is not substantially different from the assumed natural mortality of 0.2. It should be noted that a characteristic of VPA is that it is convergent for Z at age regardless of input mortalities. This means that Z also has a low value and makes estimates of F very sensitive to alternative hypotheses about M.

No demonstrably effective methods for determining terminal Fs for this stock are known to the Working Group. A self-tuning method was, therefore, adopted. Mean values of F at age over the period 1979-81 were used as input values to VPA and iterations were performed until the new calculated means differed negligibly from the input values. Fs on ages 1 and 2 were then adjusted to reduce recruits in 1982 and 1983 at age 1 corresponding to the mean recruitment for the years 1977-81. This particular solution depends on the assumed value of F on the oldest age group of 0.1.

Fisheries Directorate

Bibliothek

A new cpue index based on French data was presented to the Working Group. This index is based on data disaggregated into area and time strata and employs a multiplicative model of the kind described in the Working Group on the Use of Effort Data in Assessments (Anon., 1981). The index was used to derive an index of overall international effort (Table 7.6 and Figure 7.2). The index of effort indicated a continued decline, which is reflected in the value of $\bar{F}(3-6)$. Decreasing terminal F in VPA in order to reproduce the effort changes more closely was unsuccessful.

7.4.2 Spawning stock biomass and recruitment

Historical spawning stock biomass figures are shown in Table 7.7 and Figure 7.1.B. The estimates of spawning stock for the years 1977 onwards indicate a gradual declining trend though year classes recruiting to the spawning stock in the future are likely to check this trend.

The estimated number of recruits at age 1 is shown in Table 7.5 and Figure 7.1.B. For catch predictions a recruitment value of 26 000 was used for 1984-86, which approximates to the mean value for the period 1977-81 obtained from VPA.

7.5 Yield per Recruit

The Y/R and spawning stock biomass per recruit curves are shown in Figure 7.1.C. The analysis suggests that the present level of $\bar{F}(3-6)$ lies between $F_{0.1}$ and F_{max} (see Table 7.8) and is close to $F_{0.1}$. Management recommendations in recent years have assumed that the level of fishing mortality is close to $F_{0.1}$ (Anon., 1983). It should be stressed that equally valid alternate hypotheses concerning natural mortality alone can radically alter the level of fishing mortality in relation to $F_{0.1}$ obtained from the Y/R analysis (see Appendix).

The analysis presented in Figure 7.1.C offers no basis whatsoever for assuming that $F_{83}(3-6) \approx F_{0.1}$. Status quo recommendations should be made without reference to $F_{0.1}$.

7.6 Catch Predictions

Input data for catch predictions are shown in Table 7.7. Catch options for 1985 are shown in Figure 7.1.D and Table 7.8. Status quo catches for 1984 and 1985 are expected to be 25 000 tonnes and 24 000 tonnes, respectively.

7.7 Separable VPA

Trial runs were made using SVPA for the years 1976-83. Log catch ratio residuals were generally rather high (e.g., see Table 7.9). Values of terminal F which produced declining trends in time of $F(I)$ comparable to effort data were low and implied very low fishing mortalities in 1983 ($\bar{F}_{3-6} = 0.07$). The fishing pattern calculated by SVPA was similar to that obtained for the conventional VPA as expected. The value of using SVPA for this stock is inconclusive. In view of the high residuals and exceptionally low F suggested by the method it was not used in the assessments.

8. THE DEMERSAL FISHERIES ON THE FAROE PLATEAU

8.1 Catch and Effort Data

Based on the Faroese FISKHAG statistical system introduced in 1973 (see Coop.Res.Rep., No.91), catch and effort data are available for the Faroese vessels fishing for saithe, cod and haddock on the Faroe

Plateau. For the smaller boat groups these data are available by trips, and for the larger vessels by hauls.

The data have been split on vessel categories, the details of which are given in Table 8.1. In this table and Figure 8.1 the trends in nominal effort and corresponding catches of the three main species are shown. The nominal effort is total effort by vessel category, irrespective of which species it has been directed at. A real problem, therefore, in using these data is how to account for eventual shifts in directivity.

Although these data go back to 1973 it is difficult to make use of the data before 1977, because of the profound changes in the fishery in the Faroe area following the introduction of the 200 mile fishery zone.

8.2 Statistical Analysis of the Catch/Effort Data

The Working Group on the Use of Effort Data in Assessments (C.M. 1981/G:5) had a look at these data. They tried to estimate the catch rate of cod as a result of a vessel category factor, a month factor and a year factor. The result showed good general correspondence with trends estimated from VPA analysis.

Some later runs on the data show that the fleet category factor explains a large part of the variation.

The question about the directivity of the effort might be solved by including an area factor. A change in directivity would be expected to show up also as a change in fishing area.

During the meeting it was not possible to make any closer analysis of the data.

The Group recommends that for next year a more thorough statistical analysis of the effort data should be ready prior to the Working Group meeting, as the time available during a Working Group meeting is far too limited to perform any analysis in depth of the basic data. This analysis should attempt to correct for changes in directivity, so the effort data can be correlated with the fishing mortality on the different species.

8.3 Qualitative Description of the Different Demersal Fisheries

Before describing any further analysis, a qualitative description of the characteristics for the main vessel categories is given below.

The catchability of the two long-line categories would not be expected to have increased over the period 1977-83 because of technical improvements. The long-line fishery is a mixed fishery for cod and haddock and is known to have a lot of variability due to features inherent in the gear (saturation, influence of the relative abundance of the two stocks, bait quality and size, etc.).

The two size categories of single-boat bottom trawlers would be expected to show an increase in efficiency due to technical improvements and also to a learning factor as the Faroe area was relatively unknown ground for Faroese trawlers, when the Faroese fishing zone was established in 1977. From 1980 and onwards there is a shift from single-boat trawling to pair trawling, and the same increases will apply for the two pair trawl categories.

In addition to the vessel categories mentioned there are gill-netters, hand-liners and open boats participating in the fishery.

The increase in effort by trawlers has especially meant an increase in the landings of saithe and other species (redfish and blue ling in deeper waters), but the smaller trawler groups have during all the years taken a fair amount of cod and haddock.

Some special features in the 1983 situation should be mentioned. The relation of price/catch rates between cod/haddock and saithe went in favour of cod/haddock and in the spring difficulties in selling saithe at a reasonable price led to a stop in saithe landings for 3 weeks.

The fishery for cod and haddock will take place generally in shallower water than the main fishery for saithe. A movement of trawlers to shallower waters could also mean a shift towards exploiting younger age groups of saithe.

8.4 Analysis of the Data during the 1984 Working Group Meeting

Data for 1983 were only complete for some vessel categories. For the larger vessels, data for the first 6 months were available in the database. Values for total annual nominal effort by the larger vessel categories were estimated by raising the half-year value by a factor calculated on data from the previous year.

The Working Group agreed to try to use the total nominal effort data in the Rho-method (C.M.1982/Assess:8). It was realised that it would have been advantageous to use a model which made it possible to estimate changes in catchability by fleets, but no program was available to make these calculations. It was also appreciated that the Rho-method with total effort data does not take into account changes over the years in directivity and/or area-time of the fisheries of the different fleets.

The Rho-method gave for all three species very unlikely results and it was agreed not to rely on it.

The apparent changes in directivity (see below) might precisely be the reason for the failure of the Rho-method.

8.5 Calculation of a Crude Index of Changes in Total Effort

In order to get some use of the effort data, a crude index of total effort over the years was calculated by the formula:

$$\frac{F_{79-81}}{F_{83}} - \frac{\sum_i \frac{E_{79-81,i}}{E_{83,i}} \times \bar{C}_{83,i}}{\sum_i \bar{C}_{83,i}} \times \frac{\sum_i \bar{C}_{83,i}}{\bar{C}_{83}} \times \frac{C_{79-81}}{\sum_i C_{79-81,i}}$$

$E_{83,i}$ = Effort 1983 fleet i;

$C_{79-81,i}$ = Average catch 1979-81 fleet i, etc.

This formula is essentially the same as given in the Appendix to the North Sea Roundfish Working Group report 1982 (C.M.1982/Assess:8), but using nominal catches instead of catch in numbers. The problems with the change in the directivity remain unsolved. The following text table gives some indication of the shift in directivity for two groups of single-boat trawlers:

Catches in numbers, per effort of cod and saithe for some selected age groups by two Faroese trawler classes.

Year	Trawlers < 1 000 HP			Trawlers > 1 000 HP		
	Saithe (4-8)	Cod (3-6)	Cod/Saithe ratio	Saithe (4-8)	Cod (3-6)	Cod/Saithe ratio
1980	37	8	0.22	27	19	0.70
1981	30	9	0.30	71	43	0.61
1982	82	11	0.13	33	41	1.24
1983	56	40	0.71	33	65	1.97

The calculated index of total demersal effort is shown in Table 8.2. Basic data for the calculation are given in Table 8.1.

As it can be seen, the cod/saithe ratio more than doubles from the period 1980-81 to 1983 for both categories for the age groups contributing the majority of the catch. It was not possible during the meeting to estimate how much of this increase can be ascribed to a change in directivity and how much to changes in recruitment, but there can be no doubt that there has been a change in directivity. This means that by using the crude uncorrected effort index for calibrations of the VPAs, the fishing mortality in 1983 for cod will probably be underestimated and the fishing mortality for saithe overestimated, at least for the older age groups of saithe in deeper waters.

9. FAROE SAITHE (Division Vb)

9.1 Landings

Preliminary catch data indicate a total catch of 39 274 tonnes from the Faroe saithe stock in 1983 (Table 9.1, Figure 9.1.A). This is an increase of 8 294 tonnes compared to 1982. Foreign catches constituted less than 1% of the total catch in 1982. The Faroese catch increased by 8 156 tonnes in 1983.

9.2 Age Composition

Age compositions for 1983 were available for the Faroese landings only. The French and Federal Republic of Germany landings were distributed according to the age distribution of catches by Faroese trawlers of more than 1 000 HP. The Norwegian catch at age was estimated from Faroese gill-net catch at age compositions.

9.3 Weight at Age (Table 9.3)

The weight at age data used by the 1983 Working Group were used for the years prior to 1983. No weight at age data were available for the 1983 landings. The 1982 data for 1983 gave an SOP discrepancy within 3% of the nominal landings and were used in the assessment.

For the predictions, the average weight at age used for the years 1981 and 1982 was used.

9.4 Fishing Mortality and Stock Values from VPA

9.4.1 Estimates of fishing mortality

The exploitation pattern in 1983 was assumed to be average of the pattern for the period 1979-81. The level of fishing mortality in 1983 was chosen by using estimates of total effort for saithe (Table 8.2).

The table indicates that the effort was constant for 1979-81. As the effort in 1983 was found to be 51% higher than the average effort for 1979-81, \bar{F}_{83} was estimated in accordance with this.

The VPA results are given in Table 9.4, and trends in fishing mortality are shown in Figure 9.1.A.

9.4.2 Spawning stock biomass and recruitment (Table 9.5, Figure 9.1.B)

The spawning stock biomass has been declining since 1972. No independent estimates are available for the strengths of recruiting year classes. From the VPA the recruitment appears to have varied extensively with the recruitment of 1-year olds between 20 and 40 millions in the period 1961-66, between 50 and 70 millions in the period 1967-70, and between 15 and 35 millions in the period 1971-78. In recent years, the 1978 year class is of the same order as the 1971-73 year classes, and the same seems to be the case for the 1980 year class.

9.5 Yield per Recruit

Curves of yield and spawning stock biomass per 1-year old recruit are plotted in Figure 9.1.C. Fishing mortalities in 1983 ($\bar{F}_{(4-8)} = 0.45$) is equal to F_{\max} . $F_{0.1}$ equals 0.19.

9.6 Catch Predictions (Table 9.7, Figure 9.1.D)

Input data for the catch predictions are given in Table 9.6. The year classes 1981 onwards are assumed to be average of the 1970-80 year classes ($R_1 = 27.2 \times 10^6$). In Table 9.7, the yield in 1985 and the spawning stock biomass for 1986 are given for different assumptions of fishing mortality in 1985 on the basis that fishing mortality in 1984 is unchanged from the 1983 level.

The estimate of landings in 1984 and 1985 is, to a large extent, dependent on the estimate of the 1980 year class. Assuming an average year class strength in 1980 will reduce the predicted landings in 1984 with approximately 7 000 tonnes.

10. FAROE COD

10.1 Faroe Plateau Cod

10.1.1 Landings (Table 10.1)

Preliminary catch figures indicate a total catch in 1983 of 38 119 tonnes from the Faroe Plateau stock. This is an increase of 16 635 tonnes or 77% compared to 1982. Non-Faroese landings of cod from the Faroe Plateau were less than 1% of the total landings. The total landings in 1960-82 are shown graphically in Figure 10.1.A.

10.1.2 Age composition (Table 10.3)

Age compositions were provided only for the Faroese landings. The Norwegian and United Kingdom (Scotland) catch at age was estimated using the age composition in the larger Faroese long-liners' landings. The Federal Republic of Germany data were distributed according to the age distribution of catches by the larger Faroese trawlers (more than 1 000 HP).

10.1.3 Weight at age (Table 10.4)

As no weight at age data were available for the 1983 landings, the weight at age for 1982 was used. This resulted in a SOP discrepancy of 10%. For the predictions, the average weight at age for the period 1977-82 was used. However, these weights needed to be corrected by 10% to account for SOP discrepancies.

10.1.4 Estimates of fishing mortality

The fishing mortality for 1983 was estimated in the same way as for Faroe saithe (Section 9.4.1), using the relative effort figures arrived at in Table 8.2 (see also Section 8). This gives an $\bar{F}_{83} = 1.15 \times \bar{F}_{79-81}$. The exploitation pattern in 1983 was set equal to the average exploitation pattern for the years 1979-81.

10.1.5 Results of VPA (Tables 10.5 and 10.6)

10.1.5.1 Fishing mortality

Fishing mortalities in each calculated from VPA are given in Table 10.5, together with input values for 1982 and for the oldest age group in each year. The trend in fishing mortalities is shown graphically in Figure 10.1.A.

10.1.5.2 Spawning stock biomass and recruitment

Estimates of spawning stock biomass (age groups 4 to 10+) are given in Table 10.6 and shown graphically in Figure 10.1.B. The estimated number of recruits at age 1 for the year classes 1961-81 are given in Figure 10.1.B. Estimates of year class strength from 0-group surveys are not sufficiently reliable to predict the abundance of recruiting year classes and, therefore, the 1982-83 year classes have been assumed to be equal to the average calculated for year classes 1961-80 (22.7 million at age 1). The current assessment indicates the 1978 year class to be above average and the 1980 year class of the same order of magnitude as the very good 1972-73 year classes.

10.1.6 Yield per recruit

Curves of yield and spawning stock biomass per 1-year old recruit are plotted in Figure 10.1.C, using the data given in Table 10.7. The estimated fishing mortality in 1983 ($\bar{F}_{(3-6)} = 0.42$) is larger than $F_{\max} = 0.26$, and $F_{0.1} = 0.13$.

10.1.7 Catch predictions

Data used in the catch predictions are given in Table 10.7, and the results are given in Table 10.8 and plotted graphically in Figure 10.1.D. If fishing mortality is maintained at the 1983 level ($\bar{F}_{(3-6)} = 0.42$), landings of 37 000 tonnes are predicted in 1984 and of 35 000 tonnes in 1985.

These predictions depend on provisional weight at age data and are liable to be revised.

10.2 Faroe Bank Cod (Table 10.2)

The landings of cod from the Faroe Bank are presented in Table 10.2. No attempt was made to assess this stock.

11. FAROE HADDOCK

The assessment was made for the stock of haddock for the total Faroe area (Division Vb).

11.1 Landings (Tables 11.1 and 11.2, Figure 11.1.A)

Landings in 1983 were 12 800 tonnes, which is a slight increase of 1 000 tonnes compared to 1982. The landings were almost exclusively by Faroese vessels.

11.2 Age Composition (Table 11.3)

Age composition data for the Faroese landings from the Faroe Plateau were provided. These were used to calculate the age composition for the total landings from the Faroe Plateau and Faroe Bank combined.

11.3 Weight at Age (Table 11.4)

The weight at age data used by the 1983 Working Group were used for the years up to 1982. For 1983, no weight at age data were available, and for this year's landings the weight at age data from the 1982 landings were used. These gave a SOP discrepancy of 12%. In the predictions the average weight at age for the years 1977-80 and 1982 was used (no original data were available for 1981).

11.4 Estimates of Fishing Mortality

The fishing mortality for 1983 was estimated in the same way as for saithe and cod in the Faroe area, using the relative effort values arrived at in Table 8.1 (see Section 8). This gives an $\bar{F}_{83} = 1.22$ x \bar{F}_{79-81} . The exploitation pattern was assumed to be the same as the average exploitation pattern for the period 1979-81.

11.5 Results of VPA

11.5.1 Fishing mortality

Estimates of fishing mortality in each year calculated by the VPA are given in Table 11.5, together with the input values for 1983 and for the oldest age in each year. The trend in fishing mortalities is shown graphically in Figure 11.1.C.

11.5.2 Spawning stock biomass and recruitment

Spawning stock biomass (Table 11.6, Figure 11.1.B) was relatively stable at about 60 000 tonnes up to 1974. Subsequently, the spawning stock benefitted from the recruitment of the abundant 1972 and 1973 year classes, which increased the spawning stock to about 110 000 tonnes. By 1981, the spawning stock had returned to a lower level. The estimated numbers of recruits at age 1 are given in Table 11.6 and Figure 11.1.B.

In recent years, the 1972-74 year classes were the largest on record, but the recruitment subsequently declined and the 1977 year class appears to have failed completely, and the 1978 and 1979 year classes have also been very small compared to the average. The 1980 year class seems to be above average.

11.6 Yield per Recruit

The Y/R curve given in Figure 11.1.C has been calculated using the exploitation pattern assumed for 1983 and the mean weight at age for the years 1977-80 and 1982.

The present level of $\bar{F}_{(4-6)} = 0.28$ is close to $F_{0.1} = 0.29$ and below $F_{\max} = 0.60$.

11.7 Catch Predictions

Catch predictions were made for a recruitment level of 37.7 million 1 year old fish (average of year classes 1966-80) for the year classes 1982-85, and using the input data given in Table 11.7. The results are given in Table 11.8 and Figure 11.1.C.

12. PREDATION MORTALITY

Reference was made to papers by Daan (1983) and Gislason (1983) reporting results of stomach sampling in the North Sea. The latter was more specifically devoted to predation by saithe and emphasized the low number of fish encountered during surveys, especially in the second and fourth quarters, and the limited range of length groups sampled. Both papers summarise results of predation by saithe but not on saithe.

No quantitative evidence on cannibalism was available to the Working Group and its effect is undetermined.

Thus, at present there are no adequate data available for estimating the effect of predation on the magnitude of natural mortality and its variations with time.

13. COMMENTS ON WEIGHT AT AGE DATA

For most of the stocks dealt with by the Working Group, constant weights at age in the stock have been used up to the late 1970s, and only in recent years were these weights estimated according to the values observed each year in the catches. It is possible that weight at age could be estimated annually for the earlier part of the time series. If this were to be done, estimates of stock biomass may be changed. However, the magnitude or direction of any changes cannot be anticipated.

Although highly desirable, a better description of maturity at age using an ogive instead of the usual knife-edge array is not possible at present; past values would still be more difficult to revise, since one may suspect that fecundity is very sensitive to environmental conditions.

The appropriateness of mean weight in the catch as an estimate of weight in the stock on the 1st of January is also questionable as the former is mainly influenced by the seasonality and geographical distribution of the different fisheries aimed at saithe and their relative level of effort in each year, while the latter should be independent of this effect. In addition, the consistency of the catch weight data raises questions, since different countries estimate them in different ways and adjust either catch numbers or mean weights for SOP discrepancies.

These effects are of minor importance for short-term predictions, but the Working Group recommends that the data series of weight at age, as they exist in ICES data files or reports' tables, should be used with extreme caution for any other purpose.

14. OTHER ITEMS

The Working Group agreed to prepare for the next meeting a review of national fleets participating in saithe fisheries, either regularly or potentially during the mixed demersal stock fishery. This review need not be based on very detailed data, but should aim

at providing a synthesis of information on such items as physical characteristics of the fleet categories (number, length or power class, gear, possibly crew, and usual trip duration), seasonality and grounds worked. Comments on the evolution of these categories during recent years and, if possible, expected changes in the near future would be particularly useful to provide the Working Group with the necessary information, when trends in fishing mortality or fishing pattern are discussed.

An example of the type of data required can be found in the report of the Industrial Fisheries Working Group 1983 (Doc. C.M.1983/Assess:7).

The review will be prepared by correspondence and eventually annexed to next year's report.

[#]) Preliminary

a) Data from national Laboratories

b) In 1974 estimates of industrial by-catches were included in the Norwegian catches reported to ICES. These estimates have later been revised and the sum of industrial by-catch and human consumption landings therefore deviate somewhat from the Bulletin Statistique figures.

APPENDIX

COMMENTS ON Y/R ANALYSIS FOR WEST OF SCOTLAND SAITHE

In common with a number of other stocks, natural mortality for West Scotland saithe is assumed to take a value of 0.2. Although this assumption is a desirable expedient for consistency in the absence of contrary evidence, it is important to appreciate the consequences of the assumption for Y/R analysis, if this model is to take an active role in management recommendations. The following assessment is offered as an illustration.

The hypothesis that $M = 0.2$ can equally be replaced by $M = 0.1$ with no loss of validity. A VPA was therefore run with a natural mortality of 0.1 and tuned in precisely the same way as that given in the main assessment (Section 7). The results of this VPA are given in Appendix Tables 1 and 2. It should be noted that this analysis gives almost identical status quo catch predictions in 1984 and 1985 of 24 000 tonnes when compared to the main assessment (Section 7). The Y/R curve (Appendix Figure 1), however, gives quite different results and implies that the stock is considerably overfished. The sensitivity of the analysis to arbitrary assumptions should be borne in mind when using biological reference points.
