# Estimates of effort, CPUE, and mean length for the Norwegian commercial catch of ling, blue ling and tusk 

by<br>Kristin Helle and Michael Pennington<br>Institute of Marine Research, P.O. Box 1870 Nordnes, N-5817 Bergen, Norway<br>E-mail: kristin.helle@imr.no

## Introduction

Ling, tusk and blue ling have been fished by Norway for centuries and the amounts landed have been recorded since 1896 (Figure 1). The major fisheries for these species are taken by long lines, and the catches are to a large degree bycatches. The fishery for these three species is mainly influenced by the size of various quotas for other species, especially the quota for Arcto Norwegian cod. Therefore the total catch may not be a good indicator of the state of these stocks(Figure 2). Scientific surveys do not cover the main habitats of these species. Consequently, to estimate the relative abundance of these stocks, indicators such as CPUE series need to be generated. In order to construct CPUE series, the Institute of Marine Research (IMR), in cooperation with the Norwegian Directorate of Fisheries (NDF), began in 2003 to record in an electronic database the logbooks of long liners larger than 21 m . Vessels were selected that had a total landed catch of ling, tusk and blue ling that exceeded 8 tons in a given year. The logbooks contain records of the daily catch, date, position, and number of hooks used per day. To obtain more detailed and targeted information, the IMR initiated in 2000 a program to collect data and biological samples directly from selected commercial long-liners, the so-called "reference fleet." The fishers measure a subsample of fish at selected locations. Upon request they may also collect otoliths, stomachs, tissue for genetics, and other biological samples. Presently four long-liners are members of the reference fleet.

This paper presents time-series of effort and CPUE from these two data sources and compares the 2000-2009 data with previously submitted data for the period 19721994. It also gives estimates of the mean length of ling, tusk and blue ling during the two periods.

Only about half of the 2009 logbooks from the fleet have been entered so far and the estimates are therefore preliminary.

Development of the Norwegian fleet of long-liners, 1995-2009
In addition to data on total landed catch ${ }^{*}$, the NDF also provides data on how many of the fishing vessels satisfying the above criteria are at any time participating in the

[^0]fishery, the gear employed, areas fished and changes in vessel ownership. Table 1 provides information on the number of long liners during the period 1995 to 2009, the total landed catch by the fleet, and the average annual catch per vessel. The number of vessels peaked in 2000 and then decreased until 2006. After 2006 the number of vessels seems to have stabilized. The number of vessels declined during this period mainly because of changes in the laws concerning quotas for catching cod. The decrease in vessels was followed by a reduction in the total catches until 2004, after that there was an increase in total catch, especially in 2007 and 2008 (Figure 2a). The catch-per-vessel was relatively stable from 1995 until 2003. After 2003 there was a steady increase in catch-per-vessel (Figure 2b). In 2000 there were 72 vessels in the fishery; by 2006 the number had dropped to 35 , and in 2009 the number decreased to 34.

## Logbooks

All available logbooks for the years 2000-2008 have now been entered in the database and the data have undergone extensive quality control procedures. The entering of the logbooks from 2009 are the estimates are therefore based on a subset of logbooks. The quality of the logbooks varies considerably and a serious problem is that some lack information on the number of hooks used per day.

## Days in the fishery

The Norwegian long line fleet logbooks provide information on the geographical distribution of the fleet. In Table 2 the average number of days a vessel spent in a given area fishing for tusk, ling and blue ling jointly and separately is given for all ICES Subareas and Divisions. After 2000, when new quota laws for cod were introduced, the number of days each vessel fished for the three deep-water species increased and by 2005 and 2007 the number of days in the fishery was twice that in 2000. The data for 2006 show that the number of days in the fishery has decreased by more than 20 percent compared with the number in 2005 and 2007. Although the number of vessels was at its lowest in 2006 ( 35 vessels) this reduction in the number of vessels is not sufficient to explain the decrease number of days in the fishery. The data have been checked for errors but none have been discovered. Division IIa was the main fishing area since 2000, followed by IVa and Vb .

## Average number of hooks used per day

Table 3 provides estimates of the average number of hooks used per day in different areas and in the total fishery for the years 2000-2007. For all areas combined there was a steady increase in the number of hooks used from 2000 through 2007. This is also the overall trend for the subareas (Figure 2).

## Total number of hooks per year

Based on the number of vessels, the number of hooks per day, and number of days each vessel participated in the fishery, estimates of the total number of hooks used per year were generated (Tables 1, 2 and 3). Table 4 gives the estimated number of hooks (in thousands) set in each of the ICES subareas and in the total fishery for the years 2000-2007. Although the number of vessels has decreased considerably, the total
number of hooks has remained remarkably stable during the period 2000-2007, except for 2006 when there was a slight decrease (Figure 4).

## CPUE from log books and the reference fleet

In Tables 5 and 6 are estimates of the catch-per-unit of effort (CPUE) based on the logbook data and data from the reference fleet. The measure of CPUE is the average weight ( kg ) of fish caught per 1000 hooks. Figure 5 shows the variation in the CPUE for ling and tusk in each ICES subarea and in all areas combined. For tusk there was a slight downward trend in most of the subareas from 2000 to 2003, then an increase from 2004 to 2006 and a slight decrease in 2007. This is especially apparent in areas Vb and VIa. For ling there was a slight downward trend from 2000 through 2002, an upward trend from 2003 through 2005 followed by a slight decline in 2006 and 2007.

Entering the data from the logbooks for the entire fleet is time consuming and laborious. It has therefore been suggested only to use the data from the reference fleet. Figures 6 and 7 show the CPUE estimates from the logbook vs. the reference fleet for tusk and ling. The reference fleet does not cover the entire area in which the long liner fleet is fishing and, hence, data for the more "remote" areas are absent or inadequate (see Tables 5 and 6). Only the main fishing grounds in area IIa are sufficiently covered to achieve reliable CPUE estimates. To get good estimates of CPUE for the entire fishing area, data from the logbooks are necessary.

## Historical data vs. new data

In the 1990s a Nordic and a Norwegian project studied the fishery, age distributions and general biology of ling, blue ling, and tusk in the Northeast Atlantic (Bergstad and Hareide, 1996; Magnusson et al., 1997). These projects greatly improved our knowledge of these species and formed an important foundation for further studies. The results from these studies were presented at earlier WGDEEP meetings, and the Group used analyses of time-series for the Norwegian long liners back to 1972 for effort and CPUE as a basis for assessing abundance trends. In the present study, the 2000-2007 data and the earlier time-series were combined.

In the 1990s the data for the Norwegian fishery were derived from two sources; official logbooks from the NDF, and private logbooks submitted voluntarily by selected vessels. It was shown in Bergstad and Hareide (1996) that the official data and the private data were very similar, and that the much longer time-series from the skipper's logbooks provided reliable data on catch trends. It should be noted that the effort data were corrected for all known technological changes to account for changes in efficiency (see report for details).

A time series of CPUE was made from the early 1970ties until the mid 1990ies. The series was based on private log books, official logbooks and data from the Norwegian Directorate of Fisheries. This series showed a drastic reduction in CPUE during this period and had been used as an indicator for a severe reduction of the ling and tusk population. The time series was never published and the documentation of the results are hard to find because the data used is not available and a number of the tables in
the unpublished document describing this work is missing. When using these data there are a few points I want to discuss.
The number of hooks was as far as I can find out based on logbooks from three vessels. Each of these three vessels had their main fishery in different parts of the distribution areas for ling and tusk.
1971-1993: Three vessels were chosen because they cover typical fishing strategies of the fleet. Vessel 1 concentrated the effort in Faroese waters but fished occasionally in other areas. Vessel 2 was mainly fishing off the Hebrides and on the Rockall bank. Vessel 3 was mainly fishing off Shetland and occasionally in other areas.
There is no information about the number of official logbooks that were used. But based on knowledge about the reference fleet and the large variation in the estimates from year to year the number was probably low.

Change from handbated lines to autoline:
During the time period this series covers the fleet changed a lot and went from hand baited lines to auto lines. Although both are lines the way they are
Hand baited lines are much more labor intensive and is therefore set more careful than autolines
Hand baited lines are much shorter and is set in known "hot spots" while autolines are longer and often stretched from hot spot to hot spot.
Fresh bait was often used on the hand baited lines while frozen bait is used on autoline, fresh bait stays on the hooks better than frozen.

These data were combined with the data for 2000-2006 (Figure 10). The number of hooks used per day showed a steady increase from the early 1970s, and based on the recent data it appears that the upward trend continues (Figure 10a). Compared with 1972, the fishers presently set three times as many hooks per day. The total number of hooks used per year showed an increase from the early 70s until the early 80s.
Subsequently both the old and new data showed large year-to-year variation but no apparent trend. The total number of weeks used in the fishery declined through the entire period (Figure 10b). The new data indicate that the number of weeks in the fishery during the period 2000-2007 has stabilized at the same level as in 1994 (approximately 1100 weeks) with a decrease in 2006 to about 800 weeks.

Figure 11 shows the CPUE ( $[\mathrm{kg} / \mathrm{hook}]$ x1000) for ling, tusk and both species combined for the periods 1971 through 1993 and for 2000 through 2007. CPUE declined for both species and this decrease is especially noticeable for ling. The recent data suggest that the CPUE has remained at a low level after 1993 with an increase during the period 2003-2006 and a decline in 2007.

Figure 12 shows the recent and the historical CPUE for tusk in all areas and in areas IIa, IVa, Vb, VIa and VIb. When the tusk data were not combined with ling it is obvious that there was a declining CPUE series in the historical period. The low CPUE levels appear to continue in the recent period, although from 2004 through 2006 there was an apparent increase in CPUE.

Based on the results from the genetic analysis of tusk, which show that the Rockall population is separate from those in the other areas (Knutsen et al., 2007), it is of interest to examine separately the CPUE in each subarea. For some of the areas there
are probably insufficient data to analyse trends in CPUE. This is especially apparent for area IIa where no obvious trend is apparent in the historical data. The recent data indicate a decline during the years 2000-2004, an upward trend in 2005 through 2006 and again a small decline in 2007. In areas IVa, and VIa the historical data indicate a decline in abundance while there was a upward trend recently. In Area Vb there was a sharp decline in CPUE from 2006 to 2007. In area VIb, no trend is apparent during the historical or the recent period. The Norwegian fishery in this area was limited

In Figure 13 both the new and the historical CPUE data for ling in all areas and in areas IIa, IVa, Vb, VIa and VIb are presented. The historical data indicate a downward trend. The recent CPUE estimates continue at the same low levels as was observed in 1993. The recent data showed an upward trend for areas IVa and Vb for the years 2002 through 2006 with a decline in 2007. In area VIb there has been a continuous positive trend from 2002 through 2007. For area IIa there was an upward trend from 2001 until 2005 and then a decline in 2006 and 2007. Since the late 1970ies until the present there was no apparent trend in area VIa.

## Estimated lengths of ling, tusk and blue ling

The method for estimating the average length is given in Helle et al., (2006). In Tables 7, 8 and 9 are estimates of the average length of ling, tusk and blue ling in the commercial catch. The estimates of mean length for 1976-1995 are taken from Bergstad and Hareide (1996). During the years 2001, 2002 and to a lesser extent 2003, the reference fleet did not record the total catch from which the subsamples were taken and, therefore, the unweighted mean (eq. 2) was calculated for 2001, 2002 and for areas V and VIb in 2003 and the weighted mean (eq. 1) for the other years and areas. These estimates are in Tables 1, 2 and 3, along with sample size and estimated standard deviation (previous measurements) and standard errors for the reference fleet estimates. The estimates of mean length varied slightly from year to year but with no obvious trend.

## Conclusion

Given that other sources of information are lacking, the CPUE estimates may constitute the only source of information on temporal trends in abundance. It is a notable result that even though the catch-per-vessel increased during the period 20042008, the abundance as indicated by CPUE in the most important fishing area, subarea IIa, may be constant or even declining. For the remaining areas the results were more positive. Even though there is a time gap of six to seven years between the old and the new time series, the recent CPUE estimates seem to correspond and reflect the trends in the fishery quite well. The main pattern is that CPUE remains at a low level compared with the 1970ies and 1980ies.

Legislation to regulate the cod fishery has since 2000 resulted in a continuous reduction in the number of long liners participating in the fishery. Even though the number of vessels has decreased, the total effort does not seem to have been reduced. The number of days each vessel is in the fishery has increased and the total number of weeks the fleet is in the fishery has been nearly constant since 2000. The number of hooks used per vessel per day has increased every year. This together with the
increased time in the fishery has compensated for the reduction of vessels in the fleet and hence there is little or no reduction in the total effort.

During the period 1998 through 2003 the total catch declined from 32675 to 19000 tons while the catch per vessel was relatively stable. The data from 2004-2006 showed that the total catch has been relatively stable with a sharp increase in total catches during 2007 and 2008. The average catch-per-vessel has increased considerably every year since 2004. Current landings are higher than levels recommended by ICES in 2008. It is unlikely that measures implemented in the last 45 years has reduced fishing effort to the 1998-level as recommended by ICES in 2004.

It is recognised that caution must be exerted when using CPUE from long liners to study variation in abundance. The data presented here show clearly that the selection of the effort measure is critical. Comparatively crude measures such as "number of fishing days" would not reflect effort in this fishery correctly, and are inferior to "hooks-per-day" series, which appears to be a much preferred measure of effort. "Hooks per day" is in essence a rather readily available measure based on compulsory logbook information. Not accounted for in the 2000-2007 data were changes in efficiency, e.g., by technological advances such as hook design, bait characteristics, effects of fishing practice, e.g., soak times etc., but in the recent period, technological changes appear to have been minor.
