Preliminary Report of the
ICES Working Group on the
Bløden Tagging Experiment

## 1. Introduction

The Bldden Herring Tagging Experiment took place during July 1969 to March 1970. The tagged herring were expected to remain in the area of the juvenile herring fishery until early 1971 at least. The Working Group met again in March 1971 (C. M. 1971/H:3) to examine the material so far available and to consider useful methods of analysing the data. At this meeting a contrast between these tagging experiments and those of 1957-58 (Aasen et al. 1961) was apparent in that a higher percentage of tagged fish released was recaptured and were returned over a relatively long period. Because of these features it was thought that the greater number of recaptures might allow a more extensive model of the dispersion of tagged fish from the liberation areas. Such a model could be used to simulate the distribution of tagged fish in the fishing area. A number of requests for the supply of various data were made and it was decided to meet again at ICES Headquarters prior to the Statutory Meeting in September 1971 to further consider the available data and to discuss the type of dispersion model required.

The Marine Laboratory, Aberdeen offered the assistance of a mathematician/programmer and the facilities of a computer of adequate capacity. A time-table was drawn up for transference of the data from computer files in Copenhagen to Aberdeen and for the development of the programme, which was expected to be operational during autumn 1972. It was agreed that the Group should meet again when output from the computer was available.

The participants at the most recent meeting (27 June-3 July 1973) at ICES Headquarters were:

| Mr A. C. Burd (Chairman) | UK (England) |
| :--- | :--- |
| Mr H. Becker | Netherlands |
| Mr A. Maucorps | France |
| Mr M. D. Nicholson | UK (Scotland) |
| Mr J. A. Pope | UK (Scotland) |
| Mr K. Popp Madsen | Denmark |
| Mr $\varnothing$. Ulltang | Norway |

Apologies were received from Dr A. Ackefors and Mr G. Wagner, who were unable to attend.

### 1.1 Terms of reference

At the 5th meeting of the North East Atlantic Fisheries Commission ICES was asked to prepare plans for a new Bløden herring tagging experiment.

The purposes of this experiment would be:
"(a) to obtain a minimum estimate of the proportion of the juvenile herring stock in the Bløden area taken by the fishery there. This estimate is required to assess the effect of the Blфden fishery on recruitment to the total adult herring population in the North Sea. Further, provided adequate sampling for racial analysis is conducted, it is hoped also to provide estimates of its effect on recruitment to each of the main spawning stocks separately.
(b) In addition it should provide valuable information on the distribution and migration pattern of the juvenile herring within and away from the Bløden area."

### 1.2 Experimental design

It was considered necessary that tags should be distributed over the widest possible area during the experiment. Four tagging areas were defined in the eastern North Sea with the boundaries $54^{\circ} \mathrm{N}$ to $57^{\circ} \mathrm{N}$ and west to $1^{\circ} \mathrm{E}$ and from $5^{\circ} \mathrm{E}$ north to the Norwegian coast and into the Skagerak. It was intended that each month tags should be liberated in each area. A Norwegian purse seiner, MV GERDA MARIE, was chartered as catching and tagging vessel. At various times assistance in searching for herring shoals was given by research vessels from

Denmark, France, Germany, Norway, Poland and the Netherlands and those participating in the ICES Young Herring Survey.

Mr G. Sangolt, a member of the staff of the Institute of Marine Research, Bergen, Norway was Supervisor on board the ship and the two tagging teams, whose membership was kept unchanged, consisted of crew members. The herring were either tagged directly from keep nets alongside the ship or transferred to flooded hold tanks aboard the vessel. The tags used were small "sprat" type internal tags. The ultimate aim was to release 100000 tagged fish, however only 57496 fish were released due to scarcity of herring.

Samples of fish from each tagging experiment were measured and preserved for subsequent analysis for age and racial characters. Special arrangements were made for the biological sampling of the commercial catches in Esbjerg during the period when tags were being recaptured.

As the success of the experiment was dependent on the high efficiency of detection of tags, it was stressed that all major plants handling herring catches from the North Sea and the Skagerak should be fitted with magnets and that magnet efficiencies should be regularly tested. The collection of detailed catch and effort statistics by fishing position was not considered adequate in January 1969. At that level the Group doubted that the tagging experiment results could be analysed effectively.

### 1.3 Data processing

For each recaptured tag, the following information was prepared on an IBM punched card. The first 12 columns provide the actual recapture information and columns 13 to 56 details of the experiment from which the tagged fish was released.

| IBM column | Information |
| :--- | :--- |
|  | Tag number |
| $6-7$ | Country |
| $8-9$ | Factory |
| $10-12$ | Week number |
| $13-14$ | Experiment number |
| $15-20$ | Time and place of liberation |
| $21-23$ | Size of catch |
| $24-34$ | Weather conditions |
| $35-56$ | Further information of liberations |

Table 2.1 Dates and positions of liberations

| 29 | 27 Feb | 5441 | 0556 | 2000 |
|  |  |  | Total | 57496 |

The ages of the fish tagged and in the catches was determined from the biological data collected on the tagging vessel and at the ports. When adequate data are available from the 1967 and 1968 year-classes as spawning fish it is the intention to carry out a racial analysis.

Atits meeting in September 1971 the Group was informed that a general computer program of a dispersion model was currently being developed at the Danish Fishery Laboratory by Mr Hans Lassen and it was decided that a modified version of this program, suitable for handling the present material, should be written and applied. This task was undertaken by Mr M. Nicholson (Marine Laboratory, Aberdeen) using the large computer facilities avallable at the Scottish Office Computer Service Centre (Edinburgh) and at the North European University Computer Centre (Denmark) .

The model developed is described in detail in Section 4.

## 2. The liberations

The execution of the plan for the distribution of tags throughout the North Sea and Skagerak was unsuccessful. Primarily this was due to the scarcity of herring of a suitable size for tagging ( $15-23 \mathrm{~cm}$ ) . Research vessels reported the occurrence of echo traces to GERDA MARIE and also fished with trawls in these locations to determine the size of the fish. Despite considerable searching, the tagging locations were restricted in both time and area. Table 2.1 gives the total numbers of fish tagged and the date and location of the liberations (Figure 1). Of the total of 57496 tagged fish liberated, 6035 tags were recovered. In addition to making the tag liberations, six experiments were performed over 3-5 days to try to determine the mortality caused by tagging.

### 2.1 Tagging mortality experiments.

The experiments were either conducted in flooded hold tanks on board the ship or in keep nets alongside. A known number of tagged and untagged fish were placed in the experimental environments and after 3 or 5 days the tank or keep nets were emptied and the numbers of survivors tagged by each tagging team were recorded. The results of these

Table 2.2 Mortality experiments - GERDA MARIE

|  |  | 200 | 90 | 94 |  | 16 | 184 | 48.9 | 10.22 |
| 4 | Untagged | 100 | 77 | 20 |  | 3 | 97 | 79.4 | 4.12 |
|  | Team 1 | 104 | 88 | 16 | . |  | 104 | 84.6 | 3.08 |
| 5 | Untagged | 100 | 98 | 1 | 1 | 1 | 99 | 99.0 | 0.29 |
|  | Team 1 | 100 | 98 | 2 |  |  | 100 | 98.0 | 0.57 |
|  | Team 2 | 100 | 84 | 12 |  | 3 | 96 | '86. 6 | 3.57 |
| 6 | Untagged | 108 | 96 | 12 |  |  | 108 | 88.9 | 3.70 |
|  | Team 1 | 100 | 83 | 15 | 2 |  | 98 | 84.7 | 5.10 |
|  | Team 2 | 100 | 68 | 30 | 2 |  | 98 | 69.4 | 10.20 |

[^1]experiments are summarized in Table 2.2. The results are reasonably consistent between experiments.

The mean daily percentage mortalities, excluding experiment 5 , were:

| Untagged | $4.71 \%$ |
| :--- | :--- |
| Team 1 | $5.36 \%$ |
| Team 1 | $9.01 \%$. |

The experiments have been combined to obtain estimates of survival rates for fish tagged by teams 1 and 2 (Table 2.3).

Table 2.3 Survival of herring

|  | Untagged | Tagged |  |
| :---: | :---: | :---: | :---: |
|  |  | Team 1 | Team 2 |
| Number liberated | 798 | 387 | 382 |
| \% survival | 76.94 | 73.12 | 58.90 |
| Range | 71.3-88.9 | 60.5-84.7 | 48.9-86.6 |

The range of survival in untagged fish is only $17.6 \%$, while for team 1 the range is $24.2 \%$ and $37.7 \%$ for team 2. It is quite probable that the survival may have been much lower than the average values used in the following analysis.

### 2.2 Effective liberations

Assuming there is no further mortality due to tagging beyond the 5 days of the experiments, the total numbers of fish liberated may be adjusted to give an effective number of tags liberated. Table 2.3 gives the numbers of fish tagged by each team and the numbers recaptured.

The mean recapture rate, $p$, of fish tagged by team 2 relative to team 1 was $0.7313 \pm 0.139$.

Let $N_{i j}=$ number of fish tagged by team $i(i=1,2)$ in experiment $\mathfrak{j}(\mathrm{j}=1-29)$;
$S_{i}=$ percentage survival after tagging;
$R_{i j}=$ total number of recaptures by team $i$ from experiment j .

Table 2.4 Recaptures and liberations by tagging team

| 29 | 3.00 | 1.40 | 0.4667 | 768 | 562 | 1330 |
| Total | 11.72 | 9.02 |  | 22194 | 16072 | 38266 |

Taking the percentage survival of team 1 fish in the mortality experiments, the effective liberation is

$$
\begin{equation*}
L_{1 j}=N_{1 j} \times S_{1}+N_{2 j} \times S_{1} \times \rho, \tag{1}
\end{equation*}
$$

or in terms of survival of team 2 fish effective liberation is

$$
\begin{equation*}
L_{2 j}=\frac{1}{\rho} \times N_{1 j} \times S_{2}+N_{2 j} \times S_{2} . \tag{2}
\end{equation*}
$$

Numerically

$$
\begin{equation*}
\mathrm{L}_{1 \mathrm{j}}=0.7312 \mathrm{~N}_{1 \mathrm{j}}+0.5347 \mathrm{~N}_{2 \mathrm{j}} \tag{3}
\end{equation*}
$$

and

$$
\begin{equation*}
L_{2 j}=0.8054 N_{1 j}+0.5890 N_{2 j} . \tag{4}
\end{equation*}
$$

As there is no reason to suppose that one estimate of $S$ is better than the other, means have been taken of the values in equations 3 and 4. The following relationship was used for calculating the effective number of fish liberated in each experiment and they are given in Table 2.4:

$$
\begin{equation*}
L_{j}=0.7683 N_{1 j}+0.5618 N_{2 j} \tag{5}
\end{equation*}
$$

While tagging a record was kept of the serial numbers of each fish liberated in each hour from commencement of tagging. The recaptures for teams 1 and 2 have been grouped by hour of tagging. These have been summarized and expressed as percentages of the total tag releases in Table 2.5. In experiment 4 tagging was curtailed after 2 hours and resumed 10 hours later.

As can be seen from the table, most liberations were conducted into or beyond the third hour from commencement. Taking all liberations up to and including the third hour, analyses of variance were made within teams to test whether differences in recovery rate were associated with hour of liberation. The results are given in Table 2.6.

Table 2.6 Analysis of variance of recaptures by hour of tagging

| Team | Source | Sum of squares | df | Mean square |
| :---: | :---: | :---: | :---: | :---: |
| 1 | Between liberations | 0.2060 | 22 | 0.00936 |
|  | Between hours | 0.0009 | 2 | 0.00045 |
|  | Residual | 0.0149 | 44 | 0.00033 |
|  | Total | 0.2218 | 68 |  |
| 2 | Between liberations | 0.1243 | 22 | 0.00565 |
|  | Between hours | 0.0009 | 2 | 0.00045 |
|  | Residual | 0.0160 | 44 | 0.00036 |
|  | Total | 0.1412 | 68 |  |

Significant differences for both teams occur between liberations but not between recaptures by hour of liberation.

Considering the position of liberations, data on length and age composition of the herring tagged, some of the liberations have been combined for the purposes of further data analysis (Table 2.7). The mixed liberations tend to an average of $40 \%, 1967$ year-class, and $60 \%, 1968$ year-class.

## 3. Recaptures

In this report only recaptures up to 30 April 1971 are considered. Since that date a further 1193 tags have been returned, mostly from the fisheries in the north-western North Sea. Because of the time taken for tags to pass through processing plants it was thought that the minimum reportage time which could be considered was by month. The reaaptures up to April 1971 were tabulated by months, country and factory.

Recaptures from Sweden were too few to considex and the Scottish plant was not operative until late in the season. The English plants at Hull and Grimsby are mainly offal processing.

In order to facilitate a comparison of the number of tags returned per liberation, the returns have been raised to a standard liberation of 10000 tags. These values are given in Table 3.1 for Denmark, Norway and Germany. The data are grouped by the year-class of the fish tagged. It is interesting to note that the liberations 1 and 7 in the Skagerak and $2-5,19$ and $20-23$ south of $55^{\circ} 30^{\prime} \mathrm{N}$ consisted of almost only 1967 yearclass. Returns from 1 and 7 were almost entirely from the northern Danish plants at Skagen and Hirtsals. Whereas with the liberations 2-5 early returns came from Esbjerg, but later were returned from the northern Danish plants.

In the case of Norway a considerable quantity of the 1967 year-class recaptures were returned from May 1970 , when a major part of the Norwegian catch was reported as coming from the north-western North Sea (Table 3.5).

### 3.1 Commercial statistics

Statistics of the quantities of herring caught in the North Sea and landed for industrial purposes were available from Denmark, Norway and Germany. The Danish data, the most detailed statistics provided, ane shown by port in Tables 3.2a-d. In addition to recording the total amount of herring processed, samples were taken at Skagen, Thyboron and Esbjerg for age determination and the estimated number of herring of different year-classes obtained from these samples are also given there. Repeated measurements of magnet efficiencies at the reduction plants

were used to convert the total quantity of herring processed into effective quantities (Table 3.2).

Norwegian landings of herring (for industrial and human consumption) split according to area of capture are shown in Table 3.5. Estimates of the North Sea herring age composition for each month were not available. Magnet efficiencies on an annual basis were available from Norwegian factories (Table 3.3).

Landings of herring for industrial purposes by German cutters were presented from two sources for the period June 1969-June 1970 (Table 3.4). The agreement between the two sets of statistics is not good.

From the information on magnet efficiencies tables have been constructed showing the number of tags recaptured per 10000 tags effectively liberated in each experiment (Tables 3.6 and 3.7). In the case of the returns which came from factories at Esbjerg, Skagen and Thyborön, it was possible, by using the available age composition data, to calculate the number of recaptures per 10000 tags released per $10^{6}$ herring processed. These data are given in Tables 3.8, 3.9, 3.10 and 3.11. The data for Esbjerg show no systematic variation with time, suggesting that no change took place in the ratio between tagged and untagged fish.

### 3.2 Distribution of catch and effort

The most detailed information on the distribution of herring fisheries from July 1969 to April 1971 concerns the Danish, Norwegian and Scottish catches which, between them, account for by far the greatest part of the recaptured tags. German recaptures are quite significant in some experiments, but no data on the distribution of the German fishery are available.

The Danish catch statistics cover Esbjerg where $68-93 \%$ of the monthly landings are accounted for, and Skagen where 8-68\% coverage was obtained in individual months. There are no data available from Skagen in 1971.

The distribution of the Danish herring catches shows two rather permanent areas of fishing, one around the Skaw at the entrance to the Kattegat and an area in the south-western North Sea - identical with the

Table 3.12 Distribution of recaptured tags per 10000 released by country (not corrected for magnet efficiency)

| Tagging location | Experiment | 1967 year-class |  |  |  |  |  |  |  |

$\mathrm{Sw}=$ Sweden

Bløden ground. Fishing in the north-western North Sea is more patchy and was mainly carried out in January-April 1970 and again from September 1970 to April 1971.

The Norwegian purse-seine catches are mainly concentrated in the Skagerak and the north-eastern North Sea in the period July-December 1969. In January-June 1970 additional fishing was carried out in the central North Sea east of the Danish Bl $\phi$ den fishery. In the second half of 1970 a Norwegian fishery around the Shetland-Orkneys developed. Only sporadic landings are taken from the North Sea in the early part of 1971.

The Scottish North Sea herring fishery is mainly concentrated around the Shetland-Orkneys and only a few landings are made in the period October 1969-March 1970 and in the early months of 1971. The largest catches are taken in June-August 1970 when the Scottish herring fishery extends towards west into ICES Statistical Area VIa and only minor catches are made east of Shetland.

It is important to note that there is almost no overlap in the area of the fisheries of Norway, Scotland and Denmark. The rate of return of tags from these fisheries is in part a reflection of the emigration from the tagging areas (Table 3.12).

The distribution of I-group herring in the North Sea as described from the ICES Young Herring Surveys in February 1970 and 1971 may be compared with the distribution of the fisheries in the same months, with one exception. There is a good agreement between the locations of the fisheries and the major concentrations of herring. This exception is a major concentration of young herring in the Texel area, which is not covered by the industrial fishery. This fishery seldom extends south of $54^{\circ} \mathrm{N}$ latitude.

### 3.3 Analysis of returns

To obtain estimates of stock size and mortalities, several methods were tried.

## (a) Petersen method

As a first approach the simple Petersen method was used. stock size in numbers was calculated by

Table 3.13 Estimated stock size in miliions (upper figure) and fishing mortality (lower figure)

| Tagging location | 1967 year-class |  |  |  | 1968 year-class |  |  |

*From Table 9, C. M. 1972/H:13.

$$
\widehat{N}=T \frac{C}{R},
$$

where $T$ is the effective number of tagged fish, $R$ the number of recaptures and C the corresponding catch in numbers corrected for magnet efficiency. By using the number of recaptures and corresponding catch of one year-class, the estimate above should give the size of the yearclass at the time of tagging. Only returns from the factories in Esbjerg, Thyborön and Skagen and from the Norwegian factories were used in these estimates. The estimates from Norwegian recaptures are based on returns in January and February 1970 only. The Norwegian fleet was then fishing in the southern part of the central North Sea, just outside the Bløden area, and it was therefore assumed that the catch composition from Esbjerg in autumn 1969 could be applied to these catches. Estimates from the various experiments are summarized in Table 3.13. Fishing mortalities were estimated by assuming that the stock size estimates refer to 1 January 1970 and then calculating $F$ from

$$
C=N \times \frac{F}{Z}\left(1-e^{-Z}\right),
$$

where C is the total catch of the year-class in 1970. It was further assumed that $M=0.1$. In the cases where estimated stock sizes were lower or about equal to the catch no estimate of F could be made.

A basic assumption in the Petersen method is that the proportion of tagged fish in the catches used to estimate N is the same as in the rest of the population or year-class. The big differences in the estimates of the 1968 year-class from the southern and northern experiments may be explained by different behaviour of the tagged fish in the southern and northern parts of the area. If the tagged fish in the southern area migrated out of the main area fished, these experiments will give over-estimates of the stock size. Similarly, if fish tagged in the northern area migrated into the main area fished and concentrated there, the northern experiments will underestimate the stock size. Such under-or overrepresentation of tagged fish in the catch may result in a serious error in the estimates.

Using the German biological samples to estimate the catch in numbers, the reported recaptures in January-April 1970 from the factory with the highest production gives the following estimates of stock size (Table 3.14).

Table 3.14 Stock size estimates in millions from German data

| Tagging location | 1967 year-class |  |  | 1968 year-class |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Experiments | Returns | Stock | Experiments | Returns | Stock |
| Skagerak | 13 | 15 |  |  |  |  |
|  | 14 | 15 |  |  |  |  |
| Northern Bl $\varnothing \mathrm{den}$ |  |  |  | 8-10 | 148 | 10300 |
|  |  |  |  | 15-17 | 379 | 4000 |
|  |  |  |  | 18 | 521 | 2900 |
| Southern Bløden | 2-5 | 43 | 8800 | 11 | 148 | 10300 |
|  | 19 | 38 | 9900 | 27-29 | 13 | 117800 |
|  | 20-23 | 19 | 19900 |  |  |  |

The estimates for the 1967 year-class are much higher than those based on Danish and Norwegian recaptures. Those for the 1968 year-class, except that from experiments $27-29$, are in general agreement with the estimates based on Danish recaptures. The return of tags from liberations 13 and 14 in the Skagerak by the German plant can be due to the processing of offal from fish imported to Germany. They highlight one of the uncertainties in the German material. In addition, because of the uncertainties in the German catch figures, one should not consider the stock estimates as equally good as the others.

The Norwegian recaptures in June-August 1970 were also used to estimate stock size. Almost all the catch in this period came from area IVa W (Shetland), and it is assumed that all the reported tags came from this area.

The estimated age composition of the catch for the whole year and all countries in this area was used to estimate catch in numbers by age groups (Anon. C. M. 1972/H:13). Very little of the 1968 year-class were caught and the relative precision of the estimate of numbers caught of
this year-class is too low to make any estimate of stock size. The results for the 1967 year-class are shown in Table 3.15.

Table 3.15 Stock size estimates, in millions, for the 1967 year-class, from Norwegian data

| Tagging location |  | Experiments |  | Returns |
| :--- | :---: | :---: | :---: | :---: |
|  |  |  | N |  |
| Southern Bløden | $2 \because 5$ | 93 | 23300 |  |
|  | 19 | 181 | 12000 |  |
|  | $20-23$ | 148 | 14600 |  |

These estimates give considerably higher values than the others. Possible explanations could be that the tagged fish in the Bløden area have not migrated to Shetland in the same proportion as the rest of the year-class or the Shetland stock of adult herring is not recruited from Bløden alone.

In Table 3.13 the recoveries from experiments 1 and 7 at Skagen should give an estimate of the Skagerak 1967 year-class, as almost all returns from these experiments seem to be recaptured in that area. As the catch of the Skagerak stock is not known no estimate of $F$ could be made.
(b) Maximum likelihood estimates (Paulik 1963)

This method uses only the number of returns (corrected for magnet efficiency) with time and the effective number of tags released to estimate total and fishing mortality. Grouping the recovery period into threemonthly intervals and using all reported tags from Esbjerg, Thyborön, Skagen and Norway, the method gave the estimates shown in Table 3.16.

Table 3.16 Estimates of fishing and total mortality - Paulik method

| Yearclass | Experiments | F | Z |
| :---: | :---: | :---: | :---: |
| 1967 | 1 | 0.31 | 1.66 |
|  | 2-5 | 1.00 | 3. 02 |
|  | 7 | 0.22 | 1. 54 |
|  | 14 | 0.36 | 4.50 |
|  | 19 | 0.50 | 2. 36 |
|  | 20-23 | 0.46 | 2. 81 |
| 1968 | 8-10 | 0.18 | 0.42 |
|  | 11 | 0.17 | 2. 04 |
|  | 15-17 | 0.48 | 1. 54 |
|  | 18 | 0.52 | 1.75 |

As every return is not included, the method should underestimate $F$. The estimate of $Z$ will not be influenced if the proportion of the returns that are reported is constant from interval to interval. However, a basic assumption in this method is that fishing and total mortality are constant and the method may give seriously biased estimates if the mortalities are changing with time. In many of the experiments the number of returns with time indicates that there is a higher fishing mortality on the tagged fish just after tagging than later on. The Paulik method may in such cases seriously overestimate $Z$.
(c) Number of recaptures per unit effort

The only series of comprehensive effort data is that from the Danish port of Esbjerg. Table 3.17 gives the total number of hours fished per month by industrial vessels engaged in herring fishing. Using these data and the numbers of tags per 10000 liberated per million fish processed of Tables 3.8 and 3.9 the numbers of returns per catch per unit effort have been derived (Table 3.18). Regression of the logarithm of these recaptures per unit effort on time was made for the 1967 and 1968 yearclasses using data from Esbjerg. The time unit used was one month.

For the different experiments the following values for the slope and intercept of the regression equations were obtained (Table 3.19). The slope equals $\mathrm{F}+\mathrm{X}$, where X represents all other apparent mortality not

due to fishing ( $F$ ) and is an estimate of the monthly total mortality (Z).
Table 3.19 Regression parameters

| Year- <br> class | Experiments | Slope | Intercept |
| :--- | :---: | :---: | :---: |
| 1967 | $2-5$ |  |  |
|  | 19 |  | -0.26 |
|  |  |  |  |
|  | $20-23$ | -0.43 | 6.93 |
|  |  | -0.35 | 8.65 |
| 1968 | $8-10$ |  |  |
|  | 11 | -0.24 | 6.38 |
|  | $15-17$ | -0.15 | 5.57 |
|  | 18 | -0.26 | 7.10 |
|  | $27-29$ | -0.23 | 6.84 |
|  |  |  | 5.25 |

Attempts to estimate the fishing mortality from the intercept,

$$
\ln \frac{F N_{o}}{F+X}\left\{1-e^{-(F+X)}\right\}
$$

gave no reasonable results due to its large sampling variation.
(d) Estimation of catchability coefficient

The catch per unit effort in any time interval is proportional to the abundance at the beginning of that interval. The abundance at any time is a function of the product of the total effort expended up to that time and the catchability coefficient (q). The latter may be estimated from successive values of the catch per unit effort and the cumulative effort. This method of estimating $q$ due to DeLury (see Ricker 1958) was used, using data for Esbjerg given in Tables 3.17 and 3.18 over the period January 1970 to April 1971 inclusive. Months in which there was fishing effort but no tags were returned were omitted from the analysis, but the effort was included in the accumulated sum. The estimates of $q$ and their standard errors, obtained by carrying out an ordinary regression analysis of $\ln$ catch per unit effort on cumulative effort (measured in units of thousand hours fishing), are given in Table 3.20. These estimates of $q$ are very similar, their average (obtained by weighting by their inverse variances) being $-0.01378 \pm 0.00106$.

Table 3.20 Estimates of the catchability coefficient, q, from Esbjerg data
$\left.\begin{array}{lllll}\hline \text { Experiments } & \begin{array}{l}\text { Catchability } \\ \text { coefficient, } q\end{array} & & \begin{array}{l}\text { Standard } \\ \text { error }\end{array} & \end{array} \begin{array}{l}\text { Degrees of } \\ \text { freedom }\end{array}\right]$

## 4. The model

The numbers of tagged fish recaptured depends on the way they become dispersed over the area in relation to the fishing intensity.

Movement of the tagged fish away from the centre of liberation was assumed to be made up of two components: (a) a symmetrical dispersion outwards from the point of liberation, and (b) a general drift in a given direction. This was simulated by assuming that a fish in a particular square at the end of a time interval had a given probability of remaining in the same square and given probabilities of moving into any one of the eight surrounding squares by the beginning of the next time interval.

It was further assumed that tagged fish could not move outside the Bløden area. This was simulated by assuming that if a fish in a boundary square tried to move outside the boundary, it was reflected back into that square or into the adjacent boundary squares on either side with given probabilities.

These probabilities were derived from a dispersion coefficient (d) and parameters ( $n$, e) representing northerly and easterly components of movement.

During each time interval fish may die or may be recaptured, the number dying depending on the value of the instantaneous natural mortality coefficient (M) and the number being recaptured depending on the fishing intensity and the catchability coefficient according to the formula

$$
\text { number recaptured }=n_{i j} q_{i j}\left\{1-\exp \left(-M-q f_{i j}\right)\right\} /\left(M+q f_{i j}\right),
$$

where $n_{i j}=$ number present at beginning of interval in square (ij),
$\mathrm{q}=$ catchability coefficient (constant),
$\mathbf{f}_{\mathrm{ij}}=$ fishing intensity in square ( $\mathbf{i} \mathbf{j}$ ).
Knowing N , the effective number of tags liberated and assuming a value for $M$, the problem is to find values of $d, n$, $e$ and $q$ which will produce values for the numbers of recaptures in each time interval as nearly as possible equal to the observed number of recaptures. Because the positions of recapture of tagged fish are not known, this matching process has to be done on the total recaptures summed over all squares in each time interval.

The process of finding the best set of parameters starts by guessing initial values and thereafter proceeds by iteration to the final, best-fitting values, provided convergence is possible. The criterion chosen for obtaining the best set of parameters was that they should be the ones which minimize the sum of squares of the differences between the observed and the predicted recaptures in each time interval. The time interval chosen throughout was four weeks.

The assumption that none of the tagged fish can leave the Bløden axea was thought to be unrealistic for fish of the 1967 year-class. This was borne out by the fallure of the model to produce estimated recaptures compatible with those observed. In order to handle data from liberations composed of fish from the 1967 year-class changes will have to be made in the model to permit fish to emigrate from the area.

For the 1968 year-class it is reasonable to assume that there will be a smaller emigration as compared to the 1967 year-class and the model should provide a closer approximation to the true behaviour of the fish. A study of data from 12 four-week periods from experiments 15,16 and 17 was therefore made, and although no convergence to a best set of parameter values was achieved, the overall performance of the model was better than for 1967 year-class experiments.

After 10 iterative cycles, the sum of squared differences between obsexved and predicted tag returns reached a minimum, after which the solutions began to diverge, producing successively worse predictions of
tag returns (Table 4.1). For this computer run, only Esbjerg effort data and tags returned through Esbjerg factories have been used. Natural mortality has been set at 0.1 . The numbers liberated and numbers returned have been adjusted for tagging mortality and magnet efficiencies respectively.

Table 4.1 Summary of 9th, 10th and 11th cycles

| Period | Observed | Predicted 9 | Predicted 10 | Predicted 11 |
| :---: | :---: | :---: | :---: | :---: |
| 1 | 2.0 | 11.1 | 3.6 | 9.7 |
| 2 | 0.0 | 4.1 | 1.0 | 4.5 |
| 3 | 18.7 | 79.9 | 30.9 | 42.4 |

| Total | 688.8 | 1368.8 | 649.1 | 507.7 |

Parameter values
Catchability coefficient in Cycle $9 \quad$ Cycle 10

Cycle 11

| Catch coefficient | 0.0042 | 0.0016 | 0.0027 |
| :--- | ---: | ---: | ---: |
| Migration east | -0.8362 | -0.4280 | -0.3707 |
| Migration north | -3.0000 | -3.0000 | -3.0000 |
| Diffusion rate | 1.5000 | 2.0733 | 0.5000 |

Although the performance of the model here is better than for the 1967 year-class, it is still not very good. This may be due to shortcomings in the available data, or perhaps because this type of diffusion model does not correspond to the actual movements of a shoaling species such as herring.

## 5. Discussion

In planning the present tagging experiment it was natural to regard the young herring taggings in 1957-58 as a pilot experiment (Aasen et al. 1961). The shortcomings of the latter derived from

1. inadequate catch and effort statistics for detailed distribution in time and space;
2. too few fish liberated at too few localities;
3. too few factories with effective installations for recovery of tags;
4. no direct attempt to assess initial tagging mortality;
5. insufficient biological sampling of the tagged population and of the commercial fisheries;
6. too many different tagging teams to ensure a reasonable uniform handling of the tagging operations throughout the period. As a consequence of these deficiencies the analysis of the comparatively low number of tag returns was difficult.

In the present experiments the necessary increase in tagged fish and in tagging positions was achieved by extending the period from one month to eight months and by releasing $30 \%$ more fish per station. Even so the number achieved fell far below the intended target of 100000.

The need for experimental work on tagging mortalities was met with and facilitated by the presence of huge tanks on board the hired tagging vessel. More uniform handling of the fish was obtained by the deployment of the same two tagging teams throughout the entire experiment.

While improvements in the work at sea also included sampling each haul, it proved difficult to obtain clear improvements of the equally vital activities ashore. In working up the new data, difficulties were again met in the same categories of the commercial fishery data sampling and magnet efficiencies.

During the course of the tagging experiment fish were tagged probably of only the 1967 and 1968 year-classes. Judging from the biological samples taken at the time of tagging, some experiments were virtually conducted on single year-classes.

The 1967 year-class entered the adult fisheries in early summer 1970. Tags were recovered from liberations of this year-class from July 1969 until spring 1971 in the young herring fisheries. After that they occur with increasing rates in fisheries over deep water and even to the north of Scotland.

In contrast, the 1968 year-class was 0 -group when the taggings began in 1969 and there are indications that this year-class remained in the eastern North Sea throughout 1970. In 1971 this year-class shows the same drop in abundance as did the 1967 year-class one year earlier.

There is a striking difference between the recent experiment and the earlier one in the length of time over which tags were returned. Few tags were recovered beyond eight weeks in 1957 and 1958, while many tags were recovered after eight months in this experiment. The Working Group did not investigate the reason for this difference, but either a change in migration rate of the fish and/or an increase in fishing power and range of the industrial cutters could be explanations.

In view of the differences in the 1967 and 1968 year-classes mentioned above, the recaptures from them must be considered separately, In consequence, the lack of relevant age data has resulted in material being left out of the analysis. In effect, this means that the main analysis is again dependent on the data from Esbjerg.

A number of methods for analysing tagging data were tried, For various reasons explained above, the only reliable estimates were derived from the Petersen method relating number of tags recaptured to fish processed.

Stock and fishing mortality estimates for the 1967 and 1968 yearclasses (Table 5.1) are close to those derived by the North Sea Herring Assessment Working Group from cohort analysis.

Table 5.1 Stocks at 1 January 1970 and fishing mortalities in 1970

|  | 1967 year-class |  | 1968 year-class |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Tagging | Cohort | Tagging | Cohort |
| Stock $\times 10^{-9}$ | 3.42 | 3.32 | 7.04 | 4.93 |
| Fishing mortality | 0.94 | 0.99 | 0.20 | 0.29 |

The I-group (1968 year-class) had about the same fishing mortality in 1970 as had the corresponding age group in the 1957-58 experiments. The year-class strength might, however, be less than half that of the 1956 year-class in January 1958.

The 1957-58 experiments were analysed using a simple diffusion model. With the increased information available from the present experiment and the increased experience in the use of computers for simulation studies, a more sophisticated model was developed. The results so far obtained are not fully satisfactory but indicate that further development should be undertaken. It seems especially necessary to make some more realistic assumptions about emigration and to develop methods for testing the parameters obtained.
