## REPORT OF THE STUDY GROUP ON NORTHEAST ATLANTIC SALMON FISHERIES

Copenhagen, 1-4 March 1993

This document is a report of a Working Group of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council. Therefore, it should not be quoted without consultation with the General Secretary.

### 1.1 Terms of Reference

The terms of reference for the Study Group were set out in ICES C.Res.1992/2:8:4 as follows:
"The Study Group on the Norwegian Sea and Faroes Salmon Fishery will be renamed the Study Group on North-East Atlantic Salmon Fisheries (Chairman: Mr E.C.E. Potter, UK) and will meet at ICES Headquarters from 1-4 March 1993 to prepare the relevant data for presentation to the Working Group on North Atlantic Salmon at its meeting in March 1993. The national runreconstruction model should be re-run for the 1989 and 1990 smolt releases and a sensitivity analysis should be made".

The terms of reference for the Working Group on the North Atlantic Salmon are given in Appendix 1. The Study Group addressed the relevant questions under items 1, 2, 4 and 5 of these terms of reference, the remaining items being the responsibility of other Study Groups or the Working Group.

### 1.2 Participants

Walter Crozier
Lars P. Hansen Marianne Holm
Arni Isaksson
Jan Arge Jacobsen
Lars Karlsson
Eero Niemelä
Julian MacLean
Niall O'Maoileidigh
Ted Potter (Chairman)
Etienne Prévost
Alexei Sharov Russia
Alexander Zubchenko Russia

## 2 CATCHES OF NORTH ATLANTIC SALMON

### 2.1 Nominal Catches of Salmon

Revised estimates of the total nominal catches of salmon by country were provided for 1991, and provisional estimates for 1992 were collated. Total nominal catches are presented in Table 2.1.1 and discussed in Section 4.2.2

### 2.2 Catches in Numbers and Weight by Sea Age

Provisional data on the sea age composition of catches were provided for several northeast Atlantic countries
and are presented in Table 2.2.1. Specific information, where available, is given in Section 4.2.3.

### 2.3 Unreported Catches

### 2.3.1 Unreported catches within national EEZS

The total guess-estimated unreported catches within national EEZs in the North East Atlantic Commission (NEAC) Area of NASCO for the years 1987-1992 are given in Table 2.3.1. Data for some countries were incomplete estimates. The unreported catch for 1992 $(1,825 \mathrm{t})$ was greater than for the two preceding years. However, the Study Group emphasized that, as these were very imprecise figures, the difference could not be considered significant. In addition, it was noted that several countries estimate unreported catches as a proportion of total or regional declared catches; as a result, there was a tendency for the total unreported catch to alter in line with the nominal catch. Thus, the decrease in the values given for 1990 to 1992 (average $1,720 \mathrm{t}$ ) compared with the preceding years (average $2,216 \mathrm{t}$ ) reflects the decline in declared catches in most countries.

A radio tracking study carried out in the Teno River, Finland, in 1992 indicated that out of a sample of 66 radio-tagged fish entering the river none was caught illegally before spawning time.

### 2.3.2 Unreported catches in international waters

Sightings by Icelandic and Norwegian coastguards of vessels fishing for salmon in international waters to the north of the Faroes EEZ were reported to NASCO. NASCO informed the Study Group that 2 sightings were reported in the 1991/1992 season both in May 1992. The catch in this area during the season is therefore estimated to have been similar to 1990/1991, namely $25 \mathrm{t}-100 \mathrm{t}$.

The Study Group was aware of reports of by-catches of salmon in a horse-mackerel fishery in the Northern Norwegian Sea, but no new data were available.

## 3 STATUS OF STOCKS IN NORTH-EAST ATLANTIC COMMISSION AREA

### 3.1 Organisation of Stock Status Information

As in previous years, the Study Group collated and assessed available data on stock status in the north-east Atlantic. These comprised catch data, historical and recent counts (or estimates) of smolt and adult runs (see Section 3.2), marine survival estimates based on returns of tagged smolts to coastal waters (ie. before homewater exploitation) and returns to freshwater for wild and hatchery fish (see Section 3.3).

The Study Group also considered the types of data required to describe status of stocks with respect to escapement against spawning targets (Section 3.4).

### 3.2 Measures of Abundance and Escapement

Catches: Total nominal landings of salmon in the northeast Atlantic in 1992 (Table 2.1.1) increased relative to the 1991 value, but remained lower than the averages for the previous 10 years. The overall catch figures are not particularly informative, as various regulatory measures have reduced the catch in some countries (e.g., Norway), while in Iceland catches are influenced by ranching. The presence of fish farm escapees in commercial catches is significant in at least one country (Norway), and thus, the catch statistics may give an overestimate of the abundance of wild fish. Furthermore, catch statistics may not reflect the true abundance of wild stocks, given the range of factors that affect catches, such as effort variations, fishing conditions and variable run timing in relation to fishing seasons.

Freshwater productivity: Counts or estimates of wild smolt production are available from 11 stocks in the northeast Atlantic, as well as indices of juvenile salmon abundance from the River Bush (UK, Northern Ireland) and estimates of total $0+$ population in the R. Nivelle (France) (Table 3.2.1). Although these examples may not be representative of larger groups of stocks, they may indicate trends in freshwater productivity within regions. Annual variation in juvenile/smolt counts is evident in all stocks, with in most cases no apparent trend in fluctuations, except as previously noted in the Burrishoole (Ireland), R. Högvadsån (Sweden) and Imsa (Norway) (Anon., 1992a). Smolt numbers in the R. Burrishoole (Ireland ) recovered in 1992, with the count being close to the previous 12 year average. Smolt production on the R. Högvadsån fell to very low levels due to acidification in the late 1970s and has since been restored by liming. In most rivers the 1992 counts fell within the range observed in the last 10 years, except in the R. Bush (UK, Northern Ireland) and the R. Bresle (France). Whether the low smolt count on the R. Bush in 1992 is attributable to density-dependent mortality at high ova depositions or recent environmental degradation cannot be determined.

Despite concerns in several countries that reduced adult runs in 1990 and 1991 may have resulted in inadequate spawning populations, there is no widespread evidence in 1992 that juvenile production has been affected.

Adult escapement: Adult counts (or estimates) for 20 wild stocks are presented in Tables 3.2.2 and 3.2.3, including new data for the R. Bresle (France) and additional historical time series for the Rivers Kola and Zap. Litca (Russia). Although year to year variations in adult numbers counted in monitored rivers are evident,
runs were generally higher in 1992 compared with either or both of the previous two years. In about two thirds of the rivers monitored, adult runs in 1992 were comparable to or greater than average runs for the whole time series. For the R. Högvadsån in Sweden, wild adult counts have not increased in the last 4 years despite earlier increases attributed to mitigation liming. In 3 Russian rivers (Kola, Yokanga and Zap. Litca), adult counts were above the range for the last 10 years. These high numbers could be partly explained by management measures taken in Norway, leading to reduced exploitation on Russian stocks, though natural factors governing the dynamics of these stocks must also be considered. Given that in some cases counts/estimates represent minimum figures for adult runs, the 1992 figures for the north-east Atlantic provide some evidence that conditions causing poor adult runs in 1990 and 1991 may have been transitory.

### 3.3 Survival Indices

Estimates of marine survival for wild smolts from 6 stocks returning to homewaters (ie., before homewater exploitation) and for 9 stocks into freshwater (ie., including coastal exploitation) are presented in Tables 3.4.1 and 3.4.2, respectively. Marine survival rates for hatchery smolts are given in Tables 3.4.3 and 3.4.4 for return to homewaters (6 stocks) and freshwater (5 stocks), respectively. The Study Group noted that estimates of return to homewaters are likely to present a clearer picture of marine survival than returns to freshwater because of variation in exploitation in coastal fisheries.

Survival to coastal return as 1 SW salmon of wild smolts (Table 3.4.1) from the 4 monitored stocks where estimates are available was higher for the 1991 smolts than for the 2 previous year classes, except for the R. Bush (UK, Northern Ireland), where a reduction relative to the 1990 year class (but not 1989 smolts) was noted and for the R. Imsa where survival was similar for 1991 and 1989 smolts. The higher levels of coastal returns were also reflected in improved survival of wild smolts to 1 SW salmon into freshwater (Table 3.4.2) in 8 rivers where data are available. For 3 of the 4 stocks for which data are available, survival to coast and to freshwater of 2SW fish was still relatively poor for the 1990 smolt year class, suggesting that these fish were affected by the marine conditions that led to reduced runs in several countries of 1SW fish from this year class.

Survival indices for 1991 hatchery-reared smolts returning as 1 SW fish to coastal waters in 1992 were more variable than for wild fish (Table 3.4.3), with 3 stocks having decreased coastal returns and 2 increased relative to the 1990 year class. Different trends were noted for separate smolt age groups from the R. Bush (UK, Northern Ireland). Similar variability was evident
in 2SW coastal returns. With the exception of the Kollafjordur (Iceland), 1SW hatchery-reared returns to freshwater were generally lower for 1991 smolts than 1990 smolts (Table 3.4.4). Returns to freshwater of 2SW hatchery-reared fish in 1992 were poorer than in the previous year, in agreement with data from wild fish.

Although there are some inconsistencies in trends from wild and hatchery smolts, compared to 1991, there is evidence among the monitored river data that while 2SW survival indices still reflect poor marine survival of the 1990 smolt year class in many areas, the 1991 year class has displayed improved marine survival, reflected in 1SW returns in 1992.

### 3.4 Stock Targets

Data on abundance and escapement by themselves, while useful in indicating possible trends in numbers of salmon through time, are of limited use in assessing stock status. This is especially true of catches in homewater fisheries where catch levels can be affected by effort variations and weather condition during fishing seasons. Similarly, rod catches and freshwater escapements are susceptible to climate-induced variation. Wild smolt counts or estimates are available for only a limited number of monitored rivers, and, as smolt counts are river-specific, these cannot be routinely used to infer status of stocks outside the river in question.

The Study Group considered that status of stocks would best be appraised by considering adult escapement (in terms of ova depositions) evaluated against spawning targets, in a similar manner to that adopted for Canadian stocks (Anon., 1992a). Ideally, biologically based spawning targets would be set for each river system, such that the target for each would represent the number of ova required to optimise smolt production from that system. This would not only provide a baseline against which annual ova depositions could be compared, but allow for the possibility that estuarine and in-river fisheries for single stocks could be managed to crop only adults in excess of the target spawning number. Targets should be set sufficiently high to allow compensation for density-independent variation.

Spawning targets would ideally be set for each river system based on knowledge of the number of spawners required for optimum productivity obtained from the stock-recruitment relationship and applied to survey data of the available areas of riverine and lacustrine habitat. However, data on stock/recruitment relationships are only available for the small number of "monitored" rivers in the north-east Atlantic (Anon., 1987) plus a tributary of the R. Dee (Scotland) and some Russian rivers. Canadian spawning targets are based on different levels of freshwater productivity and may not be appropriate for north-east Atlantic rivers. Accordingly,
there is a need to carry out further research to define stock/recruitment relationships in a range of north-east Atlantic rivers and to determine whether productivity levels so far observed can be applied to other river systems. It is noted that data required for assessing stock/recruitment relationships are currently being collected in several other monitored rivers, including the R. Högvadsån (Sweden), R. Oir, R. Bresle and R. Nivelle (France), and the R. Orkla (Norway). The Study Group strongly recommends that these studies should continue.

As an example of the first use of such data, preliminary modelling of the R. Bush stock/recruitment relationship suggests that the target ova deposition in the river lies in the region of 3.7-5.5 ova $\mathrm{m}^{-2}$ of usable salmonid habitat, corresponding to a whole river ova deposition of approximately 2.03 million. Natural ova deposition (derived from trap counts of potential spawning female fish) has exceeded this target for 7 of the last 8 years.

Several significant factors need to be taken into account in setting and expressing individual river targets, such as variation in sex ratio of spawners, changing fecundity through time, changing 1SW:MSW ratios and the desired sea age composition of the spawning fish. This approach to stock assessment allows appraisal of whether target shortfalls are local in nature or more widespread, such that aggregated national targets are not being met.

In order to begin to assess stocks with respect to spawning targets the following data are needed:

Baseline data: As stock/recruitment data will not be available for each river for which targets are to be set, it will be necessary to apply optimal egg deposition rates from a limited number of experimental rivers to other rivers, provided that equivalence of productivity and ecological characteristics can be reasonably assumed. Ranges of freshwater productivity are known for many more rivers than stock/recruitment relationships, enabling them to be placed into groups. It will also be necessary to measure or estimate the total area of usable salmonid habitat in each river, such that optimal targets can be extrapolated for whole river systems. Different target egg deposition rate values will need to be applied to lacustrine and riverine habitats.

It is recommended that a standardised method of expressing targets should be adopted, such that these are comparable among rivers. The Study Group agreed that target egg deposition rates should be expressed as numbers of eggs per square metre of usable habitat. River targets should be expressed either as total numbers of eggs required by each river system, or more simply as the required numbers of spawning fish (possibly for each sea age group).

Annual assessment data: For rivers where targets have been established, it will be necessary to assess the numbers of potential spawning adults. These can be estimated directly from traps or counting fences or indirectly from tag and recapture data. From these, estimates of ova deposition can be derived using fecundity measurements applied to the sex ratio, separately for each sea age group.

In order to provide meaningful data, the number of monitored rivers would need to be increased, and this would have resource implications outside the remit of the Study Group. It should, however, be noted that the parameters required for this type of assessment comprise only annual data on spawning escapement and biological composition of potential spawners. As significant factors affecting stocks at a national level (such as acidification or increased natural marine mortality) are likely to be felt among many rivers, it would only be necessary to monitor relatively few rivers nationally to detect significant trends with respect to targets. It should be possible to set provisional targets for several river types based on currently available information, but it should be emphasised that resources should continue to be made available towards refinement of target assessment methodology and more importantly into reasons why targets may not be met in many stocks.

The Study Group recommended that a workshop be held, to consider available evidence that might be used to set stock targets and to identify what further data are necessary to implement assessment of stock status with respect to targets.

### 3.5 Causes of Apparent Reduced Survival of Salmon in Recent Years

In recent years there has been growing concern that marine survival of Atlantic salmon has been decreasing. This has been fuelled mainly by the observation in some countries that catches have decreased. However, other factors such as freshwater production and conditions in the fisheries need to be taken into consideration. The best data available to answer this question comes from the relatively small number of monitored stocks for which survival of wild or hatchery reared smolts to homewaters is available.

The Study Group considered the likely effects of factors operating at different stages in the marine phase of the life cycle. It was recognised that changes in return rates of stocks over a wide geographic area were likely to indicate factors operating in the sea rather than during the freshwater phase. Factors reducing the survival of post-smolts early in the marine phase would affect the numbers of both 1SW and MSW fish returning in succeeding years. Factors operating later could affect only one sea age group. The period in which survival
was affected might also be seen by comparing changes in tag return rates in distant water fisheries and homewaters. Finally, environmental influences in homewaters may affect the ability of fish to enter freshwater quickly; delayed fish might suffer increased mortality.

Smolt survival estimates from UK (Northern Ireland) indicate that survival to coastal return of wild 1SW fish from the 1989 smolt year was below the previously observed range but improved considerably for the 1990 smolt year class. Data for the Burrishoole show low smolt survival for 1989 but improved for 1990 for both wild and hatchery smolts. However, Norwegian data from the R.Imsa indicate that smolt survival to 1 SW returns was poor for the 1990 and 1991 smolts; changes in survival to 2 SW are more difficult to assess because of the variability of the annual estimates, which tend to be based on few returns. A similar pattern is seen in the North Esk (UK (Scotland)). There was poor survival, relative to previous years, for both the 1989 and 1990 smolt year classes in terms of 1SW returns. Returns as 1SW fish from the 1991 smolt year class were still low but higher than in the previous two years. In Iceland, survival to 1SW returns in 1991 was high in comparison with the previous two years.

It, therefore, appears that salmon stocks over a wide range in the north-east Atlantic have experienced reduced survival of the 1989 smolt year class. Survival of the 1990 smolt year class has been low in most, but not all, areas. However, there are now indications from 1SW returns in 1991, that survival may be increasing again. Given that recent reduced smolt survival has been observed in three out of the four countries where estimates are available, that both 1 SW and 2 SW returns are affected and that none of these countries are thought to have problems with freshwater productivity, it would seem that the cause of reduced survival is a marine problem that occurs at a stage between entry into the sea and the first sea winter.

The cause of the reduced survival is unclear. The Study Group noted the work of Friedland and Reddin (in press) that suggested good correlations between salmon catches in Europe and the available area of marine habitat within certain temperature ranges. There is also some hydrographical information available from Iceland relating to the observed pattern of survival of ranched fish. This suggests that during the years where $1 S W$ returns were poor, sea conditions were unusual, with cold East Greenland currents dominating North Icelandic waters rather than warmer Gulf stream currents. It is interesting to note that capelin catches also correlated with the prevailing hydrographic conditions, suggesting that capelin stocks may have been affected by the same factors as salmon.

The Study Group also noted that several countries had recorded unusually dry weather in some recent years. This was known to have affected salmon movements into freshwater in some areas. As a result, catches were affected in many rivers although, in some, adequate numbers entered the rivers late in the season and spawned successfully. In the absence of spawning targets and stock counts in most areas, it is not possible to assess the extent of the problems arising in recent years.

## 4 FISHERIES IN THE NORTH-EAST ATLANTIC COMMISSION AREA

### 4.1 Description of the Fisheries at Faroes

### 4.1.1 Gear and effort

Gear in use in the Faroese fishery did not change in the 1992.

The fishing effort was greatly reduced in the 1991/1992 season due to the buy-out of the Faroes quota by various interested parties for the years 1991-1993. Only one research vessel operated during the fishing season, under the direction of the Faroese Fisheries Laboratory. A total of 52 sets was fished by this vessel during 6 trips in the 1991/1992 season.

### 4.1.2 Catches and discards

The research fishery followed very much the normal pattern of previous seasons, beginning close to the islands and moving in a north-easterly direction out to the fishery limit during the season (Figure 4.1.1). The total catch in the 1991/1992 season was 31 t and the preliminary catch for the calendar year 1992 was 23 t , all catches being by the research fishery (Tables 4.1.1 and 4.1.2). The catch in number by month is given in Table 4.1.3. As in the last two seasons, the weather in January was very bad.

All salmon caught were measured, and the discard rate from each trip is given in Table 4.1.4, which also includes other parameters sampled in the research fishery, such as scale samples, number of finclipped salmon and tagged fish. A total of 8,927 fish was measured of which 782 were less than the permitted 60 cm total length. The discard rate from the catch ranged from 2.5 to $15.7 \%$, and the overall estimate was $8.8 \%$ (Table 4.1.4). This value is within the range observed since the 1982/1983 season (Table 4.1.5). As noted in the two preceding seasons (Anon., 1992b) the proportion of discards tends to decline as the season progresses.

### 4.1.3 Catch per unit effort

The catch in number (divided by 10) by statistical rectangle is shown in Figures 4.1.2 to 4.1.6. The catch in number per 1000 hooks (CPUE) is shown in Figures 4.1.7 to 4.1 .10 and for the whole season in Figure 4.1.11. As in the last few seasons, the CPUE in the first part of the season was very high and as in 1988/1989 it remained high during February and March and dropped off in April (Table 4.1.6a). In the 1991/1992 season no fishery took place outside the Faroes EEZ (Table 4.1.6b).

It should be noted that the overall CPUE of 79 salmon per 1000 hooks for the 1991/1992 season is the highest on record since the $1981 / 1982$ season (Table 4.1.6a). One reason for this might be the fact that the research vessel M/S "Polarlaks" has been one of the best vessels in the salmon fishery in previous seasons. However, as only one vessel was operating, it would not have had the opportunity to benefit from receiving information from vessels fishing in other areas to enable it to find the best fishing areas. In this case several vessels spread over the area would have a higher chance of spotting areas with good catches than just one vessel. If, on the other hand, the reduced exploitation in the fishery resulted in increased concentrations of salmon within the Faroes EEZ compared with previous years, more salmon would be available to the single vessel, thereby increasing the catch and the CPUE. A third, and possibly the most likely explanation, could be the high number of reared salmon observed in the Faroes area in the 1991/1992 season. As much as $37 \%$ of the salmon caught were estimated to be of reared origin (Jacobsen et al., 1992), and samples from the 1990/1991 and 1989/1990 seasons also indicate similar numbers of reared fish in the Faroes area. The presence of high numbers of reared salmon in the Faroes catch could mask a decline in the wild stock in the area.

### 4.1.4 Biological composition of the catch

Production of farmed salmon in the north-east Atlantic is shown in Table 5.1. When assessing salmon fisheries and wild salmon stocks, it is important to estimate the farmed and ranched component. If a high proportion of such fish is present, but is not accounted for, the catches of wild salmon will be overestimated and the size and status of the wild stocks will be masked. There is direct evidence that salmon that have escaped from Norwegian farms are caught in the long-line salmon fishery north of the Faroes (Hansen et al., 1987), and recent observations have shown that escaped reared fish are numerous in catches in these areas (Jacobsen et al., 1992). As a part of the sampling programme of Atlantic salmon in the long-line fishery at Faroes, fish were examined in order to estimate the occurrence of reared salmon in the fishery. Material was available from February 1990, December

1990, December 1991 and February, March and April 1992 (Table 4.1.7). In the majority of the fish sampled, body length (fork length) was recorded to the nearest cm .

Identification was carried out by scale analysis (Lund et al., 1989; Lund and Hansen, 1991) In 31 fish (5 \% of the total number examined) it was not possible to judge if the fish were reared or wild; in the analysis these fish were taken to be wild.

In all samples, reared salmon were observed in relatively high frequencies (Table 4.1.7). Both in February and December 1990, more than 40 percent of the fish examined were estimated to be of reared origin. During the 1991/1992 fishing season, when sampling occurred over a large part of the fishing season, the average proportion of reared salmon was $37 \%$. This season, the estimated proportion of reared fish was significantly lower in March and April (25-28\%) than earlier in the season ( $36-48 \%$ )( $\mathrm{X}^{2}$-test, $\mathrm{P}<0.01$ ). The methodology used to discriminate between wild and reared fish tends to underestimate the proportion of reared fish, in particular those escaped at the freshwater stage, or at an early marine stage (Lund et al., 1989; Lund and Hansen, 1991). Thus, potential error classification is directed towards reared fish being classified as wild rather than vice versa. It is not thought that these are fish that have been deliberately released because tagging programmes have shown that such fish contribute relatively little to the fishery.

The high frequency of escapees from fish farms at Faroes is in the same order of magnitude as in Norwegian home water fisheries. In 1989, 1990 and 1991 the average proportions of farmed salmon in fisheries on the outer Norwegian coast were estimated to be 45, 48 and $49 \%$, respectively, whereas in fjord fisheries the corresponding proportions were 14,15 and $10 \%$ (Lund, Økland and Hansen, 1992). The reason for this difference is that a large proportion of escaped farmed salmon enter fjords and rivers after the fishing season has closed. In a single salmon fishery in western Scotland, Webb and Youngson (1992) estimated that $22 \%$ of the catch were of reared origin. Because this value was based on morphological data alone, it cannot be compared directly with the values obtained in Norway.

Research carried out in Norway indicates that in most cases escaped farmed fish return as adults to the area from where they escaped (Hansen and Jonsson, 1991). The high proportion of farmed salmon in the Norwegian home water fisheries combined with the fact that Norway accounts for the major production of farmed salmon in the Atlantic, strongly suggest that most farmed salmon occurring in the Norwegian Sea are of Norwegian origin. It is also reasonable to assume that farmed fish escaping from cages in Scotland, Faroes and Ireland also contribute to the Faroese fishery.

To examine whether the presence of reared salmon affect the description of the composition of the catch, some biological characteristics of wild salmon obtained from scale samples were compared with those of reared fish. Age was determined by scale analysis in accordance with conventional rules described in Anon. (1984a) and smolt lengths were estimated by linear back-calculation. In reared fish, age and smolt length calculation may frequently be complicated by a diffuse transition between the freshwater and sea zones of the scale confusing the position of the last winter-band in freshwater (Lund and Hansen, 1991). When this occurred, the estimation was based on the minimum value. Back-calculation of smolt size was carried out with some of the scales taken from wild fish (the samples from 1990 and a sub-sample from February 1992).

In samples from all three seasons, the wild fish were significantly larger than the reared fish (Mann-Whitney U-test, $\mathrm{p}<0.01$ ). There also appear to be significant differences in size within all sea-age groups compared (1-3)(Mann-Whitney U-test, p<0.01) (Figure 4.1.12). Reared 1SW fish were significantly larger than wild 1SW fish, whereas among the 2SW and 3SW groups, the wild fish were larger. However, although the sea age of ranched fish are usually aged correctly, misinterpretation of sea-age may be common in salmon reared in sea pens (Lund and Hansen, 1991). This may explain the extensive size overlap between the sea-age groups in reared fish. It is possible that the sea-age composition of the reared fish is actually similar to the wild fish but their growth is different.

Among the reared fish, 12 out of 240 individuals (5.0\%) were less than 57 cm in fork length, and thus discarded, whereas among the wild fish 13 out of 356 fish (3.7\%) were discarded. This difference is not significant ( $p>0.05$ ). The size distribution of wild and reared fish in samples taken in 1991/1992 are shown in Table 4.1.8.

## Sea age distribution

The sea-age of the reared and wild fish interpreted from scale reading also differed significantly (Figure 4.1.13) (Mann-Whitney U-test, $\mathrm{P}<0.001$ ). However, in both categories, the majority of the fish were 2 SW salmon, accounting for $85 \%$ of the wild fish and $70 \%$ of reared fish. 1SW fish, on the other hand, appeared from the scale reading to be more numerous among the reared fish ( $25 \%$ ). Thus, the estimated average sea-age of reared fish was lower ( 1.8 years) than for the wild fish (2.1 years). However, this difference may reflect errors in the reading of the reared fish scales.

The sea age composition of the total catch has been estimated on the proportion of the catch thought to be of wild origin. The division of the catch into wild and
reared components was based on the four samples of scales examined (Table 4.1.7). The sea-age composition of the wild component was based on the age composition of the wild components of each sample (Table 4.1.9) and are shown in Table 4.1.10. In comparison to previous seasons (Table 4.1.11), there was an increase in the proportion of $3 S W$ fish in the catch and a consequent decrease in the proportion of 2SW fish. However, it was noted that no correction had been made to the previous years' data to account for reared fish; this may have resulted in a significant error in estimating the age composition of the catch using either scale readings or a length split.

## Weight distribution

The weight composition of the catch is only available for wild and reared fish combined (Table 4.1.12). This confirms the increase in the proportion of large ( $>5 \mathrm{~kg}$ ) fish relative to the previous seasons.

## Smolt age distribution

In the pooled samples, the smolt age (estimated from scale reading) of the reared fish was significantly higher than for the wild fish (Figure 4.1.14) (Mann-Whitney $U$ test, $\mathrm{p}<0.001$ ). The mean smolt age of the wild fish was 2.6 years (range $1-5 \mathrm{yrs}$ ), while it was 3.3 years for the reared fish (range 1-7 yrs). However, in commercial rearing of Atlantic salmon, smolts are exclusively 1 or 2 years old. The high smolt age readings from the scales are consistent with previous evaluations of scale interpretation of reared fish, which exhibit false winter-bands (Lund and Hansen, 1991). This error in the smolt age reading of farm escapees will bias the estimates of smolt age composition of the total catch if it is not accounted for. Table 4.1.13 gives estimates for wild fish alone in 1991/1992. These data give a similar smolt age composition of the catch to previous seasons; however, no account has been taken of the possible presence of farmed fish in samples in previous years, which will have resulted in some smolt ages being overestimated.

## Smolt size

The range of variation in the back-calculated smolt lengths was far greater in reared fish ( $9-41 \mathrm{~cm}$ ) than in the wild fish ( $8-19 \mathrm{~cm}$ ) (Figure 4.1.15), and the average smolt length was significantly higher in reared fish (21.9 $\mathrm{cm})$ than in wild fish $(12.8 \mathrm{~cm})$ (Mann Whitney U-test, $\mathrm{p}<0.001$ ). The production of large smolts is often a production goal in commercial rearing.

### 4.1.5 Origin of the catch

The distribution of tag recoveries in the Faroes fishery for the period 1981/1982 to 1991/1992 is given in Table 4.1.14. In 1991/1992 tags were recovered principally
from Irish salmon originating from Shannon River hatchery releases. As the overall release of this particular group was large $(320,000)$ and tags of Irish origin are recovered regularly from the Faroes fishery, this number of tags is not unexpected.

Individual tags were also recovered from 3 rivers in UK (England and Wales) and 2 rivers in UK (Scotland).

One French origin tag was recovered in the Faroes fishery in the 1991/1992 season. This is the first French microtag recovery, although Carlin tags have been recovered in the past.

Table 4.1.15 shows the derivation of raising factors for the $1984 / 1985$ to $1991 / 1992$ fishing seasons, and Table 4.1.16 gives an estimate of the total number of microtagged salmon killed (including discards) in the Faroes by sea age class and catch rates per 1,000 fish tagged. These catch rates were much lower than previously recorded due to the reduction in fishing effort and lower catch in the fishery.

The total number of external tags recovered in the Faroes fishery in the 1991/1992 season is shown in Table 4.1.17. Due to the lower catch in the experimental fishery, the number of external tags recovered was also lower than in previous years.

The Study Group noted at their last meeting that the external tag recoveries should be validated and finalised before the 1993 meeting in order to compare the catch rates per 1,000 released with data from the microtag recovery programme. Where possible this has been carried out. These values are presented by country of origin in Tables 4.1.18, 4.1.19, and 4.1.20, and summarised in Table 4.1.21 and Figure 4.1.16.

The data confirm previous observations on the relative catch rates at which stocks from different countries were represented in the fishery. All sets of data indicate a decline in the catch rate reflecting the drop in catch at Faroes in 1991/1992.

### 4.1.6 Exploitation rates in Faroese fishery

The calculation of exploitation rates in the Faroese fishery on several stocks from Norway, Sweden and UK (Scotland) is shown in Tables 4.1.21 to 4.1.26 and the results are summarised in Table 4.1.27.

The exploitation of hatchery stocks from the Drammen (Norway) and Lagan (Sweden) have shown similar changes with levels being quite low in the 1986/1987 and 1987/1988 seasons and higher in 1989/1990 and 1990/1991. Also the exploitation on the Imsa stocks (wild and hatchery) increased in 1989/1990 and 1990/1991 compared with the preceding years. The
exploitation rates on wild fish from North Esk have been lower in the last five years than previously.

Exploitation rates in 1991/1992, after the cessation of the commercial fishery, were below $5 \%$ for all stocks. This was considerably lower than the average for the preceding five-year period. The exploitation on the Norwegian Drammen and Imsa hatchery 2SW fish decreased from an average of $21 \%$ and $23 \%$ to $2 \%$ and $1 \%$, respectively.

### 4.2 Description of Homewater Fisheries

### 4.2.1 Long-term changes in effort

In order to provide a picture of management measures taken to control effort in homewater fisheries, the Study Group compiled lists of the numbers of gear units used or licensed each year (over the past 10-25 years) by country and gear type (Table 4.2.1a+b and Figures 4.2.1a to c ). It must be emphasized that these data cannot be used to estimate CPUE and may not be comparable between countries (for example, a drift net unit in Norway will be less than 100 m while in other countries it may be several times this length).

Finland: In both recreational and commercial fisheries there has been an increase in the number of gear units used over the past 10 years.

France:The number of rod and line licences issued has decreased since the early 1980s. The number of commercial freshwater net licences has declined since 1989 following the introduction of quotas on catches in 1987 although it is still greater than in the early 1980s. Licences issued for the commercial fishery in the Adour estuary show a decline in the last 10 years. However, it is felt that these figures overestimate the actual number of licences being used.

Ireland: The number of drift-net licences issued increased from the 1960s to peak in 1973. Since then the number of all commercial licences has decreased steadily. The number of rod and line licences issued shows an increase in the latter part of the series.

Norway:The numbers of bag and bend net units recorded annually in Norway show opposite trends, the number of bag nets decreasing by a factor of 5.5 to the year 1988, and the number of bend nets increasing by a factor of 2 . This reflects the greater ease of operation of bend nets as opposed to bag nets with the introduction of modern materials. Since 1989, when restrictions were introduced in the bend net fishery, there has been a slight decrease in the number of bend nets and an increase in the number of bag nets. Drift net licences were introduced in 1979 and, from this year to 1988 , the number of nets decreased by a factor of 1.5 ; their use was banned in
1989. The number of lift nets fished decreased by a factor of 7 over the period 1966 to 1990.

Sweden: About $80 \%$ of the coastal catch is taken by bag nets. The number of bag nets fished between 1980 and 1990 ranged from 70 to 80 . The 1993 figure is about 65 bag nets.

UK (England and Wales): There has been a decrease in the number of all net type licences issued over the past 10 years, the main reduction being in the number of licences for hand-held nets.

UK (Scotland): Data providing an index of effort for Scotland, by month and annually, for both the net and cobble and fixed engine fisheries were provided for the years 1982 to 1991. These figures were derived from the reported number of minimum and maximum crews fishing in the case of the net and cobble fishery and from the minimum and maximum number of traps fished in the case of the fixed engine fisheries. They do not represent an absolute value of effort but provide an index. For both types of fishery, effort is greater in the summer months when the 1SW fish are available to the fisheries and has decreased over the past 10 years. Buyouts of net fisheries in recent years and a perceived low abundance of salmon are possible explanations for this trend.

UK (Northern Ireland): Total net licenses issued have declined by $36 \%$ over the last 10 years. This is mainly accounted for by reductions in the draft net fishery.

The data available from Norway, UK (England and Wales) and UK (Scotland) all indicate a decrease in the numbers of gear units used. In Norway, the decrease has been particularly marked with the closure of the drift net fishery in 1989. In Ireland, effort in commercial fisheries appears to have decreased while rod licences increased.

### 4.2.2 Gear and effort changes in 1992

There were no reported changes in the fishing methods and gear used in 1992 for any countries. However, new regulations were introduced in some countries and a new national rod licensing scheme was introduced in UK (England and Wales). Generally, effort reflected the perceived low abundance of salmon.

Ireland: No changes were reported in gear usage in general, but extensions to the fishing season were granted for draft net fisheries on 8 rivers ( 7 extended for 5 days and 1 extended for 2 days) and for rod fisheries in 5 rivers (extended by two weeks each). A by-law introduced in 1990 restricting the areas and seasons for commercial drift netting in the Western Region was maintained for 1992. This by-law was principally aimed
at protecting sea trout but also allowed more salmon into rivers.

Norway: All salmon fishing was prohibited in the R. Vosso and some minor limitations were introduced in the Sognefjord and Österöy areas.

Sweden: New regulations introduced in 1992 for all Swedish west coast fisheries for salmonids standardised the closed season at 16 September to 28 February. As before, there are zones around river mouths where fishing is prohibited or restricted. Bag nets remain the primary fishing gear although set gill nets may be used between 20 June and 20 July. The closed season for the rod and line fishery was also standardised from 15 October to 28 February. In Svinesund, the boundary area with Norway, new regulations set the closed season at 16 August to 9 May. During the open season bag nets and set gill nets may not be operated from 6 pm Friday to 6 am Monday.

UK (Northern Ireland): The number of fishing licences issued in 1992 (232) was slightly lower than the 1991 figure (239), although overall effort was higher than in the previous year. In the Foyle fishery area, the season started one week earlier than usual and finished one month earlier than usual. The management policy of variable early closure in response to counter-based measures of escapement has been suspended. In future, the commercial netting season will stop on the last day of July. The angling season in the R. Bush has been extended by 2 weeks to 15 October.

UK (England and Wales): A new national rod licence was introduced enabling all anglers to fish for migratory salmonids subject to local access regulations. Netting restrictions on the River Camel (southwest region) ceased following a 3-year rehabilitation scheme. In the southern region, a net fishery on the R.Itchen was operated exclusively by the NRA to provide fish for tracking purposes. Also, in the south-west region 2 seine net licences were not renewed for Rivers Taw, Torridge and Tavy. Anglers had mandatory bag limits on the Taw and Torridge.

UK (Scotland): Regulations were introduced in three districts (Tay, Ugie, and Girvan) prohibiting the use of prawns and shrimps as bait. The rod fishing season on the Findhorn Salmon Fishery District was reduced by 6 days. Lawful salmon netting methods were defined.

### 4.2.3 Catches and catch per unit effort

Revised estimates of total nominal catches by country for the 1991 fishery, and provisional estimates for the 1992 fishery, were available (Table 2.1.1) It should be noted that catches of ranched fish and fish farm escapees are included in these figures (see Section 4.2.4). The figure
given in 1992 for UK (Scotland) is incomplete, and the data for Norway, UK (Northern Ireland), UK (England and Wales) and Iceland are provisional. CPUE data were available for UK (England Wales) (Table 4.2.2) and Finland (Table 4.2.3).

The total catch figure available to the Study Group for the 1992 fishery was $3,249 \mathrm{t}, 15 \%$ up on the 1991 figure but considerably lower than the previous 5 and 10 year averages (Table 2.1.1). All countries, with the exception of UK (England), Norway and Russia, had greater catches than in 1991. The 1992 catches for Finland, Iceland, UK (Northern Ireland) and Sweden were also greater than both the previous 5 and 10 year averages. Specific information was provided as follows:

Finland: The 1992 catch and CPUE (Table 4.2.3) were the highest since the mid-1970s. This is believed to be partly attributable to the coastal netting restrictions introduced in Norway and to high flows which prevented Norwegian salmon weir fishing in the lower part of the Tëno River.

France: The catch was $54 \%$ up on the 1991 figure although close to the 5 but below the 10 -year averages. $50 \%$ of the catch was taken in the southwest of France which had a good year. This pattern may be explained by a combination of dry weather and reduced fishing effort which occurred in all regions with the exception of the southwest.

Iceland: The total catch increased by $17 \%$ from the previous year. The average increase in the sports catch, primarily in the grilse component, was about $30 \%$, but on the northeast coast where catches had been depressed, it was about $100 \%$, mostly in the 1 SW component.

Ireland: The catch in 1992 was much improved over 1991 which was the lowest recorded in the period 19601991. However, the 1992 catch was $28 \%$ less than the previous 5 -year average. It was generally perceived that good numbers of salmon were in the fisheries but continuing naval protection may have reduced the overall number of fish being landed, particularly in the northern region.

Norway: The total catch was the lowest recorded for more than 30 years, probably reflecting the effects of the regulations introduced in Norway in 1989 and a reduced abundance of fish.

Russia: The total catch was the lowest recorded since 1922, reflecting a perceived low abundance and the effects of limiting the commercial catch to promote the development of the sport fishery.

Sweden: The catch in 1992 increased for the third year in succession and was the second highest on record. Dry
weather conditions resulted in an increased coastal catch but a decreased river catch.

UK (England and Wales): Following a succession of unusually dry years (1989-1991), most parts of England and Wales experienced much better weather in 1992. Although conditions for fish movements were improved, the effects on catches were variable with those in parts of the southwest showing a very marked increase while those in the north were generally reduced. CPUE has, however, continued to decline in most areas (Table 4.2.2).

### 4.2.4 Composition of the catch

The national salmon catches for several Northeast Atlantic countries are summarized in Table 2.2.1. The age classes are separated both by scale analysis and by separating weight distributions in the catches. Specific information on age composition was summarized for the following countries.

France: The overall proportion of 1SW fish ( $48 \%$ in numbers) in the catch was close to the mean of the last 5 years.

Iceland: There was an increase in the 1SW component compared with 1991, especially in northeastern Iceland. The average size of 1 SW fish was higher than in the previous year and the sex ratio in 1SW fish was fairly even.

Norway: Catches in Norway were the lowest on record and slightly lower than for the previous three years. There was a slight reduction in the 1SW component.

Russia: As in the 1989-1991 period, 1SW fish dominated the catches ( $72.5 \%$ ). The decrease in MSW salmon was primarily due to the depressed state of these stocks that have high proportions of MSW fish.

UK (Scotland): The proportion of the reported catch classified as 1SW fish was greater than in 1990 and 1991, but similar to that observed in the 1985-1989 5year period

### 4.2.5 Origin of the catch

Table 4.2.4 indicates the origin of the catch in each country based on recoveries of tags over a number of years. The table has been updated for 1992 to include any previously unreported occurrences of non-national origin tags in homewater water catches and any new records in 1992. Double crosses indicate the principal component of the catch and single crosses represent other stocks contributing regularly to the tag recoveries. Rare recoveries of one country's tags in another country's catches are indicated by dashes and are assumed to
indicate very minor contributions to the catches. It must be noted that the table may reflect the relative size of the national catches and does not imply the proportion of the stock from a given country which is taken in another country's catches. In some cases, although the majority of the catch in a given country may originate from that country, the contribution from rivers in adjacent countries may be substantial. Countries with small stocks are not likely to contribute significant numbers of fish to fisheries which mainly exploit fish from other larger stocks . However, the actual numbers of the smaller stock which are taken in the fishery may be high relative to the total size of this small stock.

There is an obvious area of exchange between most adjacent fisheries with the possible exception of the Russian fishery and the French fishery which are at the outer limits of the range of the north-east Atlantic salmon. The Study Group noted that this type of analysis gave very little information on how national stocks are exploited by different countries including the country of origin. A similar table incorporating weights of stock contributing to each national catch would provide a better assessment of the mixed homewater fisheries and this should be incorporated as part of the overall assessment of salmon stocks in the north-east Atlantic. It was felt that sufficient information was available to make, at the very least, an estimate of the contributions of nonnational origin stocks to national catches in the same way that the Faroese mixed stock fishery was currently being assessed. The Study Group recommended that an attempt be made to produce such a table in 1994.

Table 4.2.5 shows the estimated contributions of ranched and farmed fish to national catches in recent years. In this context ranching is defined as the release into the wild of reared smolts with the intention of attempting to harvest all of the returning adults. Releases of reared fish to enhance wild stocks or compensate for lost wild production are, therefore, included in wild production. However, it is acknowledged that some fish released for enhancement may not contribute to spawning for various reasons; in this respect they are similar to ranched fish.

Ranching is carried out on a large scale by Iceland. Ranched fish comprised $76 \%$ of the total catch in 1991 and $70 \%$ in 1992. In addition 14 t in 1991 and 24 t in 1992 of the Swedish catch were made up of fish which had been released but were not expected to contribute to wild spawning populations. Small-scale ranching for research purposes is carried out from the R. Bush, UK (Northern Ireland) and at several sites in Norway. Ranching to enhance the rod fishery is carried out from the R. Burrishoole, Ireland. In this case only limited numbers of ranched fish have been allowed upstream to supplement wild spawning stocks.

Farmed fish make a significant contribution to the catches of Norway, Faroes and UK (Scotland). The proportion of farmed fish in Norwegian catches have remained relatively stable in the period 1989-1992 (Table 4.2.6). The proportion of farmed fish in freshwater catches is much lower than in catches at sea because reared fish enter freshwater later than wild fish, many of them outwith the season.

In UK (Scotland), sampling in 1990 indicated that most of the reared fish caught in the fisheries had escaped or been lost from sea cages. In 1991 and 1992, however, sampling on the west coast revealed that most of the farm-origin fish were derived from losses or releases of smolts or parr. On the east coast, where the incidence of farm escapees was low, most of the farm-origin fish were adult escapees.

While farmed fish are present in most other countries except Russia, France and UK (England \& Wales), the exact contribution is not known. Levels of between 7 and $20 \%$ farmed fish have been reported from some catches in regional fisheries (coastal and estuarine) in Ireland. In most other countries, farmed fish are thought to form only a very minor (or negligible) part of the catch.

The Study Group recommends that countries should attempt to estimate the numbers and stages of fish farm escapees in each year.

### 4.2.6 Exploitation rates in homewater fisheries

Tables giving exploitation rates on stocks from the Rivers Drammen, Imsa, Bush and North Esk stocks are shown in Tables 4.1.21 to 4.1.26 and 4.2.7. The exploitation rates in homewaters for these and a number of other stocks are summarised in Tables 4.2.8 and 4.2.9.

A comparison of exploitation patterns for different stocks does not show any obvious similarities, except that hatchery stocks are often more heavily exploited than wild stocks. This is the case even when wild and reared fish originate from the same stock, as is the case for the R. Bush and R. Imsa stocks.

The levels of exploitation in 1992 seemed to be about average in most cases, except for the Russian River Ponoy where exploitation was reduced. Exploitation rates on the three Russian rivers shown in Table 4.2.9 are adjusted by altering the proportion of days on which fish caught in traps on the rivers are released or killed. In 1991 and 1992, it was decided to reduce the exploitation rate in R. Ponoy in order to increase spawning stocks and make more fish available for the developing recreational fishery.

An illegal fishery of considerable magnitude occurs in many of the Russian rivers. The illegal fishery was estimated to catch $15 \%$ of the spawning stock in R. Varzuga, $25 \%$ in R. Pechora and $26 \%$ in R. Umba. There is no clear sign that the illegal fishery is changing in size from year to year.

### 4.2.7 Management measures in Norway

Full details of the management measures introduced in Norway in 1989 are given in Anon. (1990), Appendices 2 and 3.

The impact of the measures on catches in Norwegian homewaters between 1989 and 1992 is shown in Table 4.2.10 and Figure 4.2.2. In the period 1982-1988 the nominal catch of salmon fluctuated between $1,076 \mathrm{t}$ and $1,623 \mathrm{t}$. Since 1989 , it has decreased to 850 t to 980 t , probably as a result of the new management measures. Since 1989, the marine catches of salmon have varied between 423 t and 488 t , much lower than for 1982-1988 when catches varied between 841 and $1,324 \mathrm{t}$. The catch in the marine salmon fisheries, excluding drift netting, was close to the average for this period.

It is likely that the ban on driftnetting in 1989 has resulted in a larger number of salmon being available to other marine homewater fisheries. The additional regulations of these fisheries have probably resulted in a substantial increase in freshwater escapement suggested by increased catches in freshwater despite the fact that freshwater fisheries have also been regulated by extending the annual closed time and that fishing for salmon has been totally banned in several rivers. Between 1989 and 1992, the freshwater catch accounted for $45 \%$ to $50 \%$ of the total nominal catch, annually, compared to between $18 \%$ and $27 \%$ over the years 1982-1988. Increased freshwater escapement is also suggested by the reduction in marine exploitation rates on most components of the R. Imsa stock during 1989-1992. This was not evident for the R. Drammen stock, because drift net exploitation on this stock has always been low.

The frequency of net-marked salmon entering a river will also give information about changes in netting effort on the migration route. The proportion of net-marked salmon has been recorded in several Norwegian rivers since 1978. In most of these rivers, sampling took place from 1978 to 1986 and was then re-established in 1990, 1991 and 1992. Table 4.2 .11 shows unweighted means of the proportion of net-marked salmon in angling catches from 12 rivers in the period before the extensive homewater regulations were introduced, and the unweighted means of the proportion of net-marked salmon recorded in 1990-1992 in the same rivers. In all except one river, the proportion of net-marked salmon recorded in 1990-1992 was much lower than unweighted means during the period 1978-1988. The reduced
proportion of net-marked fish may be accounted for by the management measures introduced in the Norwegian homewater fishery in 1989.

The salmon fishery on the Norwegian coast intercepts stocks from Sweden, Finland and Russia on their way back to their home rivers. Exploitation in Norway on 1SW fish tagged as smolts in the River Lagan, Sweden, in 1989-1992 was lower (average $1 \%$ ) than in 1985-1988 (average 7\%) (Table 4.2.12). Table 4.2 .13 shows numbers of external tags recovered in Norway of salmon tagged as smolts in Sweden since 1975. The number of tags recovered in Norway per 1000 smolts released was very high at the end of 1970s and beginning of 1980s. It declined through the 1980s, and from 1989 to 1992 it was extremely low and much lower than all other years. The unweighted mean in the catch years 1977-1988 was 10.9 tags recovered per 1000 smolts released, whereas the corresponding average for 1989-1992 was 0.5. It is concluded that the regulations introduced in the Norwegian homewater fishery in 1989 benefitted Swedish west coast stocks.

CPUE data are available from Finnish fisheries in the Rivers Tana and Neiden (Table 4.2.3). These data show an increase in the catch per angler day and per angler season for the four years since the introduction of the new Norwegian regulations (1989-1992) compared with the previous four years (1985-1988).

### 4.3 By-Catch and Mortalities of Salmon in NonSalmon Directed Fisheries

Landing of salmon caught in fisheries targeting other species is illegal in most of the Study Group member countries except France, where it is authorized, and Sweden, where landing is allowed during the regular salmon fishing season (March - September). In the countries where the by-catch cannot be landed legally, these catches are included in the estimates of unreported catches.

The shore-based gillnet fishery for species such as mullet/bass (England and Wales), lumpsuckers (Iceland) and mackerel (Norway) may represent a potential danger of taking salmon by-catches, especially in cases where mesh sizes, fishing areas or fishing seasons are not regulated to reduce the impact on salmonid stocks. However, the information available to the Study Group suggests that only small catches of salmon are taken in these fisheries. In Iceland, where there are known to be some illegal catches of salmon in the fishery for male (small) lumpsuckers, the authorities are currently negotiating a closure of this fishery in June and July in order to protect salmon. In Norway, fishing experiments with mackerel gillnets showed a relatively high catch efficiency of those nets also for small salmon. Mackerel
nets, therefore, would be of greatest risk to salmonids if used in fjords into which grilse rivers flow. However, the Norwegian authorities are currently discussing regulations on mesh sizes, and a closed season in June and July for the mackerel fishery.

There are only occasional instances of salmon being taken in near- or off-shore fisheries with purse-seines, pelagic trawls and drift nets for commercial pelagic species, e.g. mackerel, sprat and herring. The by-catch of salmon from these fisheries is, therefore, considered to be negligible.

### 4.4 Predictive Indicators for Abundance of Salmon in the Northeast Atlantic

Several biological and physical indicators can possibly be used to predict the abundance of salmon stocks in subsequent years. Most common are population estimates conducted at various points in the salmon's lifecycle, both in fresh and salt water.

### 4.4.1 Freshwater assessments

Biological indices used in freshwater include catches, run or escapement counts (spawning targets), estimates of egg, fry or parr abundance and smolt counts. These methods tend to be less costly than marine assessments and have thus been used to some extent in all countries bordering the North Atlantic. These methods give good estimates of the utilization of the rearing capacity in individual rivers and smolt counts can in some cases be a good indicator of grilse and salmon abundance in subsequent years.

In general, one can say that the precision of these methods to predict future salmon abundance decreases as one goes forward in the life cycle due to the additive mortalities encountered in freshwater from egg to smolt as well as those in the marine environment.

Counts of runs and escapement are undertaken in many countries. These methods give very accurate information about the status of the stock in question and, in some cases, can be used to calculate egg deposition. The method has been used successfully to estimate spawning targets in Canada. Counters and their operation, however, are expensive and are usually only applied to a limited number of rivers.

Estimation of egg deposition by sampling river beds or counting redds does not seem to be a practical method to predict future abundance of Atlantic salmon, although it is extensively used in Pacific salmon.

Electrofishing surveys of fry and parr give good indications of the utilization of the rearing capacity of individ-
ual rivers. In some cases they can be useful as predictors for future abundance of salmon. These methods are, however, mostly usable for relatively small rivers, which can be easily electrofished.

In the River Bush (UK, Northern Ireland), fry estimates $(0+)$ have been found to be fairly representative of 1 and 2-year smolt production as observed in the downstream smolt traps. A method to estimate smolt production from habitat assessments and juvenile surveys has also been developed and successfully tested in France. In Iceland, where juveniles spend 2-5 years in freshwater, electrofishing surveys have only given moderate success in predicting future salmon abundance. It seems likely, therefore, that the longer the stocks stay in freshwater as juveniles, the less applicable this technique will be, considering the variable mortality in fresh and salt water depending on climatic and oceanographic factors. It was also noted that variable precocious maturity in parr would reduce the applicability of these methods.

Smolt counts are by far the best method to predict future abundance of salmon. Traps are used on index rivers in several countries, but these are expensive to construct and operate. Information from these has, however, sometimes been used as an index for larger areas, especially with respect to marine survival.

### 4.4.2 Marine assessments

Methods used to predict salmon abundance through assessments during the marine phase include test fishing at various stages, acoustic surveys and prediction of non-maturing 1SW salmon abundance from returning 1SW salmon in home waters. In some cases, oceanographic and meteorological factors, as well as the abundance of prey and possibly predatory species could be used to improve the predictive ability of the model. It has been noted that good salmon years in certain parts of Iceland seem to coincide with high catches in the capelin fishery.

It seems likely that a large fraction of the marine mortality of salmon takes place fairly soon after migration into seawater. Early feeding in the sea might be an important factor in survival as well as the impact of various predators. Sampling of post-smolts and their predators during this early marine period might, in time, give some useful indices for a predictive model. Sampling of post-smolts, however, has been found to be a very difficult task all around the Atlantic.

Sampling the abundance of prey species might also be a useful index to use in a predictive model. Such survival indices have been developed in the Pacific and zooplankton indices are used to determine proper release time for pink and chum salmon in Alaskan ranching operations.

Test fishing on the feeding grounds might in theory provide a meaningful indicator of abundance of fish. If some of the fish are carrying tags, it might give an indication of relative stock abundance. The benefits of these approaches, however, are dependent on the value of the information in relation to the cost of running such a project; test fisheries tend to be very costly.

When considering test fisheries, it is important to consider that salmon from Europe are distributed over the entire North Atlantic from West Greenland to the Norwegian Sea with variable contribution, from the countries of origin. Oceanic conditions might be highly variable from one area to another making sampling in one area a poor indicator of overall marine survival and subsequent homewater catches. Test fishing at key locations during the spawning migration might in some countries yield useful advance information on the run size. However, in many cases this technique would not be very cost-effective.

### 4.4.3 Acoustic assessments

Acoustic methods have been used to estimate the abundance of pelagic fish for decades. Some difficulties have been encountered in estimating salmon abundance with these methods as the salmon feed close to the surface and do not aggregate in dense schools. Improved technology might, however, provide a solution to this problem in future years. A new 95 KHz sector-scanning sonar modified for fisheries research will be tested as an aid in assessing abundance and distribution of pelagic species (including salmon) within the framework of the "Ecology of the Nordic Seas" programme that will be implemented in Norway in 1994.

### 4.4.4 Forecasts of salmon abundance from 1SW returns

The abundance of 1SW fish can possibly be used as a rough predictor of the abundance of 2 SW salmon in the following year. The method was first used in the Pacific to predict sockeye salmon abundance from the returns of jacks (1SW males) the previous year. Run reconstruction models have in the past indicated that age of maturity is one of the more stable biological parameters in individual salmon stocks.

The method has been tried in Iceland, Canada and Scotland. In northern Iceland the catches of 2SW salmon in freshwater were highly correlated with the catches of grilse in the previous year (Scarnecchia et al., 1989). In the study, a strong relationship ( $p<0.01$ ) was found between grilse abundance and subsequent 2 SW returns in 18 out of 22 rivers in northern Iceland, whereas a similar relationship only existed for 12 out of 21 rivers in western Iceland. On the north coast, environmental conditions favour late maturation and there is also
greatest fluctuation in salmon abundance due to changing environmental conditions. Forecasting of MSW returns from 1SW returns in the previous year has not proved successful in Scottish studies. In Canada, a number of parametric models (linear + multiple linear regressions) were developed (Anon. 1992c) but few have withstood the test of time.

### 4.4.5 Future prediction models

It seems likely that future predictive models will have to combine data from various sources. It can be concluded that the most efficient methods are based on the counting of smolts followed by counting of upstream migrating salmon, which could be used to estimate egg deposition. In the absence of such information electrofishing surveys might yield useful information on juvenile abundance. Knowledge of various biological and physical parameters related to sea conditions, both in the inshore and oceanic areas, would probably increase the predictive value of such models.

Marine assessments of salmon are costly and seem unlikely to be viable for prediction of salmon abundance in various distant water fisheries or homewaters.

Assessment of 2SW salmon from the abundance of 1SW fish in homewaters seems to be a promising method in some areas with relatively high proportions of 2 SW fish.

Development of predictive models is not only important for salmon managers around the North Atlantic but is also considered a top priority research project for the salmon ranching industry, which needs to know in advance with some certainty about the tonnage to be marketed during a particular salmon season. In this case, however, the numbers of smolts released are usually known and the success of the operation is more dependent on smolt quality, release techniques and conditions in the sea.

### 4.5 Effects of the NASCO Tag Return Incentive Scheme

Most of the North-East Atlantic countries provided data to NASCO for the Tag Return Incentive Scheme (UK (England and Wales), Scotland, Ireland, Norway, Sweden, Russia and Finland)). However, Northern Ireland do not use any external tags and in UK (England and Wales) and Ireland they are only used on kelts and as external indicators of the presence of transmitter tags. Iceland does not participate in the scheme and Norway only provide data on Norwegian tags caught outside their homewaters. No information was available for France.

At the moment there is no good evidence for positive effects of the scheme on the rates of tag returns. The
main reasons are the small numbers of external tags used and insufficient awareness of fishermen about the NASCO lottery in most participating countries. The only positive effect of the scheme was reported from Finland, where tag reporting rates (estimated by observers) are thought to have increased, but there are no quantitative estimates. Iceland has no interest in this programme as its stocks are not exploited by other countries. Norway, on the other hand, conducts a lot of tagging experiments, but does not participate in the incentive scheme in order not to interfere with ongoing assessments of recent homewater measures. In Scotland it was thought that the scheme had no effect on catch return rates; in the principal fisheries taking tagged fish, reporting rates are thought to be close to $100 \%$ already. In other fisheries the numbers of tag recoveries are too small to detect a change.

The Study Group felt that more intensive advertising of the objectives of tagging programmes might be more successful than the lottery at improving tag returns rates.

### 4.6 Effects of the Cessation of Fishing Activities at Faroes

The mean catch in the Faroes fishery in the 3 fishing seasons 1988/1989 to 1990/1991 was 87,454 salmon (292 t) per season. The catch in the 1991/1992 research fishery, after the buy-out of the quota, was 8,464 fish ( 31 t ). Thus, the catch at Faroes was reduced by 78,990 fish (261 t) compared to the previous 3 seasons.
Data presented to the Study Group (Jacobsen et al., 1992) suggests that about $37 \%$ of the fish taken at Faroes in the 1991/1992 seasons may have been of farmed origin, and the proportion may have been similar in preceding years. Thus, the extra number of wild fish not caught as a result of the cessation of fishing may be about 50,000 fish ( 164 t ), the remaining $\sim 29,000$ fish ( 97 t ) being fish farm escapees.

The Working Group has previously provided a model to assess the effects of the catch at Faroes on stocks returning to homewaters (Anon., 1984b). It was estimated at that time that $78 \%$ of fish in the Faroes area will mature in the same year and $97 \%$ of these will survive to reach home waters if they are not caught. Using these data, the estimated increase in wild fish returning to home waters is about 37,800 salmon. Some additional fish saved from the fishery in 1991/1992 will be expected to return to home waters in 1993.

The Study Group was unable to model reliably the fate of the farmed salmon from the Faroes fishery, but it is believed that these will also return to homewaters. Assuming that the farmed fish behave in the same way as the wild fish, the predicted increase in the numbers of fish returning to homewaters in 1992 would be approximately:

| Wild 1SW | 3,400 |
| :--- | ---: |
| Wild 2SW | 34,400 |
| Farmed | 22,000 |

[NB. Ageing of the farmed component is thought to be unreliable and all age groups are, therefore, grouped].

These fish will probably have contributed to homewater fisheries in most salmon producing countries in the north-east Atlantic. However, it is unlikely that it will be possible to demonstrate a significant change in catches after a single year. The majority (perhaps $60-80 \%$ ) of the wild fish caught at Faroes are thought to originate from Scandinavian, Finnish and Russian stocks (Anon., 1991b, 1992b, and Section 4.1.5) and thus, the greatest impact should be seen in the fisheries of these countries. The total homewater catch in these countries in 1992 was 326,603 of which $17 \%(56,000)$ were estimated to be farm escapees (Table 4.2.2) and of the wild fish, 173,000 were estimated to be 1 SW and $147,000 \mathrm{MSW}$ salmon. Assuming that the mean exploitation rate in homewater fisheries is $40-70 \%$, the additional catch should have been 800-1,900 1SW wild fish, 8,20019,000 MSW wild fish and 5,300-12,300 farm escapees.

These increased catches would, therefore, have represented the following proportions of the recorded catches:

| Wild 1SW | $\sim 1 \%$ |
| :--- | ---: |
| Wild 2SW | $6-13 \%$ |
| Farmed | $10-22 \%$ |

Such small increases will have been within the annual variation of catches in these countries and will not represent a statistically significant increase. (It is not possible to provide reliable standard deviations on catches in these countries in recent years because of changes in fishery regulations, the contribution of farmed fish and the lack of appropriate catch data.)

Exploitation rates on stocks from UK and Ireland have been very low at Faroes in most years. The buy-out of the quota must be expected to have resulted in additional fish returning to these countries, but the predicted improvements in catches will be very small. In view of the variability of homewater catches it is not expected that they will be statistically significant even after many years.

If we assume that monitored stocks have been relatively stable over the past 4 years, the cessation of fishing should have reduced exploitation at Faroes to about $10 \%$ of levels in the previous 3 seasons. For stocks in UK and Ireland the numbers of tag recoveries in the last 4 seasons have been too low for such a reduction to be statistically significant. However, exploitation rates on Imsa and Drammen stocks in 1991/1992 were 0-4\% and $2 \%$ respectively in comparison with rates between

1988/1989 to 1990/1991 seasons of 0-37\% and 13-45\% respectively.

## 5 PRODUCTION OF FARMED SALMON

The reported production of farmed salmon in countries in the North-East Atlantic Commission area is given in Table 5.1. The total production of 204,632 $t$ in 1992 was 18,224 $t$ less than in 1991. Production increased in Northern Ireland and Faroe Islands. Production of farmed salmon in 1992 was 63 times higher than the reported catch of salmon in the North-East Atlantic Commission area.

## 6 NATIONAL SALMON RUN-RECONSTRUCTION MODEL

### 6.1 Sensitivity Analysis of the National RunReconstruction Model

In their 1991 report (Anon., 1991c), the ICES Study Group on the Norwegian Sea and Faroes Salmon Fishery presented the preliminary results from a model which used the results of the run-reconstruction model (Potter and Dunkley, in press) to estimate the numbers of fish from each country caught in fisheries outside home waters. (This model was called the national run-reconstruction model.) The Study Group recognised that some of the data used in the national models were very limited and that the model might be very sensitive to certain parameters. The Study Group has, therefore, been asked to make a sensitivity analysis of the national run-reconstruction model.

The model provides a means for scaling-up tag recoveries from a 'monitored' stock (Anon., 1987) to national stock numbers. It assumes that fish of each sea-age class in the monitored stock are exploited at the same rate in the West Greenland and Faroes fisheries as all fish of the same ages from the national stocks. However, it applies different scaling factors to the different sea-age classes to account for the fact that the age composition of the national stock may differ from the monitored stock. It also allows for 'correction factors' to be included to adjust for differences in the levels of exploitation on the monitored stock and national stocks in the home-water fisheries (both the country of origin and other interceptory homewater fisheries).

The model thus estimates catches of salmon, C, of each age-class from one nation or region in each fishery using the estimates of exploitation rates, U , derived from the normal run-reconstruction model. The generalised form of the model is as follows:

| Fishery | Exp. rate | Catch of national stock |  |
| :---: | :---: | :---: | :---: |
| Homewater | $\mathrm{U}_{\mathrm{hi}}$ | $\mathrm{C}_{\mathrm{hi}}=$ input data |  |
| Other homewater interception | $\mathrm{U}_{\mathrm{ji}}$ | $\mathrm{C}_{\mathrm{ji}}=\left(\mathrm{C}_{\mathrm{ii}} / \mathrm{U}_{\mathrm{hi}} * \mathrm{y}_{\mathrm{i}}\right) * \mathrm{e}^{\mathrm{Mi}} \mathrm{U}_{\mathrm{ji}}{ }^{*} \mathrm{x}_{\mathrm{i}} /\left(1-\mathrm{U}_{\mathrm{ji}} * \mathrm{x}_{\mathrm{i}}\right)$ | Eq. 1 |
| W. Greenland | $\mathrm{U}_{\mathrm{gi}}$ | $\mathrm{C}_{\mathrm{gi}}=\left(\mathrm{C}_{\mathrm{fi}+1} / \mathrm{U}_{\mathrm{fi}+1}\right) * \mathrm{e}^{\mathrm{Mi} *} \mathrm{U}_{\mathrm{gi}} /\left(1-\mathrm{U}_{\mathrm{gi}}\right)$ | Eq. 2 |
| Faroes | $\mathrm{Ufi}_{\text {fi }}$ | $\left.\mathrm{C}_{\mathrm{fi}}=\left[\mathrm{C}_{\mathrm{gi}} / \mathrm{U}_{\mathrm{gi}}\right) * \mathrm{e}^{\mathrm{Mt}}+\left(\mathrm{C}_{\mathrm{ji}} / \mathrm{U}_{\mathrm{ji}} * \mathrm{x}_{\mathrm{i}}\right) * \mathrm{e}^{\mathrm{Mt}}\right] * \mathrm{U}_{\mathrm{fi}} /\left(1-\mathrm{U}_{\mathrm{fi}}\right)$ | Eq. 3 |

[Eq. 3 must be solved first for maximum ' i ' when $\mathrm{C}_{\mathrm{gi}} / \mathrm{U}_{\mathrm{gi}}$ will be zero.]
where:-
suffixes ' $h$ ', ' $j$ ', ' $g$ ' and ' $f$ ' refer to homewater, other homewater interception, West Greenland and Faroes fisheries, respectively;
suffix ' $i$ ' refers to the sea age group;
' $t$ ' in each case is the time in months between the fishery and the previous fishery affecting the year class (as used in the run-reconstruction model);
' M ' is the instantaneous rate of natural mortality for salmon after the first sea year;
' $y_{i}$ ' is the correction factor for the exploitation rates on 'i' sea-winter fish in the homewater fisheries;
' $x_{i}$ ' is the correction factor for the exploitation rates on ' $i$ ' sea-winter fish in the other homewater interception fisheries.

### 6.1.1 Sensitivity analysis

Although the original model (Anon., 1991c) included homewater rod fisheries in the scaling estimates, it was always recognised that these were likely to be very unreliable because of the difficulties of obtaining good tag recovery and catch data from these fisheries and the very considerable differences between the fisheries in different rivers. Rod fisheries are not, therefore, included in the sensitivity analysis.

The main input and output parameters for the runreconstruction model are listed in Table 6.1. Although the run-reconstruction model also provides estimates of levels of exploitation on the monitored stock, the proportions of 1 SW and 2 SW fish in the sea maturing and the post-smolt survival, these are not important outputs of
the national run-reconstruction model; they are, therefore, ignored in this sensitivity analysis.

Altering some of the parameters has effects on more than one of the outputs. In addition, the effects may vary depending upon the relative values of the input parameters. The following description gives an indication of the likely magnitude of the changes described on typical data-sets.

For simplicity the following analysis considers only 1SW and $2 S W$ fish. It should be noted, however, that errors in the estimates for MSW fish are likely to be greater than for 1SW fish because they are usually based on fewer tags (see below).

Mortality rate: The mortality value is used to estimate the proportion of extant stocks that would survive between different fisheries. The largest variations in natural mortality during the marine phase are thought to occur in the first few months in the sea. Natural mortality after about the first 9 months in the sea is thought to be fairly low and stable. The Working Group on North Atlantic salmon has used a value of $\mathrm{M}=0.01$ per month in their assessments. Altering this by a large amount (e.g. halving or doubling) usually has only a very small effect on the outputs. For some combinations of inputs outputs may change by as much as shown below:

If M is decreased to $0.005 \quad \mathrm{Rf} 1$ increases by up to $7.5 \%$
Rf2 increases by up to $5 \%$
Rg 1 increases by up to $5 \%$
If $M$ is increased to $0.02 \quad$ Rf1 decreases by up to $7.5 \%$
Rf2 decreases by up to $5 \%$
Rg1 decreases by up to $5 \%$
However, under most circumstances the errors are much less than $5 \%$.

Time: The time values affect the model in the same way as ' M ' by altering the proportion of the extant stock estimated to have survived between consecutive fisheries. However, each value of ' $t$ ' affects only a very small part
of the model. In addition, increasing one value of ' $t$ ' will often decrease the value of ' $t$ ' between the next two fisheries. There may, therefore, be an element of compensation.

Even large changes in individual values of ' $t$ ' have negligible ( $<1 \%$ ) effect on the output.

Spawning escapement: The confidence limits on estimates of the number of tagged fish recaptured $\left(R_{1}\right)$ in a fishery or the home river are mainly related to the number of tags recovered (R).

If 70 tags are recovered, the confidence limits on the recapture rate will be about $25 \%$. With larger numbers of recaptures the relative size of the confidence limits decreases only slowly. With smaller numbers of tag recoveries, however, the confidence limits increase quite rapidly.

In most tagging experiments, the number of tagged fish in the spawning escapement (or the spawning escapement plus the homewater catch) will be large enough to reduce the confidence limits on the estimate of the number of tagged fish returning to homewaters to less than $30 \%$.

A $30 \%$ change in the number of spawners or homewater recaptures also has only a very small effect on the output. The effect on the 1 SW catch at Faroes is greatest and will usually be less than $3 \%$.

Tag recoveries in fisheries: The number of recaptures in some fisheries may be very small and this will have a greater effect on the precision of those data.

Changes in the following tag recapture estimates will have an equal effect on the estimate of the national catch of the same year class in the same fishery:

| 1SW recaptures at Faroes | $\mathrm{R}_{\mathrm{f}}$ |
| :--- | :--- |
| 2SW recaptures at Faroes |  |
| 1SW recaptures at West Greenland |  |
| 1SW recaptures in homewater fisheries <br> of neighbouring country | $\mathrm{R}_{\mathrm{f} 1}$ |
| 2SW recaptures in homewater fisheries <br> of neighbouring country | $\mathrm{R}_{\mathrm{j} 1}$ |
|  | $\mathrm{R}_{\mathrm{j} 2}$ |

Under normal circumstances, there is a minimal knockon effect on other outputs from the model.

Alterations to the tag recapture data $R_{h 1}$ and $R_{h 2}$ have greater effects on the estimates. The relationship between the error in the estimated number of tags recaptured ( $\mathrm{R}_{\mathrm{h}}$ ) and the effect on the estimated catch $\left(\mathrm{N}_{\mathrm{zi}}\right)$ in the fishery ' z ' are:

$$
\begin{aligned}
\text { If } R_{h 1} \text { is increased by } P \% & N_{j i} \text { changes by } Q \% \\
& N_{f 1} \text { changes by less than } Q \% \\
\text { If } R_{h 2} \text { is increased by } P \% & N_{j 2} \text { changes by } Q \% \\
& N_{81} \text { changes by } Q \% \\
& N_{f 2} \text { changes by } Q \% \\
& N_{f 1} \text { changes by less than } Q \%
\end{aligned}
$$

where the relationship between $\mathrm{P} \%$ and $\mathrm{Q} \%$ is expressed by:

$$
Q=(10,0001(100+P))-100
$$

and is shown in Figure 6.1.
Exploitation correction factors: Because the factors $x$ and $y$ effectively scale the principal inputs to the model they can have a fairly large effect on certain outputs.

If $\mathrm{x}_{1}$ is altered, $\mathrm{N}_{\mathrm{j} 1}$ and $\mathrm{N}_{\mathrm{fl}}$ will be affected. The size of the changes will be related mainly to the exploitation rate in fishery ' j '. If this exploitation rate is high ( $>50 \%$ ) the effect on $\mathrm{N}_{\mathrm{j} 1}$ may be very large; the effect on $\mathrm{N}_{\mathrm{f} 1}$ will be smaller but may still be important ( $>20 \%$ ). If the exploitation rate in the fisheries is small $(<20 \%)$ the change in $\mathrm{N}_{\mathrm{j} 1}$ will be slightly greater than the alteration in $x_{1}$; the effect on $N_{f 1}$ will be small.

If $\mathrm{x}_{2}$ is altered, $\mathrm{N}_{\mathrm{j} 2}, \mathrm{~N}_{\mathrm{g} 1}, \mathrm{~N}_{\mathrm{f} 2}$ and $\mathrm{N}_{\mathrm{f} 1}$ will all be affected. As for $\mathrm{x}_{1}$, if the exploitation rate in fishery ' j ' is high then the effect on $\mathrm{N}_{\mathrm{j} 2}$ may be very large and on the other values also significant. However, at low exploitation rates in fishery ' j ', $\mathrm{N}_{\mathrm{j} 2}$ will change by about the same amount as the alteration in $\mathrm{x}_{2}$, and the change in the other outputs will be small.

If $y_{1}$ is altered by $P \%, N_{j 1}$ will change by $Q \%$ (see above) and $\mathrm{N}_{\mathrm{fl}}$ by a smaller amount.

If $y_{2}$ is altered by $P \%, N_{j 2}, N_{g 1}$ and $N_{f 2}$ will change by $\mathrm{Q} \%$ and $\mathrm{N}_{\mathrm{fl}}$ will be affected by a smaller amount.

If both $y_{1}$ and $y_{2}$ are altered by $P \%$ then $N_{f 1} N_{f 2}, N_{g 1}, N_{j 1}$ and $\mathrm{N}_{\mathrm{j} 2}$ will all change by $\mathrm{Q} \%$.

Homewater catch data: The homewater catch data should be equivalent to the population from which the homewater tag recoveries were sampled. In the case of microtag studies this is likley to be the case because tags are normally recovered by scanning part of the catch. Biases may be more common with external tags, however, because fishermen may report tagged fish more readily than they report their catch (or vice versa).

Errors in the homewater catches of one sea-age will affect all the estimates of catches of fish of that age by the same amount.

### 6.1.2 Conclusions from Sensitivity Analysis

The analysis confirms that the national run-reconstruction model is very insensitive to variations in ' M ' and ' $t$ '.

The model is dependent upon reliable tag recovery data. If tag recoveries in any fishery are small ( $<10$ ), then the reliability of the recapture estimates and consequent estimates of exploitation rates will have large confidence limits ( $\geq= \pm 60 \%$ ). Similar errors will be introduced into the estimates of catches of national stocks.

If the reason for the number of tag recoveries being small is that the catch scanning rate is low, then the errors may be significantly reduced by increasing the proportion of the catch examined for tags. Where external tags are used, efforts should be made to maximise reporting rates. If the number of tag recoveries is small because the exploitation rate is low, it may not matter that the resulting estimate of exploitation rate is imprecise. Where the exploitation rate is higher the number of tags recovered may be greater and this will give a more a precise estimate of exploitation rate.

Parts of the model can be sensitive to the correction factors ' $x$ ' + ' $y$ ' used to adjust levels of exploitation in homewater fisheries on the monitored and national stocks. However, this is only a critical problem (for factor ' $x$ ' only) when the exploitation rate on the monitored stock in the homewater interception fishery is very high ( $>50 \%$ ). This can present a major problem because these values may have to be based on limited data or educated guesses.

### 6.2 Model Runs for 1989 and 1990 Smolt Year Classes

### 6.2.1 Input data

The Study Group was asked to provide runs of the model for the smolt year classes of 1989 and 1990. Data were available for these years for smolt tagging carried out on the Rivers Burrishoole (Ireland), Imsa and Drammen (Norway), Lagen (Sweden), Bush (UK, Northern Ireland) and N.Esk (Scotland). No new data were available for smolt tagging carried out in Faroes, France, Finland, UK (England \& Wales) or Russia, and it was considered unreliable to extrapolate data from neighbouring countries for individual years. The available input data to the model are given in Tables 6.2.1 and 6.2.2.

For all countries except Ireland, the tag recapture data are those from the monitored stock. The Irish data also
include tag returns from the national smolt tagging programme; the spawning escapement for these stocks are based upon the exploitation rate on the monitored stock in the homewater fisheries. Thus:

Recovery of national tags in homewaters

No. national tagged spawners
Recovery of
Burrishoole tags
No. Burrishoole tagged spawners
in homewaters
Spawning escapements for the tagged fish from the Rivers Lagen and Wear were based upon estimated exploitation rates in homewaters (see tables). For some rivers, data from rod fisheries are combined with homewater net catches or the spawning escapement.

### 6.2.2 Results of the runs

The results of the runs are shown in Tables 6.2.3 and 6.2.4. The model uses separate data sets for each country and each country's results are, therefore, independent. If, however, data are available for all countries, the total estimated catches in each fishery by age class can be compared with the observed catches to provide an additional check on the validity of the results (Anon., 1991). In the absence of data from several countries for the runs shown in the tables, it was not possible to make this additional check.

The small numbers of tag returns from some countries in some fisheries will mean that the confidence limits on the relevant exploitation rate estimates will be very large, in some cases $>100 \%$. This accounts for much of the variation in the estimated harvests of national stocks at Faroes and West Greenland between the two years.

For Sweden, the exploitation rate in homewater interception fisheries is estimated to be very high. This may be erroneous and reflects problems of estimating the population returning to the river.

The Study Group noted that unless the run-reconstruction model could be based on larger numbers of tag recoveries, it would not be possible to make meaningful comparisons between annual runs. With current levels of tagging it was felt that the national run-reconstruction model was best used on combined data for a number of years, although it was recognised that this presented additional problems, for example where exploitation rates had changed significantly. The Study Group recommended that more work should be undertaken to develop indicator stocks that could be used to represent stocks on a regional or national basis.

## RECOMMENDATIONS

1. The Study Group noted that although it was desirable to prepare data from the North-East Atlantic prior to the Working Group meeting, there was no advantage in holding a separate meeting unless it could be organised at least a full week earlier. Unfortunately many members of the Study Group would be unable to attend both meetings in such circumstances. The Study Group, therefore, recommends that they should not meet in 1994 unless specific questions were asked of it. Instead, an extra 3 days should be added to the Working Group meeting to permit it to collate the data from the NASCO Commission areas in split sessions.
2. The Study Group recommends that a workshop be held, to consider available evidence that might be used to set targets and to identify what further data are necessary to implement assessment of stock status with respect to targets. Attempts to set spawning targets should be made wherever possible before the next meeting.
3. The Study Group recommends that countries should attempt to estimate the numbers and stages of fish farm escapees each year.
4. The Study Group recommends that samples of scales from the available time series be examined to investigate the development of the occurrence of farmed fish in the Faroese waters.
5. The Study Group recommends that an attempt be made to estimate the contributions (in tonnes) of non-national origin stocks to national catches.
6. The Study Group recommends that more work should be carried out to develop indicator stocks that could be used to represent stocks on a regional or national basis. Although the 'monitored' stocks may be used for this purpose, in most cases more research needs to be carried out to provide more reliable estimates of the exploitation correction factors.
7. The Study Group recommends that current studies of the stock/recruitment relationship in salmon should continue.

Table 2.1.1 Nominal homewater catch of salmon by country (in tonnes round fresh weight) 1981-1992.

| Year | $\begin{gathered} \text { UK } \\ \text { (E\&W) } \end{gathered}$ | Finland | France | Iceland | Ireland ${ }^{2,3}$ | $\begin{gathered} \mathrm{UK}^{2,4} \\ (\mathrm{NI}) \\ \hline \end{gathered}$ | Norway | UK <br> (Scotland) | Sweden <br> (W.Coast) | Russia | Total NE <br> Atlantic |

${ }^{1}$ Provisional figures.
${ }^{2}$ Catch on River Foyle allocated $50 \%$ Ireland and $50 \%$ Northern Ireland.
${ }^{3}$ Includes only catches sold through dealers.
${ }^{4}$ Not including angling catch (mainly grilse).
 on weight.

${ }^{\prime}$ Minimum count.
In both the UK (E\&W) Severn and UK (E\&W) Dee, the counters are some distance upstream so that the counts do not represent total counts for these systems. In the UK(Scoti.)Girnock, the trap is located in the Girnock Burn, a tributary in the upper reaches of the River Dee (Aberdeenshire). In the UK(Scotl.) N. Esk, counts are recorded upstream of the in-river commercial fishery and most important angling fishery. Thus, the counts do not necssarily reflect the numbers of fish entering the river.

Table 3.4.1 Estimated survival of wild smolts (\%) to return to homewaters (prior to coastal fisheries) for various monitored rivers in the NE Atlantic area.

${ }^{1}$ Microtags.
${ }^{2}$ Carlin tags, not corrected for tagging mortality.
${ }^{3}$ Microtags, corrected for tagging mortality.
${ }^{4}$ Assumes $50 \%$ exploitation in rod fishery.

${ }^{1}$ microtags.
${ }^{2}$ external tags.
${ }^{3}$ preliminary data only.
${ }^{4}$ Releases in UK (Engl. \& Wales) are mainly of parr.

Table 4.1.22 Estimated number of 1SW and 2SW salmon of the River Imsa stock available to the Norwegian Sea fishery and Norwegian homewater fishery, and estimated exploitation rates. The number of salmon caught in the trap in River Imsa is considered to be the total river escapement. The estimates are based on $75 \%$ and $50 \%$ tag reporting rate in Norwegian Sea and Norwegian homewaters respectively. Exploitation rates for 1992 are provisional.

Table 6.1 Input and output data for the national run reconstruction model.

INPUT DATA FOR THE MODEL:
Natural mortality after first sea winter: M
Tag recapture data for:
1SW recaptures at Faroes $\quad R_{f 1}$
2SW recaptures at Faroes $\quad R_{r 2}$
1SW recaptures at West Greenland $\quad R_{81}$
1SW recaptures in homewater fisheries of neighbouring country $\quad R_{j 1}$
2SW recaptures in homewater fisheries of neighbouring country $\quad R_{j 2}$
1SW recaptures in homewaters $\quad R_{h 1}$
2SW recaptures in homewaters $\quad R_{\mathrm{b} 2}$
1SW spawning escapement . $S_{1}$
2SW spawning escapement $\mathrm{S}_{2}$
Correction factors for:
1SW exploitation level in fisheries of neighbouring country $X_{1}$
2SW exploitation lebel in fisheries of neighbouring country $X_{2}$
1SW exploitation in homewaters $\quad Y_{1}$
2SW exploitation in homewaters $\quad \mathrm{Y}_{2}$
Total homewater catches of:
1SW salmon $\mathrm{N}_{1}$
2SW salmon $\mathrm{N}_{2}$

## OUTPUT FROM THE MODEL:

Estimates of total catches of salmon from a nation as:
1SW salmon at Faroes $\mathrm{N}_{\mathrm{n}}$
2SW salmon at Faroes $\quad \mathrm{N}_{12}$
1SW salmon at West Greenland $\mathrm{N}_{\mathrm{g} 1}$
1SW salmon in homewater fisheries of neighbouring country $\quad \mathrm{N}_{\mathrm{j} 1}$
2SW salmon in homewater fisheries of neighbouring country $\quad \mathrm{N}_{\mathrm{j} 2}$

## APPENDIX 1

## TERMS OF REFERENCE FOR THE NORTH ATLANTIC SALMON WORKING GROUP

The Working Group on North Atlantic Salmon (Chairman: Dr K. Friedland, USA) will meet in Dublin from 5-12 March 1992 to:

1. With respect to Atlantic salmon in each Commission area, where relevant:
a) describe the events of the 1991 fisheries with respect to catches, gear, effort, composition and origin of the catch (including escapees and sea ranched fish), and rates of exploitation;
b) describe the status of the stock occurring in the Commission area;
c) begin a time series of aggregate estimates of all unreported catches, including those taken in international waters (the latter should be provided separately);
d) specify data deficiencies and research needs;
e) evaluate the by-catches of fish, birds and marine mammals in the salmon drift-net fisheries.
2. With respect to the West Greenland Commission, propose and evaluate methods to estimate:
a) abundance of salmon in the area of the fishery at the time it operates;
b) total abundance of stocks exploited by the fishery wherever they are;
c) possible catch levels based upon maintaining adequate spawning biomass;
d) some index based on the rivers which make a major contribution to the West Greenland fishery.
3. Evaluate the following management measures on the stocks and fisheries occurring in the respective Commission areas:
a) regulations introduced into the Norwegian salmon fisheries in 1989;
b) quota management measures taken in 1990 and 1991 in the Newfoundland and Labrador commercial fisheries.
4. With respect to Atlantic salmon in the North-East Atlantic Commission and West Greenland Commission areas, provide an inventory of parasites and diseases of wild and reared salmon by country.
5. With respect to Atlantic salmon in the West Greenland Commission area, evaluate the effects which management of the West Greenland fishery has had on stocks in homewaters.
6. With respect to Atlantic salmon in the NASCO area, provide a compilation of microtag, finclip and external tag releases by ICES member countries in 1991.
7. With respect to Atlantic salmon in the West Greenland Commission area, examine historical data on catches and stock composition for the presence of predictable patterns and evaluate the adequacy of sampling programs to estimate stock composition by area and time period.

Webb, J.H. and Youngson, A.F. 1992. Reared Atlantic salmon, Salmo salar L., in the catches of a salmon fishery on the western coast of Scotland. Aquat. Fish. Mgmt. 23:393-397.

[^0]:    ${ }^{1}$ The smolt trap catch a part of the smolt run.
    ${ }^{2}$ Juvenile surveys represent index of fry ( $\mathrm{o}+$ ) abundance (number per 5 minutes electrofishing) at 137 sites, based on natural spawning in the previous year.
    ${ }^{3}$ These smolt counts show effects of enhancement.
    ${ }^{4}$ Estimate of the $0+$ parr population size in autumn.
    ${ }^{5}$ Influenced by enhancement (fry releases).

[^1]:    ${ }^{1}$ Microtagged.
    ${ }^{2}$ Carlin tagged, not corrected for tagging mortality.
    ${ }^{3}$ Return rates to rod fishery with constant effort.

[^2]:    Partly from research fishery.
    Research fishery, preliminary figures.
    ${ }^{3}$ Research fishery.

[^3]:    ${ }^{1}$ Common licence for salmon and seatrout.
    ${ }^{2}$ Introduction of quotas/fisherman, obligation to declare the catches.
    ${ }^{3}$ The number of licences indicates only the number of fishermen (or boats allowed to fish for salmon. It overestimates the actual number of fishermen fishing for salmon up to 2 or 3 times.
    ${ }^{4}$ Adour estuary only (southwest of France).
