### 1.2 Terms of Reference

The Herring Assessment Working Group for the Area South of $62^{\circ} \mathrm{N}$ (Chairman: Mr Ø Ulltang) met at ICES headquarters from 23 March to l April 1982, in accordance with C.Res.1981/2:27:9, to:
(i) assess the state of the herring stocks in Sub-areas IV and VII and Divisions IIIa and VIa and to provide management options for 1983,
(ii) collate any new data available on herring by-catch in the sprat fisheries by small time and area subdivisions,
(iii) evaluate any new data available in stock components in Division IIIa herring,
(iv) specify deficiencies in data required for assessments.

### 1.3 The Use of Reference Points on the Yield per Recruit Curve

For the calculation of yield/recruit curves, the treatment of the oldest age group as a plus group simulates a continuation of the exploitation beyond the oldest age in the assessment.
In calculating $Y / R$ curves, Beverton and Holt (1957, p.351) referred to the "fishable lifespan", using 15 years in case of North Sea plaice. In this context the interpretation is that the calculation should not be expanded beyond the age groups which are observed in the catches.
The differences between these two approaches are entirely dependent on the contribution which the oldest age group makes to the total yield. The relative contribution to yield per recruit of the oldest age group decreases with increasing fishing mortality, but it is very high on
very small Fs which are used in calculating the slope of the tangent at the origin of the $Y / R$ curve used to estimate $F_{0.1}$ The implication are that by treating the oldest age group as a plus group the slope is much steeper resulting in smaller $F_{0.1}$ and $F_{\max }$ values (Figure 1 ).

This discussion will have practical importance if management objectives are being defined by reference points on the $Y / R$ curve.
To illustrate the magnitude of the problem, the Downs herring may serve as an example.

|  | $\mathrm{F}_{0.1}$ | Corresponding yield in <br> $1982(1000$ tonnes $)$ |
| :--- | :---: | :---: |
| Age 9+ group <br> Age 9 not a plus <br> group | 0.15 | 53 |

For these reasons, the Working Group did not include reference points on the $Y / R$ curve in the tables giving management options.

The Working Group, therefore, would like to see these questions considered by ACFM, if management strategies should be based on $Y / R$ considerations.
2. NORTH SEA HERRING CATCHES
2.1 The Fishery
2.1.1 Regulation of North Sea herring fisheries

1975 was the last year of unrestricted herring fishing. In 1976 a ban on directed fishing for herring for fish meal was introduced. From that year about all catches of juvenile herring have been taken as by-catches of small-meshed fisheries and, in particular, those directed at sprat.
Except for some limited catches in early summer of 1977 in Division IVb and in November and December in Division VIId, all directed fishing for herring has been banned. Since that date and until the re-opening of Division IVc in October 1981, any herring have been reported as bycatches in trawl and purse-seine fisheries directed at other species.
ACFM recommended in its 1981 report that:
I) a limited fishery could be allowed in Division IVc-VIId stocks, but the TAC should not be more than 20000 tonnes;
2) it should only be taken in the area south of $53^{\circ} \mathrm{N}$ in Division IVc . . VIId and within the time period October 1981 to March 1982;
3) no herring fishery for 1981 be allowed in Division IVa and IVb.

This recommendation was accepted by the Commission of the European Communities and was an integral part of their EEC/Norwegian fisheries management agreement. Nevertheless, the enforcement of this recommendation was dependent upon national government actions.
2.1.2 The fishery in 1981

Table 2.1 gives the catch data from 1972. For 1981 the table is compiled from official reports to ICES.

Despite the ACFM recommendation directed fisheries took place in areas outside Division IVc and Division VIId both on adult and juvenile fish. Table 2.2 gives the catches by Sub-divisions for direoted catches, while Tables 2.3.1-2.3.4 show the catches reported as by-catch of both adult and juvenile herring. The data presented in these tables are summarized below:

| Year | Reported catches |  |  | Reported <br> by-catches 2) |
| :---: | :---: | :---: | :---: | :---: |
|  | Herring | Sprat | Herring juveniles |  |
|  |  |  |  |  |
| 1975 | 312.8 | 651.6 | 90.7 | 12.0 |
| 1976 | 176.6 | 609.7 |  | 9.5 |
| 1977 | 45.6 | 311.1 |  | 7.8 |
| 1979 | 7.8 | 401.7 |  | 15.3 |
| 1980 | 7.7 | 396.4 |  | 7.3 |
| 1981 | 15.9 | 407.6 |  | $14.4^{1)}$ |
|  |  | $\left.318.0^{1}\right)$ |  |  |

1) Preliminary
2) Further updated estimates from C.M.1981/H:8 and C.M.1982/Assess: 6

From information provided by Working Group members and an attempt at estimating the total quantity of 0 and 1 group fish caught in Division IVb, the total North Sea catch has been estimated to be not less than 95000 tonnes, of which about 43000 tonnes do not appear in the official statistics.

The Working Group confirms, once more, its great concern regarding the efficiency of the monitoring of landings and the reporting of them. The present situation was unanimously found unacceptable.

Management bodies must be aware that if a drastic improvement of catch and biological data is not immediately undertaken by countries, no assessment can be made for North Sea herring next year.

### 2.1.3 Catch in number

Table 2.4 gives the updated catch in number by age for 1980 , and those Divisions of the North Sea for which adequate data on age composition and catch are available in 1981. The l0-year summary is given in Table 2.5.

No data are included in Table 2.4 for the industrial catches in Division IVb in 1981. Most of this catch is derived from sprat fisheries of which the following percentages represent that part of the total taken in Division IVb:

|  | $\frac{1975}{94}$ | $\frac{1976}{92}$ | $\frac{1977}{83}$ | $\frac{1978}{94}$ | $\frac{1979}{96}$ | $\frac{1980}{92}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |

Sampling for by-catch presented considerable logistic difficulties. It may be questioned, how realistic are the reported figures in view of the continued high level of sprat catch and the area and timing of the fishery. It might be supposed that subject to unrestricted fishing of sprat, the quantity of herring would be taken simply in proportion to the size of the year class available.

Considering the results of the recent IYFSs and without any information about a drastic reduction in effort, the reported bycatch which in 1981 went to the fishmeal plants would appear to be a serious underestimate. The Working Group therefore decided to make an estimate based upon the historic relation between IYFS and the recorded catches. The following text table gives the abundance index from the IYFS with the corresponding estimates of the catches in number of each year class as 0-and l-ringers for Division IVb.

IYFS abundance indices and number of 0 -and l-ringed herring caught in Division IVb

| IYFS Index |  | Catch in millions |  |
| :---: | :---: | :---: | :---: |
| Year <br> class | No./hour | 0 -ringers | l-ringers |
|  |  | $y^{\prime}$ | $y^{\prime \prime}$ |
| 1968 | 822 | 112.0 | 1118.7 |
| 1969 | 2647 | 898.1 | 3440.9 |
| 1970 | 1629 | 533.0 | 2896.6 |
| 1971 | 827 | 750.4 | 2070.5 |
| 1972 | 1195 | 289.4 | 493.5 |
| 1973 | 1529 | 925.1 | 1818.1 |
| 1974 | 452 | 262.8 | 49.5 |
| 1975 | 342 | 273.3 | 136.3 |
| 1976 | 575 | 253.8 | 168.0 |
| 1977 | 139 | 138.0 | 156.4 |
| 1978 | 535 | 542.0 | 137.3 |
| 1979 | 551 | 624.9 |  |
| 1980 | I 314 |  |  |
| Parameters of functional regression |  | $x / y^{1}$ | $x / y^{\prime \prime}$ |
|  |  | 488.05 | -505.25 |
|  |  | v 0.4044 | 1.6876 |
|  |  | त 0.66 | 0.88 |
|  |  | $\overline{\text { x }} 936.92$ | 972.0 |
|  |  | 4466.90 | 1135.07 |
|  |  | th 12 | 11 |

Projected catches from regression:

|  | Age (rings): |  |
| :---: | :---: | ---: |
| 1980 | $\frac{0}{619.4}$ | $\frac{1}{424.6}$ |
| 1981 | $?$ | 1712.3 |

The functional regressions of catch in IYFS indices are shown in Figure 2.1. The correlation coefficient is less good for the 0-group regression, but it should be noted that the Working Group commented in 1981 that the $0-g r o u p$ estimates, particularly for earlier years, were believed to be underestimates, which might lead to increased variances. It also pointed to an increase in catch of this age group
by a factor of 6 times between 1978 and 1980. Using these regressions, projected catches have been made of the total catches of 0- and l-group in 1981. These are far in excess of the values reported.
2.2 Age Composition in 1981

The data given in Table 2.4 are basically derived from the following sampling by sub-divisions, but, in addition, some age compositions from commercial sampling by Denmark, Norway and the Netherlands have been included.

## Percentage age composition per area

| $\begin{aligned} & \text { Age } \\ & \text { group } \\ & (\text { w.r. }) \end{aligned}$ | Year <br> class | IVa W Echo surveys |  | IVb Adult | IVc and VIId |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Moray Firth Aug. | Shetlands area <br> Jul. + Aug. | August ${ }^{\text {1) }}$ | November ${ }^{\text {l }}$ | 1)2) |
| 1 | 1979 | 1.0 | 0.23 |  | 0.63 | 12.7 |
| 2 | 1978 | 79.2 | 1.30 | 33.4 | 85.06 | 61.3 |
| 3 | 1977 | 10.4 | 6.60 | 17.2 | 9.62 | 13.6 |
| 4 | 1976 | 6.3 | 30.60 | 13.8 | 3.13 | 6.2 |
| 5 | 1975 | 1.7 | 12.80 | 14.0 | 1.45 | 4.9 |
| 6 | 1974 | 0.3 | 10.70 | 17.4 | 0.06 | 1.1 |
| 7 | 1973 | 1.0 | 35.97 | 0.6 | $0.05{ }^{\text {3r3 }}$ | $0.3{ }^{\text {3x }}$ |
| 8 | 1972 |  | 1.70 | 2.0 |  |  |
| 8+ | 1972 |  |  | 1.6 |  |  |
| No. of fish |  | $168^{35}$ | $770^{36}$ | 338 | 3803 | 1461 |

1) Research ship sampling
2) Landing sampling
¥ Otolith number
अ喽 Age group 7+ (w.r.)

In Sub-division IVa $W$ (of $2^{\circ} E$ ) the coordinated acoustic survey carried out on herring in the Shetland area provided age composition from an intensive sampling. In this area, the 1973 and 1976 year classes remain predominant with respectively $35.6 \%$ and $30.6 \%$. Since the beginning of this survey in 1979, the sampling has revealed the deficiency of the recruiting year class in that area. Nevertheless, the sampling during the Moray Firth acoustic survey was dominated by 2-ring fish (year class 1979) which, being at stage 4 in August, are expected to recruit in the northern North Sea.
In the central North Sea the sampling made in August during another acoustic survey on spawning concentration indicates a higher proportion of recruiting fish ( $33.4 \%$ ) but shows an almost equal representation of the year classes 1974-77.

In the southern North Sea and Eastern Channel samples taken during acoustic surveys and from landings of commercial catches indicate the very high representation of the 1978 year class which recruited to the Downs stock in 1981. The slightly different age structure found in sampling commercial catches in December in the Eastern Channel was
already found during the acoustic survey in November on North-Hinder (southeast of Division IVc). This tends to confirm the arrival of pre-spawners to the Channel spawning grounds in several successive waves.

In order to make some assessment of the likely age structure in the 1981 catch, some estimate of the juvenile herring catch needs to be derived. Data by age groups are available only for the first half of the year.

Assuming the predicted catches from the regression to be valid estimates and knowing the percentage age composition of the second half year in the industrial by-catch, estimates of the total industrial by-catch can be calculated. The age composition of the industrial catch in the second half year expressed relative to the l-group abundance is as follows:

| Winter rings | 1 | 2 | 3 | 4 |
| :--- | :---: | :---: | :---: | :---: |
| Relative abundance | 1.00 | .100 | 0.024 | 0.004 |

As 0-group are not sufficiently well sampled, the calculated value will be taken as the best estimate of catch. This will give the following projected age compositions for 1981 (in millions):

| Age | IVa W | IVa E | IVb |  |  | IVc/VIId | Total |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | Adult | Juvenile |  |  |  |
|  |  |  |  | Jan-Jun | Jul-Dec |  |  |
| 0 |  |  |  |  | $619.4{ }^{\text {1) }}$ |  | 619.4 |
| 1 |  | 0.1 |  | $144.7{ }^{\text {I }}$ | 279.91) | 6.7 | 619.4 431.4 |
| 2 | 7.7 | 0.1 | 0.8 | 11.9 | 28.0 | 210.4 | 258.9 |
| 3 | 6.2 | 0.1 | 0.4 | 0.6 | 6.7 | 38.5 | 52.5 |
| 4 | 23.4 | + | 0.3 |  | 1.1 | 18.6 | 43.4 |
| 5 | 16.6 | $+$ | 0.3 |  |  | 6.7 | 23.6 |
| 6 | 11.1 | + | 0.4 |  |  | 2.8 | 14.3 |
| 7 | 15.2 | + | + |  |  | 0.5 | 15.7 |
| 8 | 3.4 |  | + |  |  |  | 3.4 |
| $>8$ | 1.1 |  | $+$ |  |  |  | 1.1 |

1) From regression estimates

Applying the standard weight at age this would suggest the 1981 catch to be of the order of 95000 tonnes compared with the present reported level of 23000 tonnes. The Working Group has used this estimate for assessment, and it believes that in the absence of the proper reportir. of data it is a more realistic figure, but perhaps still below the real one.

Numbers of herring caught by age and area, which are given in Tables 2.4 and 2.5 , are summarized in the text table below for the past five years with the revised figures for 1980 and those derived above for 1981:

| Year | 0 | 1 | 2 | 3 | 4 | 5 and older | Total |
| :---: | :---: | :---: | ---: | ---: | ---: | ---: | ---: |
| 1977 | 257 | 144 | 45 | 186 | 11 | 13 | 656 |
| 1978 | 130 | 169 | 5 | 6 | 5 | 1 | 316 |
| 1979 | 542 | 159 | 34 | 10 | 10 | 4 | 759 |
| 1980 | 792 | 161 | 108 | 92 | 32 | 26 | 11 |
| 1981 | 619 | 431 | 259 | 52 | 43 | 58 | 162 |

### 2.3 Recruitment

2.3.1 Results of IKMT sampling during International Young Fish Surveys

Now that 6 years of data have been collected from this programme, it is useful to compare the results for the various years and see, whether any conclusions can be drawn as regards recruitment to the North Sea populations. It should be noted that the herring larvae born in the southern North Sea and English Channel are probably not represented in any significant numbers in the IKMT-catches in February. These larvae do not show up in Dutch and English coastal waters until April, when they have reached a length of approximately 30 mm . In February, therefore, most of these larvae are probably not yet available to the IKMT.

Figure 2.2 shows the distribution of larvae in each of the years 1977-82. The picture is very different for the first three years of the programme and the last three years. During the surveys in 1977-79, hardly any larvae were found in the central and southern North Sea, and very few in the Skagerrak. The only significant catches of larvae were taken off the Scottish coast and in the northern North Sea.

Starting from 1980, the situation changed drastically, with major concentrations of larvae appearing in the central North Sea, particularly on the eastern side, and also in the Skagerrak.

Although the general abundance of larvae was high in all the years 1980-82, the actual distribution pattern was rather different. In 1980, the major concentration occurred off the Jutland coast and in the entrance of the Skagerrak. For 1981, the general direction of the larval drift must have been the same, but now the larvae had proceeded further east than in previous years. It is likely that the larval concentrations found in Skagerrak/Kattegat and in the German Bight originated from the same wave of larvae, coming from the direction of Shetland/Orkney, which had already been split into two components. In the most recent year (1982), the main concentration of larvae was found further to the south in the central North Sea. Either this concentration contains Shetland/Orkney larvae that have followed a more southerly course than during the previous 2 years, or this concentration is mainly derived from spawning grounds in the central North Sea.
2.3.2 Possible underestimates of Downs recruits during the IYFS

It should be borne in mind that the regression presently used to predict year class strength from IYFS abundance was based on the years 1958-59 and 1968-74, in which Downs herring constituted a very small proportion of total North Sea recruitment. It is quite possible, therefore, that this regression has not given accurate predictions in recent years, when a large proportion of the overall North Sea recruitment consisted of Downs recruits.

Downs recruits are born later in the year than all other recruits in the North Sea, and they stay in inshore waters for a relatively long period. It is likely that not all l-ringers belonging to the Downs stock have already migrated towards the open sea in February, in which case the IYFS only samples part of the year class.

### 2.3.3 Year class 1978

In the previous report of the Working Group, the strength of the 1978 year class as l-ringers was estimated at $1.45 \times 109$, which is $21 \%$ of an average year class during the period 1951-70.
From the data on catches per age group (Section 2.2) it appears that year class 1978 has recruited predominantly to the Downs stock in 1981. This confirms the expectations expressed in last year's report of the Working Group (Section 2.3.2).

As mentioned in the section above, there is a possibility that the year class was underestimated during the IYFS because it consisted mainly of Downs recruits.

### 2.3.4 Year class 1979

The final abundance index for this year class from the 1981 International Young Fish Survey was 551 fish per hour. At the previous meeting of the Working Group, a provisional abundance index of 504 fish/hour was used for this year class.

Substituting the final figure for year class 1979 into the usual formula

$$
Y=0.0031 x-0.21
$$

results in a year class strength of $1.50 \times 10^{9}$ instead of $1.35 \mathrm{x} 10^{9}$ as used previously. This new figure is $21 \%$ of the mean for year classes born in the period 1951-70. The conclusion from last year's report, that year class 1979 is of the same magnitude as its predecessor remains unaltered.

There are some indications as to what sub-populations year class 1979 will predominantly recruit to. In last year's report (Section 2.3.5) it was mentioned that during the 1981 IYFS a high percentage of opaque nucleii was found among year class 1979, suggesting that it contained a high proportion of Downs recruits. Results of the Dutch monitoring programme on pre-metamorphosis larvae in the Wadden Sea pointed in the same direction (Table 2.6).
Further evidence for a substantial proportion of Downs recruits among year class 1979 is provided by the age composition of Dutch commercial catches in the southern North Sea in early 1982. These catches show a high percentage of 2 -ringers, most of which are assumed to be Downs recruits because of their southerly distribution, and a high percentage of opaque nucleii.

Percentage age composition - Dutch pair-trawl catches in the Southern Bight in early 1982

| Month | Year class |  |  |  |  |  | Total |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 1980 | 1979 | 1978 | 1977 | 1976 | $1975+$ |  |
| catch (tonnes) |  |  |  |  |  |  |  |
| Jan. | 0.0 | 34.4 | 57.7 | 6.1 | 1.5 | 0.3 | 4700 |
| Feb. | 5.3 | 49.0 | 38.0 | 5.7 | 1.6 | 0.4 | 1500 |

In last year's report (Section 2.3.3) it is also stated that during the 1981 IYFS many l-group herring were taken in the western part of the North Sea. No conclusions were drawn from this observation, but it is likely that these westerly distributed herring contain a certain proportion of Division VIa or IVa recruits.

Attention is also drawn to the results of the IKMT sampling in 1980 (Figure 2.2), which for the first time showed a significant survival of herring larvae born in the northern parts of the North Sea or Division VIa. This would also suggest that year class 1979 might contain a larger proportion of recruits to these northern populations than the three preceding year classes.

### 2.3.5 Year class 1980

From the IYFS in February 1982, a preliminary abundance index of 1314 fish/hour was obtained for the herring standard area. This indicates the first appearance of a reasonably good year class in the North Sea since 1973.
Applying the regression formula

$$
Y=0.0031 x-0.21
$$

the strength of the year class as l-ringer is estimated at $3.86 \times 10^{9}$. This figure is $55 \%$ of the mean for year classes born in the period 1951-70.

| Year <br> class | Abundance index IYFS | Year class strength as 1-ringers (x $10^{-9}$ ) estimated from VPA | Year class strength as 1 -ringers $\left(x 10^{-9}\right)$ predicted from regression formula |
| :---: | :---: | :---: | :---: |
| 1968 | 822 | 3.35 |  |
| 1969 | 2647 | 7.35 |  |
| 1970 | 1629 | 5.79 |  |
| 1971 | 827 | 3.82 |  |
| 1972 | 1195 | 1.75 |  |
| 1973 | 1592 | 4.39 |  |
| 1974 | 452 | 0.73 |  |
| 1975 | 342 | -- | 0.85 |
| 1976 | 575 | - | 1.57 |
| 1977 | 139 | - | $0.43{ }^{\text {\% }}$ |
| 1978 | 535 | - | 1.45 |
| 1979 | 551 | - | 1.50 |
| 1980 | 1314 | - | 3.86 |

抔) Ignoring constant in regression formula

The distribution of l-ringers during the 1982 IYFS is shown in Figure 2.3. In contrast to the preceding year, the main concentrations were found in the German Bight, particularly in the coastal waters. The fish in these areas had a mean length between $11.0-14.5 \mathrm{~cm}$, which is extraordinarily low. Recent experience with year class 1978 confirmed that a low mean length of l-group herring during the IYFS indicates a high proportion of Downs recruits. A great majority of the small herring had opaque nucleii, which is also characteristic for Downs recruits.

Further indications of a good recruitment to the Downs stock of the 1980 year class were obtained from the Dutch sampling programme of pre-metamorphosis larvae in the Wadden Sea. As shown in Table 2.6 catches of Downs larvae in April 1981 were the highest ever observed since the beginning of this programme in 1967.
Also the English O-group surveys in July (Table 2.6) indicate a relatively high recruitment of year class 1980 to the Downs stock, although the year class in these surveys is not as outstanding as in the Dutch data.

Apart from an important Downs component, the year class could also contain a significant proportion of recruits to the northern North Sea population. IKMT-data for February 1981 show that larvae from presumably the northwestern spawning areas had penetrated in high numbers far into Division IIIa and the German Bight.

### 2.3.6 Year class 1981

For this year class, the only information available yet was derived from the IKMT-sampling during the 1982 IYFS (Figure 2.2). These data still cannot be used for quantitative predictions, but they do show again a high abundance of larvae, this time especially in the central North Sea.

### 2.4 Acoustic Surveys

2.4.1 The 1981 acoustic survey in the Orkney/Shetland area

A report on the ICES coordinated survey in the Orkney/Shetland area was submitted to the 1981 Statutory Meeting (Doc. C.M.1981/H:50), and an evaluation of it was carried out at a meeting of the Acoustic Survey Planning Group held in Aberdeen, United Kingdom, from 2-5 March 1982。

To convert echointegration values to biomass, a new relationship between target strength per kg and length of fish was used, and the values of target strength for each $2-c m$ length group are given in the text table below:

| Length $(\mathrm{cm})$ | Target strength $(\mathrm{dB} / \mathrm{kg})$ |
| :---: | :---: |
|  | -33.3 |
| 21 | -33.8 |
| 23 | -34.2 |
| 25 | -34.6 |
| 27 | -34.9 |
| 29 | -35.3 |
| 31 | -35.6 |
| 33 | -35.9 |
| 35 | -36.2 |

Using this new relationship between target strength per kg and length of fish, four estimates of herring biomass were made in 1981, as given in the text table below:

| Ship | Dates | No. of quarter stat. <br> rectangles surveyed | Estimated herring <br> biomass (tonnes) |
| :--- | :--- | :--- | :--- |
| "G 0 Sars" | 15-20 July | 62 | 110000 |
| "G0 Sars" | 26-28 July | 21 | 74000 |
| "Tridens" | $27 \mathrm{Jul}-7 \mathrm{Aug}$ | 28 | 69000 |
| "Scotia" | 12-31 August | 65 | 118000 |

Whereas on the first three surveys herring echotraces identifyed by trawl were distinguishable from other traces, in August the proportion of the total biomass contributed by herring was estimated from their proportion in trawl hauls. Since the herring caught in July were mainly mature, and those in August mainly spent, this change in behaviour may have been associated with spawning.

When differences in coverage are taken into account, the estimates of herring biomass in 1981 suggest that the random error in a single estimate is relatively low. The values of target strength used, however, are based on measurements in experimental situations and no allowance is made for the possible reaction of fish to the survey vessel. The biomass estimates are therefore more likely to be too low than too high.
The results of the 1981 survey are compared with those of previous years in Table 2.7. To allow for differences in coverage, the biomass estimates are given for a set of six statistical rectangles in the south Shetland area which has been covered on most surveys, and which contained the major part of the herring population in most cases. The complete surveys of this area in 1980 and 1981 indicate a decrease in biomass between the two years. The estimate of 110000 tonnes in July 1981 does not include a concentration of recruits recorded in the northern part of the Moray Firth in August (an estimated 57000 tonnes). Thus, the best available estimate of spawning biomass in July-August 1981 from acoustic surveys is 167000 tonnes.

The survey carried out in July 1981 by "G 0 Sars" extended into the northern part of Division VIa. During this period, herring were found in the area southwest of Shetland and in the area around North Rona, but there was no evidence of shoals in the intervening area.

The Working Group considered that the absolute estimates of herring biomass provided by these surveys could not at present be substantiated. They also expressed some reservations about the validity of the change in biomass between the two years. The agreement between survey vessels, however, had improved markedly since the survey began, and they therefore agreed that the survey in this area should be continued. Since the validity of the surveys depends on correct methodology, they further agreed that this aspect should be concentrated on, in particular, to determine the variability to be expected in the estimates. For this reason, it was agreed that the effort on the summer survey should be concentrated in the Orkney/Shetland area.
2.4.2 Acoustic biomass estimates from the southern North Sea and Eastern Channel

Acoustic biomass estimates were available from three surveys, which were carried out in Divisions IVc and VII d during winter 1981/82. Few fish of other species were taken in either research vessel sample hauls or catches from the commercial fishery in the areas which were
surveyed, and allocation of biomass to species did not present any problems. Biomass estimates were based on a target strength value of $-34.6 \mathrm{~dB} / \mathrm{kg}$ for 25 cm herring as recommended by the Acoustic Survey Planning Group.
"Thalassa" surveyed five separate small areas from 5-15 November. The herring were at this time approaching spawning and were mainly in maturity stage V. An acoustic biomass estimate of 64000 tonnes was derived from this survey. "Clione" again covered the same general area from 2-15 December but found herring to be very dispersed and mainly newly spent, in maturity stage VII. An acoustic biomass estimate of 53000 tonnes was obtained from this survey.
"Thalassa" and "Clione", from past experience, expected to cover all important areas of herring distribution in the Southern Bight and Eastern Channel. However, subsequent surveys of herring larvae indicated that a substantial part of a very important spawning area in the Eastern Channel had not been covered by either vessel. In addition, "Clione" did not cover a concentration of herring being fished by Dutch pair trawlers near to the Bligh Bank during early December.

An area of diffuse mid-water echo trace in the Southern Bight off the Dutch coast, composed of spent herring with an admixture of immatures, was surveyed at the end of January and beginning of February by "Corella". An acoustic biomass estimate for the adult herring of 144000 tonnes was derived from this survey.

These surveys are the first ones to have been carried out for herring in the Southern Bight and Eastern Channel. They have demonstrated that acoustic surveys can be made of pre-spawning and spawning concentrations in November--December and of spent herring in JanuaryFebruary giving encouraging results. The biomass estimates which were obtained must all be considered as underestimates of the total stock, the November-December estimates for the reasons given above, and the January-February estimate because spent herring would also have been distributed in the Eastern Channel at that time.
Because of the long duration of the spawning season (NovemberJanuary) and the fact that part of the stock migrates through the Southern Bight to spawn in the Eastern Channel, while another part remains and spawns within the Southern Bight, arriving at a total acoustic biomass estimate for the whole of the spawning stock will present considerable difficulties. Perhaps in further years with sufficient ship participation it may be possible to survey each spawning concentration in turn and then sum the biomass estimate obtained from them.

### 2.5 North Sea Herring Larval Surveys

The data available from the larval surveys in 1981/82 were more satisfactory than in previous years in that in all areas the sampling intensity was higher and its distribution over the hatching period resulted in no gap which had to be filled by interpolation except in the southern North Sea. In all areas, the indices of larval abundance were estimated as described in C.M.1981/H:3.

### 2.5.1 Division IVa

Surveys were carried out by the Netherlands and the Federal Republic of Germany in the first half of September, and by Denmark and Scotland in the second half of September. The resulting indices of
larvae less than 10 mm long are: Ist half of September: 4444 , $2 n \bar{d}$ half of September: 238, resulting in a mean of 2341 . This value inserted in the regression equation given by MoKay (1981) of

$$
\hat{Y}=0.0798 X+48.77
$$

where $\hat{Y}$ is the spawning stock biomass in 1000 tonnes units, and $X$ is the larval index $x 10^{-9}$, gives an estimated spawning stock size in 1981 of 235000 tonnes compared with an estimate of 214000 tonnes in 1980. In the light of the confidence limits on estimates from this technique, this in effect means that there has been no significant change in the size of the spawning stock in this area since 1978. This is supported by the age composition of both research vessel and commercial catches, which would suggest that recruitment to this stock has been low in recent years.
In the text table below the larval indices and the resulting estimates of spawning stock biomasses are given for 1978-81.

|  | $\underline{1978}$ | $\underline{1979}$ | $\underline{1980}$ | $\underline{1981}$ |
| :--- | ---: | ---: | ---: | ---: |
| Larval index | 3345 | 3325 | 2074 | 2341 |
| Spawning stock <br> biomass (tonnes) | 316000 | 314000 | 214000 | 236000 |

### 2.5.2 Division IVb

One survey was carried out by scotland in the Buchan area resulting in an index of larvae less than 10 mm of $9 \times 10^{9}$. In the central North Sea two surveys by the Netherlands in September gave estimates of $989 \times 10^{9}$ in the first half of September and $324 \times 10^{9}$ in the second half of September. A survey in early October by England gave an estimate of $27 \times 10^{9}$ (after correcting for efficiency), and one by Norway in the second half of October a value of 0 giving a mean, as calculated in Anon. (1981) for use in the regression of $344 \times 109$ larvae.
In a background document to this meeting of the Working Group, the historic spawning stocks in Division IVb were recalculated. This resulted in very small changes in the values used in Anon. (1981), but the regression equation has been re-estimated. The new form is

$$
\hat{Y}=10.179 X+8.698
$$

where $\hat{Y}$ is the spawning stock biomass in 1000 tonnes units, and $X$ is the larval index $\times 10^{-11}$. This results in an estimate of spawning stock size in 1981 of 43000 tonnes.

The larval indices and resulting spawning stock biomass in this Division for the years 1978-81 are given in the text table below.

|  | $\underline{1978}$ | $\underline{1979}$ | $\underline{1980}$ | $\underline{1981}$ |
| :--- | :---: | :---: | :---: | ---: |
| Larval index | 2.23 | 2.26 | 0.59 | 3.44 |
| Spawning stock <br> biomass | 31000 | 32000 | 15000 | 43000 |

These values suggest that the spawning stock in this Division had increased quite dramatically between 1980 and 1981, but as pointed out in last year's report the 1980 estimate was of a somewhat
dubious accuracy because of gaps in the sampling in that year which had to be filled by interpolation. It now seems most likely that the spawning stock was at a fairly stable level from 1978-80 but has increased slightly in 1981. This would be supported by some evidence from research vessel sampling, which suggests that this stock may have had rather better recruitment in 1981.

### 2.5.3 Divisions IVc and VIId

Surveys were carried out by England, France, the Federal Republic of Germany and the Netherlands. The mean estimates of abundance of all size groups of larvae were $2722 \times 109$ in December, and $380 \times 109$ in January, giving an overall mean of 1531.0 x 109.
A revision of the data input for the VPA for the Downs stock, carried out by the Working Group on Herring Larval Surveys South of $62^{\circ} \mathrm{N}$, uncovered a major error in the input catch in number data for one age group in one year. This resulted in quite major discrepancies on the estimated spawning stock estimates and, therefore, in the parameter. of the regression equation between spawning stock and larval abundance. The Working Group made a new VPA for the Downs stock, starting from the year 1981, which is described in para.2.7.1.3. From this, new estimates of spawning stock biomass were made, and a new regression calculated for the spawning seasons $1958 / 59$ to $1978 / 79$. The equation is

$$
\hat{Y}=0.282 X+8.590
$$

where $\hat{Y}$ is the spawning stock biomass in tonnes $x 10^{-3}$, and $X$ is larval index $x$ 10-9. This regression is significant at the $5 \%$ level.
Little reliance can be placed on an estimate of spawning stock in 1981-82 from this source. The larval index for 1981m82 is higher, by a factor of over 10 , than the largest index used in calculating the regression equation. Under these circumstances, the assumption that the same relationship holds is entirely unlikely.
In the text table below the larval indices for the seasons 78/79 to $1981 / 82$ are given as well as the corresponding estimated spawning stock sizes for the years when these estimates have some reliability.

|  | $\frac{1978 / 79}{16.4}$ | $\frac{1979 / 80}{147.3}$ | $\frac{1980 / 81}{363.7}$ | $\frac{1981 / 82}{1531.0}$ |
| :--- | :---: | :---: | :---: | :---: |
| Larval index <br> Spawning stock <br> biomass | 13200 | 50000 | 111000 | - |

### 2.6 Effects of By-Catches of Herring

2.6.1 VPA on the total North Sea herring stock

Since it is several years ago since a VPA has been run on the total North Sea herring catches, and since such a VPA would be useful for studying the effects of by-catches on the North Sea herring stock, a VPA was run, using the total North Sea catches for the years 1955-81. The Working Group had serious doubts about the validity of the estimated 1981 catches. It was therefore decided to use an input procedure for the last year, that would not use the catch in 1981.

The input Fs for the last year were based on the following asumptions:

1) Spawning stock 1/9-81

Spawning stock 1/9-81 Spawning stock 1/9-81 Divs. IVc and VIId 250000 tonnes
2) No catches of adult herring in 1981 were taken before 1 September. This assumption might be questioned for Division IVb , while it is considered realistic for the other areas.

Using the available age composition of the spawning stock, the spawning stock in numbers in each area were scaled to the assumed biomass. The weightsat age are taken as the values of C.M.1978/H:2.
Using $2 / 3$ of natural mortality, the spawning stock in numbers were backtraced to the 1 of January 1981. The number of 0-group as at $1 / 1-1981$ was chosen to give $3.86 \times 10^{-9}$ as l-group is at 1/I-1982, this being the IYFS estimate in February 1982. The number of l-group was chosen as $1.35 \times 10^{-9}$, this being the IYFS estimate. Using the above method, the stock as at l/l-1981 was:

| W.r. | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | $8+$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| No. <br> $\mathrm{x} 10^{-9}$ | 4.80 | 1.35 | 1.53 | 0.31 | 0.39 | 0.28 | 0.27 | 0.29 | 0.07 | 0.03 |

The Fs for 1981 were chosen to produce the stock shown in the text table. The output from the VPA is found in Tables 2.8-2.11.

### 2.6.2 Effects of the by-catch of 0-group and l-group

In order to illustrate the effects of the fishery of $0-g r o u p$ and l-group on the spawning stock size, the spawning stock sizes in the years 1977-81 were calculated, using different assumptions on the fishing mortality on juvenile herring. The estimated stock in numbers as at $1 / 1-1977$ (VPA, Table 2.10) was used as a basis for the prediction. The recruitment in the years 1978-81 was selected as estimated from the VPA. Using a fishing pattern of constant mortality on 0 - and l-group and zero mortality on older fish, a prediction was run:

| W.r | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | $8+$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Stock <br> in no. <br> $\mathrm{x} \mathrm{10-9}$ | 1.18 | 0.62 | 0.48 | 0.63 | 0.12 | 0.01 | 0.02 | 0.01 | - | - |
| Fishing <br> pattern | $F_{0}$ | $F_{1}$ | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |

|  | 0 | 0.1 | 0.2 | 0.3 |
| :--- | :--- | :--- | :--- | :--- |
| Years |  |  |  |  |
| 1977 | 194 | 194 | 194 | 194 |
| 1978 | 285 | 279 | 273 | 268 |
| 1979 | 427 | 396 | 372 | 352 |
| 1981 | 847 | 496 | 453 | 418 |
|  |  | 725 | 639 | 568 |

It is likely that the by-catches have affected the recruitment to Divisions IVb and IVa to a higher extent than to Divisions IVc-VIId. The mean $F$ on 0 - and 1 -group for the years 1977-81 has been estimated to about 0.25. However, this estimate, or any other estimates from the VPA, do not take into account catches of North Sea herring taken in other areas.
2.7 State of Stocks and Management Considerations
2.7.1 Divisions IVc and VIId Stocks (Downs)
2.7.1.1 The fishery in Divisions IVc_and VIId

Over the post-war period catches reached an exceptionally high level of about 280000 tonnes in 1954, when bottom trawling was carried out extensively on the spawning grounds. This record was followed by a very sharp decrease to about 11000 tonnes in the years 1966-68. The catches during the period 1969-76 averaged 22400 tonnes (Figure 2.4).
After a ban on a directed herring fishery had been set in Sub-area IV and Division VIId from 1977, catches fell to a negligible level in Divisions IVc-VIId in 1977 and 1978 when this ban was effectively enforced. But in 1979 and even more in 1980 substantial illegal fisheries directed to herring occurred and reached in 1980 about 45000 tonnes, of which the major part was taken in the Eastern Channel.

Fishing was carried out chiefly in November and December on the main spawning and pre-spawning concentrations.
In both the 1980/81 and 1981/82 seasons fishing took place on spent herring in January-March. Such a fishery was almost non-existent over the last decade when the stock was at its lowest level.

The overall catch in 1981 amounted to about 40500 tonnes
(including estimate of discarded or dumped fish).

### 2.7.1.2 Catch in number <br> The Downs stock is defined as spawning in the southern North Sea and Eastern Channel (ICES Divisions IVc and VIId). However, Wood (1958) and Burd (1962) have pointed out that Downs spawners are also taken in appreciable quantities in Division IVb, particularly prior to the Division IVb spawning season.

Central North Sea and Downs components in Division IVb catches can be distinguished by differences in fat content, $l_{1}$, and mainly by maturity stages. Downs components have been identified as being predominantly less mature than stage IV in the period July-September. Such an analysis, which has been carried out for the years prior to 1977, shows that the percentage of Downs component can vary rather widely from year to year, depending on the period during which the main fishery is exerted.
These results for the years $1971-76$ are given in the text table below.

| Year | 1971 | 1972 | 1973 | 1974 | 1975 | $\frac{1976}{0.18}$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Proportion | 0.18 | 0.12 | 0.55 | 0.31 | 0.12 | 0.23 |

For the most recent years, where no adequate data were available, a mean of $25 \%$ was applied to the Division IVb adult catches in number and transferred to the Divisions IVc and IVd catches. The resulting figures have been used as input catch in number for the VPA carried out for the Downs stock (Table 2.7.1).
2.7.1.3 Estimate of spawning stock size_and fishing_mortality in 1981

As explained in Section 2.5 on estimates of spawning stock biomass from larval surveys, it was possible to estimate the size of the spawning stock at the end of 1981 based on the 1981/82 larval abundance index, since this would require extrapolation far beyond the range of the available observations. Estimates of the spawning stock biomass at the end of 1981 and the corresponding fishing mortality in 1981 have been made as follows:
For the 1978 year class, terminal $F$ was estimated based on its abundance as l-ringers in the IYFS. It was assumed that this year class has recruited entirely to the Downs stock and has been subject to only natural mortality before recruiting to the fishery as 2-ringers in 1981. Its contribution to the spawning stock at the end of 1981 was calculated by applying the catch of 2 -ringers to it. The resulting $F$ on that age group for 1981 was 0.185.
Spawning stock biomass at the end of 1980 (year classes 1977 and older) estimated from the corrected regression of SSB against larval survey indices (see Section 2.5) was 111000 tonnes $\pm 31000$ t. This estimate was considered reliable, since the larval index for that year does not require a too large extrapolation beyond the range of observed data. A VPA with a terminal $F$ of 0.185 and 0.1 for the year classes 1978 and 1977 and older, respectively, resulted in an estimate for the 1980 SSB of 115000 tonnes, which is close to the estimate from the regression. The resulting SSB at the end of 1981 was 244000 tonnes. The underlying assumption that fishing in 1981 was concentrated mainly on the 1978 year class is not unlikely in view of the fact that this year class was the dominating one in the stock.
2.7.1.4 Results of VPA

The results of the VPA are given in Table 2.12 and are summarized in Figure 2.5 .
Fishing mortality fluctuated at a level of about 1.0 up to 1975. After an increase to a level of 2.5 in 1976 it decreased by 1977 and remained at relatively low levels as a result of the ban on directed herring fishery in the North Sea.

The spawning stock biomass at spawning time (i.e., the end of the year) increased slightly from 1968 onwards to a peak in 1972 of about 40000 tonnes, followed by a steady decrease to a level as low as about 3000 tonnes in 1976.
Due to increasing recruitment since 1978, the spawning stock biomass increased rapidly. Although the estimate of the 1981 spawning stock biomass has some uncertainties attached to it, it is quite obvious that the positive development of the spawning stock since 1978 must have resulted from the protection of the Downs herring in the years 1977-79. The quick reaction of the Downs stock to the ban on directed herring fishing compared to the central and northern North Sea may be explained by a lower level of exploitation of juvenile herring of this stock in the mixed fisheries.
2.7.1.5 Projection of catch and spawning_stock size_for_1982

Catohes and the corresponding spawning stock biomass for different levels of fishing mortality in 1982 have been calculated, using the data given in Table 2.12(c).
The estimated age composition of the stock in numbers derived from VPA shows that the 3 - and 4 -ringers are making up a higher proportion of the stock in 1982 compared to the preceding period. Therefore, the exploitation pattern which was applied in the VPA, assuming that fishing had been concentrated on the good year class 1978 in 1981, had to be changed based on the assumption that fishing mortality is about the same on all age groups $\geq 2$ in 1982.
Recruitment at age 2 in 1982 (year class 1979) was derived from the IYFS results. As in last year's assessment, it was assumed as a first approach that $50 \%$ of the recruits are Downs herring and, after applying natural mortality on l-ringers, about $680 \times 10^{6}$ are estimated to recruit to the Downs stock as 2-ringers in 1982.
This approach taken in estimating recruitment has to be seen in the light of qualitative information as discussed in Sections 2.3.4 and 2.3 .5 , indicating that a high proportion of the recruits as estimated from the IYFS for these two year classes might recruit to the Downs stock. It is also possible that the most recent year classes are underestimated in the IYFS. It should also be noted in this context that the assumption made in last year's assessment of the number of recruits of the 1978 year class to the Downs stock ( $50 \%$ of the IYFS estimate for the total North Sea) has to be considered as an underestimate (see Sections 2.3.2 and 2.3.3). These qualitative indications should not be ignored, even if they could not be quantified at present. For these reasons, the Working Group prepared two catch projections under two different assumptions on the recruitment of the 1979 year class to the Downs stock as 2-ringers in 1982.
A. $50 \%$ of the IYFS estimate are Downs herring ( $680 \times 10^{6}$ )
B. Recruits from 1979 year class the same as for the 1978 year class ( $1300 \times 10^{-6}$ ).
Although the 1980 year class in the IYFS appears to be very strong for the total North Sea and might contain a high proportion of Downs recruits (see Section 2.3 .5 ), the Working Group refrained from expanding the projection beyond the end of 1982, since the evaluation of the qualitative information on the proportion of Downs recruits in quantitative terms would contain a too great element of speculation. The detailed results of the catch projection are given in Figure 2.6, and some selected management options in the text table below.
A. Recruitment 1979 year class $=680 \times 10^{6}$

| 1981 |  |  |  | Management option for 1982 | 1982 |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Stock biom. (2+) | $\bar{F}_{(2-9)}$ | Catch | Spawn stockbiom <br>  |  | tock biom. $(2+)$ | $\overline{\mathrm{F}}(2-9)$ | Catch | $\begin{aligned} & \hline \text { Sp. } \\ & \text { stock } \\ & \text { biom. } \\ & (2+)^{\prime} \\ & \hline \end{aligned}$ |
| 311 | . 154 | 40.5 | 243 | $F=.10$ | 396 | . 10 | 36 | 325 |
|  |  |  |  | $F_{82}=F_{81}$ |  | . 15 | 53 | 310 |
|  |  |  |  | $F=.20$ |  | . 20 | 69 | 294 |

B. Recruitment 1979 year class $=1300 \times 10^{6}$

| 1981 |  |  |  | Management option for 1982 | 1982 |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Stock biom. $(2+)$ | $\overline{\mathrm{F}}(2-9)$ | Catch | Spawn stock biomm $(2+)$ |  | $\begin{array}{r} \text { Stook } \\ \text { biome } \\ (2+) \end{array}$ | $\overline{\mathrm{F}}(2-9)$ | Catch | Sp. stock $\begin{array}{r}\text { biom. } \\ (2+) \\ \hline\end{array}$ |

|  |  |  |  | $F_{82}=F_{81}$ |  | . 15 | 63 | 370 |
|  |  |  |  | $\mathrm{F}=.20$ |  | . 20 | 82 | 350 |

Weights in thousand tonnes.
Stock biomass refers to the beginning of the year.
Spawning stock biomass refers to spawning time (end of the year).
2.7.2 Division IVb Stock (Bank)

Age compositions of the spawning stock in the central North Sea are given in the text table below for the period 1977-81. The figures for earlier years are taken from the previous report, and those for 1981 from English sampling of research vessel catches on the spawning grounds at the spawning time.

| Year | 2 | 3 | 4 | 5 | 6 | 7 | $\geq 8$ | Total |
| :--- | :---: | ---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1977 | 72.4 | 19.0 | 0.7 | 5.4 | 2.5 | - | - | 100 |
| 1978 | 15.7 | 52.8 | 17.0 | 2.2 | 5.6 | 6.4 | 0.3 | 100 |
| 1979 | 12.8 | 4.3 | 40.4 | 28.7 | 2.1 | 5.3 | 6.4 | 100 |
| 1980 | 20.9 | 9.7 | 1.4 | 53.2 | 7.2 | 0.6 | 7.0 | 100 |
| 1981 | 33.4 | 17.2 | 13.8 | 14.0 | 17.4 | 0.6 | 3.6 | 100 |
|  |  |  |  |  |  |  |  |  |

It is clear that this stock had received no appreciable increment from recruitment in 1978-80. In 1981, however, the recruit year class was the largest component, and this would suggest that in 1981 recruitment was somewhat better than in any year since 1977.

The only other source of data on the stock in this area is that derived from the herring larval surveys given in Section 2.5 . The relevant text table from that is reproduced below:

|  | $\underline{1978}$ | 1979 | $\underline{1980}$ | 1981 |
| :--- | :---: | :---: | :---: | :---: |
| Larval index <br> Estimate <br> spawning stock <br> (tonnes) | 2.23 | 2.26 | 0.59 | 3.44 |

\% Inadequate sampling

The data from the 1980 larval survey, as commented in Section 2.5, are not very reliable, and the estimate of spawning stock in that year given above might well be seriously underestimated. If that were so, the data given in the text table would be in some conformity with those given on stock composition in suggesting a rather stable spawning stock from 1978-80 but some small increment in it in 1981.
2.7.3 Division IVa stock

The age composition of the stock in Division IVa, derived from sampling during research vessel surveys in this area, are given in the text table below, together with the age compositions of landings from this area in 1977:

- 21 -

| Wear | 1 | 2 | 3 | 4 | 5 | 6 | 7 | $\geq_{8}$ | Total |
| :--- | ---: | ---: | ---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1977 | 1.4 | 4.7 | 86.2 | 4.3 | 1.9 | 1.0 | 0.4 | 0.1 | 100 |
| 1978 | - | 42.6 | 21.8 | 30.9 | 1.6 | 1.9 | 1.0 | 0.3 | 100 |
| 1979 | 27.4 | 16.6 | 7.9 | 28.7 | 18.6 | 0.6 | 0.2 | - | 100 |
| 1980 | - | 15.9 | 41.5 | 14.3 | 10.2 | 15.2 | 1.7 | 1.2 | 100 |
| 1981 | 0.2 | 1.4 | 6.6 | 30.6 | 12.8 | 10.7 | 36.0 | 1.7 | 100 |

The age composition data from the acoustic survey in the Orkney/Shetiand area are in very close agreement with those of illegal commercial landings from this area in 1981. Sampling by one of the survey vessels in the northern Moray Firth in 1981, however, would suggest that there may have been some addition of recruit spawners to the stock in that area. But the overall conclusion from these data is that over the period 1978-81 the increment to the spawning stock from recruitment has been very small. This conclusion is supported by the larval data, taken from Section 2.5, given in the text table below:

| Larval index | $\frac{1978}{3345}$ | $\frac{1979}{3325}$ | $\frac{1980}{2074}$ | $\frac{1981}{2341}$ |
| :--- | :---: | :---: | :---: | :---: |
| Spawning <br> stock (tonnes) | 316000 | 314000 | 214000 | 236000 |

There would indeed appear from the larval indices to have been a drop in larval abundance and in spawning stock in the most recent two years, but, bearing in mind the confidence limits on these estimates, it would seem more likely that the situation is one of stability. Acoustic surveys carried out in Division IVa in these years would also tend to suggest that there has been no major changes in the stock size.

### 2.7.4 Management considerations

It is clear from last year's report of the Herring Assessment Working Group for the Area South of $62^{\circ} \mathrm{N}$, and from assessments carried out by this Working Group in 1982, that the reactions of the populations in the different sub-divisions of the North Sea to management regulations have been very different. The population spawning in Divisions IVc and VIId has shown a very marked recovery, in Divisions IVb and IVa the recovery to date has been very small. It is quite clear that the differences in the rates of recovery between the Divisions IVc and VIId populations, and those in the remaining Sub-divisions of Sub-area IV have arisen from the very different levels of recruitment to them in the last two years. The reasons for this difference in recruitment are not yet completely explicable, but it is suggested elsewhere in this report, that the explanation may lie in the differences in their distribution as juveniles, and the concomitant differences in the exploitation to which they are subject during this stage of their life cycle.

Irrespective of the reasons for these differences, however, the fact remains that the populations in Divisions IVc and VIId have recovered very rapidly, whilst those in Divisions IVa and IVb have shown little change. At its meeting in 1981, the Working Group
accepted this difference and advised a re-opening of the fishery in Divisions IVc and VIId on a limited TAC, to be taken in these divisions where the catches would be solely from the population spawning there.
The results of the new data available, and of the analysis of them, carried out during the 1982 meeting, suggest little change in this situation. The population spawning in Divisions IVc and VIId has been increased even further by good recruitment, whilst the population spawning in Division IVb may have increased, but only marginally, in 1981, and that in Division IVa has remained stable over the last four years. The data available on recruitment to these populations would suggest little change in this situation in 1982 and 1983. They would suggest that the spawning population in Divisions IVc and VIId will gain a further large recruitment in that year, whilst those in Divisions IVa and IVb can expect only very small increments.
In the light of these new data there is no doubt that the populations spawning in Divisions IVc and VIId could continue to be exploited in 1982 and 1983, whilst the exploitation of those spawning in Division IVa and IVb should, on purely biological considerations, continue to be prohibited. Such a policy is likely to result in a TAC of the order of $60000-80000$ tonnes, to be taken solely in Divisions IVc and VIId in the period 1 October 1982 - 28 February 1983, as it is only in that area, and during that time period, that one can be sure of catching only the Downs population. This may not be the most effective way of utilizing the resource, and, on this basis, consideration should be given to what is known of the distribution of the populations during other periods.

As stated in an earlier section, there is good evidence that the Downs stock, during late spring and summer, are distributed in the central North Sea and, to some extent, also in the southern fringe of Division IVa. In this situation, the Downs stock could be fished in early summer in Division IVb, and in the light of the evidence that the Downs population is about 5-8 times larger than the Division IVb one would be expected to constitute a major component of the catches. The relative proportions of the populations in the catches are, however, not relevant to management considerations - the important factor is the fishing mortality which these catches will cause in the two populations. This cannot be quantified, but the best assumption might be that any catch taken in Division IVb, during early summer, would generate the same mortality rates on the central North Sea and Downs populations. The effects of this fishing mortality rate on the prospects of recovery of the central North Sea population must be the prime consideration in deciding what proportion, if any, of the TAC for the Downs stock in 1982 should be taken in Division IVb. In the light of the current situation in respect of management and enforcement, consideration should also be given to the prospects of any proportion of the TAC for the Downs stock, allocated to Division IVb , being effectively enforced. The evidence for the Downs population being distributed in Division IVa is less firm, but it certainly appears that this population has never penetrated far into this Division.
3. DIVISION IIIa HERRING
3.1 Stock Composition

In Division IIIa three different stocks were identified in 1981: the Kattegat spring spawners (including Danish coastal spawners (VS: 55.8-56.4)), the Skagerrak spring spawners (VS: 56.6-57.3), and the North Sea autumn spawners (VS: 56.3-56.6). In addition,
herring from the western Baltic mix with these stocks. Baltic herring (VS: 55.5-56.2) can at present not be separated from Kattegat spring spawned herring and their proportion in the catches is therefore unknown. North Sea autumn spawned herring occur in Division IIIa predominantly as 0 - and l-group herring.

In the commercial Swedish samples from 1981, herring with meristic charaoteristics of the Kattegat spring spawners (VS $\approx 56.0$ )
dominated among the 2 -group and older herring. In July and August, herring with these characteristics migrated from the North Sea into the Skagerrak and made up the predominant part in samples from purseseine and pelagic trawl catches in the western Skagerrak during that time。

Separation of 0 - and l-group herring into spring and autumn spawned fish can be made from fish length and otolith length measurements (C.M.1981/H:28), and the identity after such a separation should preferably be checked by the means of VS. A series of length frequency diagrams of $0-$ and l-group herring are shown, which, however, indicates that more than one stock were present in Division IIIa in 1981 (Figure 3.1). The results are from the Swedish catches and are given for each quarter for the Kattegat and for the third quarter for the Skagerrak. The numbers of herring landed in this fishery are presented in each graph.
The interpretation of the length frequency diagrams with respect to stock separation must, at this stage, be considered as preliminary.
In the first quarter, the length distribution suggests that l-group autumn spawned herring dominated in the catches in the Kattegat. In the second quarter, the length distribution is bimodal indicating that both spring $(<\sim 15 \mathrm{~cm})$ and autumn ( $>\sim 15 \mathrm{~cm}$ ) spawned herring were fished upon.
In the third quarter, the peak of the I-group consisted of rather small fish suggesting a dominance of spring spawners, part of the autumn spawners had probably left the Kattegat by this time. In this quarter, also the $0-g r o u p$ appeared in the catches in the Kattegat, and these were, based on the length distribution, mainly autumn spawned herring. The stock classification in the third quarter was supported by the samples from the acoustic survey in September. In these samples, the means of VS of the 0-group were about 56.5. The l-group herring were separated according to length, resulting in that fish smaller than about 20 cm showed a mean VS of either 56.0 or 56.7 , i.e., corresponding to Kattegat and Skagerrak spawners, respectively. Larger l-group herring had means of VS of about 56.5 indicating autumn spawned origin.

In the fourth quarter, the catches of 0 - and l-group seem to have been made up predominantly by autumn and spring spawned herring, respectively.

The Swedish samples from the third quarter in the Skagerrak resulted in bimodal length frequency diagrams for both the 0-and l-group herring. These peaks are probably made up by spring and autumn spawned herring. If so, a comparison with the samples from the Kattegat from the same quarter suggests that the herring in the Skagerrak had a larger size at that time than in the Kattegat.
The number of 0 - and l-group herring landed in the Swedish fishery in Division IIIa was less than $20 \%$ of the total, and the Working Group felt that at the present state, these figures could not be used for an estimation of the numbers of autumn and spring spawners caught in Division IIIa during 1981.

### 3.2 The Fishery in 1981

### 3.2.1 Catch data

The landings of herring during the last decade are given in Table 3.l. The preliminary total landings based upon official figures in 1981 for Division IIIa amounted to approximately ll4 000 tonnes, which is a drastic increase from the official figures in 1980. The increase is most pronounced in the Skagerrak, where the landings almost trebled.

Denmark was not able to produce reliable data on the catch composition of industrial landings for the second half of the year, and in order to get an indication of the likely level of this part of the landings, the Working Group made an estimate from a regression of research vessel data on earlier catches of 0-group herring. This exercise, which is described in the following section, indicated that an additional 42000 tonnes of herring might have been landed in July-December. This together with another 4000 tonnes of unallocated landings would indicate a total catch of some 160000 tonnes. The official figures appear, therefore, to be an underestimate of the catch taken in Division IIIa.
It is stressed that the validity of the indirect estimation depends upon a number of assumptions, which are not likely to be fulfilled, and it can never replace a direct estimate based on an efficient sampling scheme. Without such a sampling scheme and reliable figures for total landings, one will not have the data base required for making a proper assessment.

### 3.2.2 Catch in numbers at age

Catch in numbers at age data were available for all major fisheries except landings for processing in Danish harbours in the second half of 1981. In the latter case, percentage age distributions were available, but reliable data on the actual landings of herring in weight could not be presented.
In order to obtain an indication of the possible level of catch in numbers, the Working Group used an indirect method. In the text table below is given the estimated catch in numbers of 0-group herring in the years 1975-80 and the corresponding abundance indices obtained from IYFS in 1976-82.
Year Catch of 0-group IYFS index of l-group

| 1975 | 2006 |  |
| :---: | ---: | ---: |
| 1976 | 433 | 339 |
| 1977 | 934 | 204 |
| 1978 | 147 | 575 |
| 1979 | 457 | 3 |
| 1980 | 682 | 504 |
| 1981 | $?$ | 544 |
| 1982 | - | 1647 |

The regression of catch of 0-group on abundance indices of l-ringers of the same year class is shown in Figure 3.2. Inserting the abundance index obtained from the recent 1982 survey in the regression equation indicates a catch of $2.4 \times 10^{9}$ 0-group herring in 1981.
Table 3.2 shows the age distribution in numbers of the "known" landings. It also shows the percentage age distribution of Danish samples in the second half of 1981. By subtracting the known number of 0 -ringers from $2.4 \times 10^{9}$ obtained by the regression equation, an
indication of the catch in numbers of older fish could be arrived at by applying the percentage age composition. The results are shown in the same table, together with average weights at age, by which an indication of total weight was obtained. As the unknown landings were calculated by SOP, they were corrected by the ratio of actual catch and SOP of the known landings.

The validity of the estimate depends largely on two assumptions:
a) Fishing patterns and effort have not changed over the period 1975-81.
b) The age composition applied to the unknown landings in the second half of 1981 is representative.

Neither of these can be evaluated at present.
Catch in number by age for previous years are shown in Table 3.2.

### 3.3 Biomass Estimates from Acoustic Surveys

An acoustic survey was carried out in September 1981 by the Swedish and Danish research vessels "Argos" and "Dana". Preliminary results were reported to the ACFM at its meeting in November 1981. ACFM expressed doubts about the actual level of biomass arrived at, mainly because of the target strength used $(-38.3 \mathrm{~dB} / \mathrm{kg}$ for a herring of 23.7 cm ) and because of insufficient calibration of "Dana's" new equipment. New calibration data were not presented to the Working Group, which, however, expressed its interest in these surveys being continued.
3.4 Recruitment

The annual young fish survey was carried out in Division IIIa during 8-19 February 1982. In the first week of February, ice made trawling impossible. Bottom trawling with the GOV was made on 12 stations in the Kattegat and $I l$ in the Skagerrak. The index of the l-group herring, calculated as the geometric mean of the arithmetic means of seven standard squares, was 1 647, which is the highest so far recorded. The number of herring was, as in previous years, highex in the Kattegat than in the Skagerrak. Two stations in the southeastern part of the Kattegat, where herring are normally abundant, could not be trawled because of ice.

The abundance index indicates that year class 1980/81 is strong. No attempt to separate the herring into spring and autumn spawned components has been made yet. However, the international young fish survey conducted in February 1981 indicated, that the amount of North Sea herring larvae drifting into Division IIIa was unusually high (see Section 2.3). This suggests that North Sea autumn spawned herring, at least partly, contribute to the high index. This is also supported by data on mean length (about 16.6 cm ) of the fish taken during the survey. The mean length would also suggest that these l-group fish of North Sea origin are predominantly from the northwestern North Sea or central North a Sea spawning grounds.
Abundance indices for 1972-82 (year classes 1970/71 - 1980/81) are given in the following text table:

| Year | Index of 1-group |
| :--- | ---: |
|  | 78 |
| 1973 | 181 |
| 1974 | 726 |
| 1975 | 455 |
| 1976 | 1339 |
| 1977 | 204 |
| 1978 | 575 |
| 1979 | 3 |
| 1980 | 504 |
| 1981 | 544 |
| 1982 | 1647 |

### 3.5 Management Considerations

The Working Group refrained from doing a stock estimate and trying to produce a prognosis upon which a TAC could be based. There were two main reasons for this decision:
a) The lack of reliable data on the actual amount of herring landed in 1981 makes it impossible to estimate the number of each age group removed from the stock by the fishery.
b) There are strong indications that the 2 youngest age groups contain an important, and in some years even a dominant, component of North Sea origin. An estimate of the likely recruitment to the Division IIIa stock cannot, therefore, be made from any index of abundance of immatures, before these can be split into the relevant components.

Even though a VPA is not feasible for these reasons, the age compositions of the landings alone indicate that the fishing mortality is very high, and that the spawning stock must be heavily dependent on one year class, i.e., 3-ringed recruit spawners. The high numbers of 0 and especially l-group fish show that the fishing pattern is very much like the one observed in the North Sea herring fisheries before they finally collapsed.

Judging from the age composition of the catches, it seems that the local spawning stocks are quite small at present, and it seems highly unlikely that they would be able to produce the high numbers of juvenile herring which have been caught in Division IIIa in recent years. Moreover, tagging experiments show that Baltic herring migrate into Division IIIa, which would also tend to give an overestimate of the amount of local Division IIIa spawners.
The local stocks may indeed be below their minimum level for normal recruitment, and the herring fishery mainly supported by North Sea juveniles and Baltic adults. It is not clear, how big a proportion of North Sea juveniles enter Division IIIa or how big a proportion they form of the juvenile catches in Division IIIa. A large part of the problem in answering these questions could be solved by the meeting of the Workshop recommended in Section 9 and which was in fact recommended in last year's report.

The numbers are, however, of the same order, or even larger, than the recorded landings of juveniles from the North Sea, and even if the North Sea component is only $50 \%$ the impact on the rebuilding of the North Sea stocks could be significant. The apparent slower recovery of the stocks in Divisions IVa and IVb as compared with Divisions IVc and VIa could partly be an effect of the juvenile catches in Division IIIa.

The Working Group can consequently only reiterate advice given in earlier reports, both of the present Working Group and the Working Group on Division IIIa stocks, as follows:
a) Fishing mortality on the adult stock should be reduced in order to increase the component of older fish and stabilize the spawning stock.
b) Catches of juvenile herring should be reduced as much as possible in order to increase recruitment both to the North Sea stocks and to Division IIIa itself.

In order to achieve these improvements in the exploitation pattern and hence in the herring fisheries, TACs, minimum landing sizes and mesh sizes, together with by-catch regulations and a ban on direct fisheries for reduction purposes have been recommended and even agreed upon amongst the interested parties. The development in the landings strongly suggests, that the main problem in Division IIIa is a lack of will and/or capability of implementing the agreed measures. It is difficult to imagine what other regulations could be effective as long as the intention to avoid a very possible collapse of the herring stocks in Division IIIa is not stronger than it appears to be at present.
4. CELTIC SEA HERRING
4.1 The Fishery
4.1.1 Catch data

Fishing for herring in the Celtic Sea has now been prohibited since 1977. In spite of this, considerable catches were again made during 1981/82, and the total catch of over 9000 tonnes was the highest recorded since 1975/76. These catches were again taken mainly by Irish pelagic trawlers and drifters. Total catches by countries per year and per season are shown in Tables 4.1 and 4.2. As in the previous seasons, the lack of markets greatly curtailed catches during 1981/82, and boats were working under a quota system for most of the season.

### 4.1.2 Catch in number per age

The total catch in numbers of fish per age class is shown in Table 4.3 . This has been estimated from Irish and Dutch data. In the Irish catches there are considerable differences betweeen the age distribution of the autumn and winter spawning components. The autumn spawning component, which is mainly exploited during August-October, contain considerably more older herring than the winter spawning component. l-winter-ring fish were well represented in the catches taken during the early part of the season.
4.2 Spawning Stock
4.2.1 Larval surveys

Larval surveys were conducted in 1981/82 for the fourth successive season, and station coverage was similar to that in 1980/81 (Doc. C.M.1981/H: 44).

Sampling coverage, when considered on the time scale, was better than in preceding seasons with a cruise every second week between midOctober and mid-February. The distribution of $<10 \mathrm{~mm}$ larvae in October was between Old Head of Kinsale and Mine Head, but in early November it also extended east of Waterford Harbour. Larval production
in late November was restricted to the Mine Head area, but early December distribution was widespread though the main concentration was offshore between Mine Head and Waterford Harbour. Abundance of $<10 \mathrm{~mm}$ larvae in late December was very low, and from January onwards none were sampled. The larval abundances for each cruise are given in Table 4.4 and plotted with data from other seasons in Figure 4.1.

The larval index for the whole season was calculated as described in the 1981 Herring Larval Survey Working Group Report (C.M.1981/H:3). The areas under the straight lines joining < 10 mm larval abundance estimates plotted on time were found for each of the periods before and after 1 January. Each larval production index for the latter period was multiplied by 1.465 (to adjust for lower fecundities of winter spawners) and added to the corresponding autumn index to produce an index of total spawning stock biomass for each season. These are as follows:

|  | Autumn index | $\begin{aligned} & \text { Winter } \\ & \text { index x } 1.465 \\ & \hline \end{aligned}$ | Total |
| :---: | :---: | :---: | :---: |
| 1978/79 | $702^{35}$ | $326^{\text {F }}$ | $1028^{\text {F }}$ |
| 1979/80 | 733 | 75 | 808 |
| 1980/81 | 655 | 97 | 752 |
| 1981/82 | 1090 | 1 | 1091 |

3 Monthly surveys only - not good estimates.

While the autumn index for $1981 / 82$ is high relative to other years, the winter larval index was practically nil. However, the moderate abundance of $10-15 \mathrm{~mm}$ larvae (mostly from one station) during the last cruise suggests that some $<10 \mathrm{~mm}$ larvae were missed on the previous cruise (Table 4.4), resulting in an underestimate of the total larval index for 1981/82. Thus, the larval abundance index for this year is somewhat higher than in previous seasons.

### 4.3 Recruitment

There is still no method available to estimate recruitment to the Celtic Sea stock. Examination of stock numbers from VPA indicates that recruitment has been low since l974, with the exception of the 1977 year class. This recruited to the fishery as l winter ring fish in 1979, when it constituted $20 \%$ of the total catch. The percentage of 1 winter ring fish present in 1981/82 was $24 \%$ of the total catch in numbers, and this might suggest that the 1979 year class would also be above the low values of recent years. There is no evidence of change in the exploitation pattern in recent years. l-ring fish also appeared to be very abundant in the catches taken in the adjoining Division VIIj during 1981.

### 4.4 Estimates of Fishing Mortality

As in previous years, it has not been possible to obtain any estimate of $F$ for the most recent years on the Celtic Sea stock. The 1981 Working Group examined trends in $F$, estimated from catch curves and the mean ages of the catches for different periods, when effort was thought to be different. As a result of this, it has been calculated that $F$ in the period 1976-80 was about 0.8. This value was, therefore, used by the 1981 Working Group as an input F on VPA for the 1980/81 catch in numbers data.

It has not been possible to calculate $F$ for the 1981/82 catches from catch per effort data.
VPA was again carried out on the $1981 / 82$ catch in number data, using a range of $F$ values from $0.4-1.2$. It was found that no input $F$ value on the 1981/82 data generated an $F$ in 1980/81 as high as 0.8. It must, therefore, be concluded that the $F=0.8$ for $1980 / 81$ was overestimated or that the $F$ in 1981/82 was in excess of 1.2. The spawning stock sizes, calculated from the different VPAs, were also compared with the larval indices but no similarities were evident. This was probably because the VPAs were carried out on the catches in age data for both the autumn and winter spawning components of the Celtic Sea combined. More meaningful comparisons might be obtained, if stock sizes for both components were separately calculated by VPA. However, the data necessary to enable this separation to be made were not available at this meeting.

### 1.4.1 Results from VPA

There is, therefore, no method of calculating the appropriate for 1981/82. The output from the VPA, based on assumed input $F$ adult $=$ 0.8 and 0.4 and $F$ l-ring $=0.2$ and 0.1 , respectively, are shown in Tables 4.5-4.8. Both analyses show that the spawning stock size has increased since the initial closure of the fishery in 1977 and at spawning time in 1981 was calculated to be either 26000 tonnes $(F=0.4)$ or 13800 tonnes $(F=0.8)$, compared to 9000 tonnes in 1976. The VPA also indicates that the 1977/78 year class, which entered the fishery in 1979/80, was the strongest one since 1971, as suggested by the 1981 Working Group. Preliminary data from the 1981 catches indicate that the 1979/80 year class might also be a strong one and even stronger than the 1977/78 year class. This year class also appears to be abundant in the catches from the adjoining Division VIIj. There therefore appears to be some evidence that two good year classes have entered the fishery since 1979. Yield per recruit curves and spawning biomass per recruit curves are shown in Figure 4.2
4.5 State of the Stock and Management Considerations

The prognosis of the stock is shown in the following text table and in Figure 4.3.

Prognosis of Celtic Sea herring

| 1981/82 |  |  |  | 1982/83 |  |  |  | 1983/84 |  |  |  |

| 20400 | 13800 | 0.8 | 9471 | 17100 | $\begin{aligned} & 14600 \\ & 14300 \\ & 14100 \\ & 13800 \end{aligned}$ | $\begin{gathered} 0 \\ 0.1 \\ 0.2 \\ 0.3 \end{gathered}$ | $\begin{array}{ll}  & 0 \\ 1 & 600 \\ 3 & 000 \\ 4 & 300 \end{array}$ | $\begin{aligned} & 21800 \\ & 18600 \\ & 19100 \\ & 17900 \end{aligned}$ | 19100 <br> 17400 <br> 15900 <br> 14500 | $\begin{gathered} 0 \\ 0.1 \\ 0.2 \\ 0.3 \end{gathered}$ | $\begin{array}{ll}  & 0 \\ 1 & 900 \\ 3 & 400 \\ 4 & 500 \end{array}$ |

The stock size, calculated at 1 April 1981, was used to calculate stock sizes at 1 April 1982, using $F$ values of 0.4 and 0.8 . The mean weights per age class used were the same as in the 1981 assessment, and a minimal recruitment of 30 million fish was taken for the 1980/81 year class. The stock size has increased considerably due to the influx of the strong 1979/80 year class and is calculated to be either 17100 tonnes or 34300 tonnes. The 1982 spawning stock size has been further projected to 1983, using a range of $F$ values of $0.0 \rightarrow 0.3$ on adults and $F$ on l-ringers to be 0.25 of that on the adults. Recruitment of the 1981/82 year class was again taken as the minimal level of 30 million fish. The resultant very different stock sizes and catches with different levels of $F$ are very clearly shown.
The initial closure of the Celtic Sea herring fishery was recommended by ICES in 1976. It was recommended that the fishery should remain closed "until the spawning stock had recovered to a sufficiently high level". This level was defined as "I/3 of the stock size in a period of light exploitation". The estimated stock size during the period of light exploitation was taken as 120000 tonnes, and the desired spa stock level was, therefore, estimated to be 40000 tonnes. The present Working Group has not been able to find the basis on which the 120000 tonnes were estimated.
However, it has not been possible by the present Working Group to redefine the desired minimum spawning stock.

The spawning stock size in 1981 is estimated to be somewhere between 14000 tonnes and 26000 tonnes.
4.6 Comparison between Herring Stocks in Division VIIj (southwest Ireland) and the Celtic Sea
The fisheries in both these areas have in recent years exploited stocks, which are predominantly autumn spawners. The spawning grounds in the western part of the Celtic Sea and the eastern part of Division VIIj are situated very close to each other, and since spawning occurs at the same time there must be a considerable mixture of the larvae. It has been suggested that the nursery grounds of the herring recruiting to the Celtic Sea may lie in Division VIIj, and similarities have been shown between 2 -winter ringed herring belonging to both areas (Molloy, 1968). This Working Group examined the age compositions of the Irish catches from both areas in the most recent years (1980 and 1981) for the months September-November. These months were taken because the catches would almost certainly be composed of autumn spawners.

Comparison of percentage age distribution between catches of Celtic Sea and Division VIIj (autumn spawners).

|  |  |  | Winter rings |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | >8 |
| Sep 1980 |  | Div. VIIj | - | 13.4 | 36.9 | 16.0 | 4.9 | 15.2 | 5.1 | 3.5 | 3.6 | 1.4 |
|  |  | Celtic Sea |  | 5.2 | 46.1 | 22.1 | 7.0 | 11.7 | 3.5 | 0.9 | 0.6 | 2.9 |
| Oct | 1980 | Div. VIIj | - | 10.1 | 30.6 | 24.6 | 8.7 | 9.4 | 5.5 | 4.5 | 5.9 | 0.7 |
|  |  | Celtic Sea | - | 7.9 | 41.3 | 22.2 | 7.7 | 13.3 | 4.3 | 1.4 | 1.0 | 0.9 |
| Sep | 1981 | Div. VIIj | - | 33.9 | 57.2 | 8.5 | - | - | - | - | - | - |
|  |  | Celtic Sea | - | 7.6 | 10.0 | 32.0 | 10.6 | 7.3 | 21.5 | 3.8 | 1.6 | 5.6 |
| Oct | 1981 | Div. VIIj | - | 56.5 | 11.6 | 23.9 | 4.8 | 1.0 | 1.8 | 0.4 | - | - |
|  |  | Celtic Sea | - | 49.7 | 11.6 | 18.9 | 5.7 | 5.4 | 3.8 | 2.3 | 0.5 | 2.1 |
| Nov | 1981 | Div. VIIj | - | 74.7 | 12.7 | 9.8 | 0.3 | 0.3 | 1.6 | 0.4 | - | 0.2 |
|  |  | Celtic Sea | 2.5 | 71.8 | 10.2 | 11.0 | 2.3 | 1.7 | 0.3 | 0.2 | - | - |

The age compositions were strikingly similar in nearly all months. In 1980, both areas were dominated by the 1977 year class, while the 1976 and 1974 year classes were well represented. In 1981, there was a considerable influx of the 1979 year class, while the 1977 year class was also well represented.

As both fisheries are exploited by the same fleets and the herring from both areas are very similar, consideration should be given to managing both areas as one unit.

### 4.7 Herring Stocks in Division VIIj

4.7.1 Introduction

No previous assessments have been carried out on herring stocks in Division VIIj, because of the inadequacy of the data presented at previous meetings. In 1981, however, the Working Group decided to attempt an assessment at its next meeting and that data should be made available to enable this assessment to be made. ACFM recommended that the catch in the area in 1979-81 should not exceed 6000 tonnes. The purpose of this recommendation was to stabilize the fishery and to prevent a diversion of effort to the area because of oatch restrictions in the adjacent Celtic Sea and Division VIIb,c.
4.7.2 Catches

The total catches from the area (Table 4.9) are taken, as far as can be determined, exclusively by Irish boats. The total catch has increased from 1500 tonnes in 1971 to over 7000 tonnes in 1981. It must be pointed out, however, that the collection of accurate catch statistics from this area is extremely difficult, because illegal catches taken in the Celtic Sea are regularly landed in Division VIIj, and herring taken from the northern part of Division VIIj are occasionally landed in Division VIIb,c. In view of this and because of the location of the different spawning grounds along the south coast of Ireland, the boundary defining the western extremity of the Celtic Sea does not seem to be a realistic one. Catches in 1980 and 1981 in Division VIIj may have been limited due to poor markets.
4.7.3 Catches in number per age class

Catches in number per age class, based on Irish data, are only available from 1975-81 and these are shown in Table 4.10. It must be pointed out, that the sampling data from the earlier years of this period are severely restricted. However, it would appear from an examination of the data, that the 1974 year class, which entered the fishery in 1976, was a particularly strong one. Preliminary evidence from the 1981 catches would suggest that the 1979 year class, which also appears to be very abundant in the catches in the Celtic Sea, is also a very strong one.

### 4.7.4 Effort and catch per effort statistics

Accurate effort and catch per effort figures are not available for the entire fleet fishing in this area. The total effort is very much affected by the situation in the Celtic Sea, the decreased demand for herring, the increased efficiency of the fleet and a change from herring to mackerel fishing. Figures are available for one section of the fleet, which takes approximately $70 \%$ of the total catch (Table 4.9). These data would seem to indicate a slight increase in both effort and catch per effort since 1975.

### 4.7.5 Estimates of Z

The limited catch per effort and age data have been used to calculate Z. The results given in Table 4.9 indicate, although highly variable, that $Z$ has increased in recent years. If $M=0.1$, then the $\overline{\mathrm{F}}$ from 1979-81 appears to be about 0.4 .

## VPA

A VPA run with input $F=0.4$ (Tables 4.11-4.12). Allowing for some increase in fishing power in the most recent years, separable VPAs indicated that this input $F$ and an $S=0.7$ give a historic series of $F$ values in conformity with the trend in effort.

The spawning stock biomass at spawning time in 1981 appears to be about 14400 tonnes, and this has increased from 6400 tonnes in 1975. Recruitment from $1975-80$ has averaged 36 million fish. The 1974, 1977 and 1979 year classes appear to have been relatively strong ones. Values of $\overline{\mathrm{F}}_{2-9+}$ seem to show an increase in recent years.
The mean weights used were as follows:

| Rings | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Catch (g) | 105 | 150 | 186 | 205 | 218 | 231 | 235 | 232 | 244 |
| Stock (g) | 41 | 102 | 141 | 169 | 186 | 198 | 216 | 203 | 229 |

4.8 State of the Stock and Management Considerations

Predictions were carried out starting with the 1981 stock generated by the VPA with input $F=0.4$ for a range of $F s$ in 1982 and 1983 between 0 to 0.3 , and the results are shown in the text table below and in Figure 4.5.

Prognosis of Division VIIj Herring

| 1981 |  |  |  | 1982 |  |  |  | 1983 |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Total Stock Biomass 1 January | Spawning Stock Biomass at Spawning Time | $F$ | Catch | Stock Biomass 1 January | Spawning Stock Biomass at Spawning Time | F | Catch | Stock Biomass 1 January | Spawning Stock Biomass at Spawning Time | $F$ | Catch |
| 21600 | 14400 | 0.4 | 7176 | 31300 | 29300 | 0 | 0 | 39000 | 36700 | 0 | 0 |
|  |  |  |  |  | 28700 | 0.1 | 3929 | 35500 | 32700 | 0.1 | 4100 |
|  |  |  |  |  | 28200 | 0.2 | 7500 | 32400 | 29200 | 0.2 | 7200 |
|  |  |  |  |  | 27600 | 0.3 | 10700 | 31300 | 26100 | 0.3 | 9400 |

Recruitment as l-ringers in 1982 and 1983 was taken as 22 milion, which is the lowest observed. With $F=0.2$ in 1982, the total catch would be about 7500 tonnes (i.e, , the same as in 1981).

## 5. WEST OF SCOTLAND HERRING

### 5.1 Assessment Procedures

In the previous report of the Working Group (C.M.1981/H:8) it was stated that in 1982 an attempt would be made to allocate catches to the northern and southern parts of Division VIa, subdivided at $56^{\circ} \mathrm{N}$ and west of $7^{\circ} \mathrm{W}$ (Figure 5.1), and do assessments of the southern part of Division VIa combined with Divisions VIIb and c, the northern part as a separate unit, and the whole of Division VIa combined with VIIb and c.
In doing so, some assumptions had to be made about the allocation of the catches taken by some countries between the sub-divisions of Division VIa and of the age distributions of their catches. But these are not likely to have resulted in major errors in the outputs. The procedure used in estimating the catches and their age compositions in the two constituent sub-divisions of Division VIa for the period 1970-80 has resulted in the summed totals for Division VIa as a whole differing somewhat from the catch in numbers per age group used for this Division in previous years. This new data set has been used in all the subsequent assessments carried out during the 1982 meeting of the Working Group.
The preliminary assessments carried out for each of the areas mentioned above resulted in VPA outputs which were compatible with the known history of the fisheries in these areas during the period considered and gave estimated spawning stock biomasses which related satisfactorily to the appropriate larval abundance indices for that area. Logistically, therefore, it would have been possible to have done assessments and catch predictions for any of the area groupings considered, but under those circumstances it was considered that the choice should be made on biological grounds of areas which showed the greatest homogeneity of stock structure. On this basis it was considered that the best subdivision was the northern part of Division VIa as one unit and the southern part of Division VIa combined with Divisions VIIb and $c$ as a second unit. Such a subdivision also has the advantage that fisheries in these two areas are rather distinct ones, to a large extent exploited by different countries, and with rather different patterns of fishing activity in the last decade.
5.2 Division VIa North
5.2.1 Catch data

The catches reported by each country from this area in the period 1970-80, and the preliminary estimates of catches in 1981, are given in Table 5.1. It should be noted that these catches do not include those taken in the Clyde, which has in the past been treated as a separate unit, but do include herring taken as by-catch in the Moray Firth sprat fishery. As a result of the re-opening of the Division VIa fishery in July 1981, the catches increased markedly from 306 tonnes in 1980 to 49112 tonnes in 1981.

### 5.2.2 Catch in numbers at age

The estimated numbers at age caught in this area in each of the years 1970-81 and including the by-catches of herring in the Moray Firth sprat fishery are given in Table 5.2. Not all countries fishing in this area in 1981 had carried out adequate sampling of their catches, and the age compositions of French, English and German catches had to be estimated by assuming that they corresponded to those of the Netherlands. The total international catch in numbers at age shows
the features which would have been expected from the assessment carried out in 1981 with 3 - and 4-ringers (1977 and 1976 year classes) to be strongly represented. The 1979 year class was also taken in fairly large numbers, considering the very limited fishing activity for sprat in the Moray Firth, and this might be indicative of this year class being a fairly strong one when it recruits more fully to the directed herring fishery in Division VIa (north) in 1982.

### 5.2.3 Larval surveys

Larval surveys were carried out in this area throughout September and October by the Federal Republic of Germany and Scottish research vessels resulting in a very satisfactory sampling coverage both in space and time. The resulting index of abundance for the smallest size category of herring larvae was the highest which has been attained since 1972. An initial VPA was run from 1978 to 1972 to give preliminary estimates of spawning stock biomass in each year of this period, and a regression calculated between these estimates and the larval indices. This regression was highly significant, and using it a preliminary estimate of spawning stock biomass in 1981 was made from the larval index of that year to provide an input $F$ for a VPA.

### 5.2.4 VPA outputs

Using the catch at age data given in Table 5.2 and an input $F$ of 0.12 on fully recruited age groups derived as described above, a VPA was run. The outputs of fishing mortality at age, stock in numbers at age, and spawning stock biomass at 1 September are given in Tables 5.3 and 5.4, respectively. These outputs demonstrate the very marked increase in spawning stock biomass, which took place in this area in 1979 and the very appreciably subsequent increases in 1980 and 1981, arising from the better recruitment to the stock by the 1976, 1977, and 1978 year classes. Table 5.3 also demonstrates the very high exploitation rate to which the herring population in this area was subjected in the period 1971-76, resulting in a heavily depleted spawning stock in 1977 and the need to close the fishery to give it an opportunity to recover.

Using the new spawning stock biomasses given in Table 5.4, new regressions have been calculated between spawning stock and larval abundance indices from 1972-81. The input data and the resulting regression parameters are given in Table 5.5, and these data are shown in Figure 5.2. The correlation coefficient is very high, and the very close agreements between the VPA estimates of spawning biomass from the VPA and the predicted values from the regression equation demonstrate that little would be gained by carrying out further iterations. It might be considered that using inputs from 1981 in calculating the regression parameters has its dangers, because of the uncertainty about the stock biomass estimates in that year and in the immediately preceding years, but it was in fact demonstrated that it had little effect on the outputs.

### 5.3 Recruitment

As stated in paragraph 5.2 .2 , catches of l-ringers in 1981 were higher than for several years, and in view of the very limited sprat fishery in the Moray Firth this might be indicative of better recruitment to the Division VIa fishery in 1982. However, there is no objective way of fixing an input $F$ for either 0 -group or l-group in this fishery, so the size of the 1979 and 1980 year classes are not adequately measured from the VPA stock sizes. The only data available
to get some measure of this are trawl surveys carried out by the Scottish research vessel "Scotia", covering the whole of Division VIa in February-March 1981 and 1982. These gave mean catches per hour of 2-group fish in the northern part of Division VIa of 1103 in 1981 and 1680 in 1982. From VPA the strength of the 1978 year class as $2-r i n g e r s$ is $848020 \times 10^{3}$ and this would suggest that the 1979 year class in 1982 would be expected to be about $1290000 \times 103$. This value has been used for catch predictions in the absence of any other objective way of measuring the strength of this year class.
5.4 Management Considerations

As stated earlier, the spawning stock biomass in this area has now recovered almost to the high level of 1972, and recruitment in recent years has been at a fairly satisfactory level. TACs have been calculated, over a range of Fs, for 1982 using the starting parameters given in Table 5.b. The stock in numbers data are derived from Table 5.4, apart from the recent year class, which was estimated as discussed in paragraph 5.3. The weights at age for the catch and for the spawning stock are the same values as used previously by the Working Group for the whole of Division VIa. Inspection of Table 5.3 suggests that 2 -ringers in this fishery are not fully recruited to the exploited stock and an exploitation pattern of 0.80 on $2-g r o u p$ and full exploitation on all older fish was used. The resulting catches and spawning stock biomasses over a range of Fs are illustrated in Figure 5.3.
For this population the yield per recruit and spawning stock biomass per recruit are shown in Figure 5.4. The yield per recruit curve has no maximum.

Projections of stock size and catches for a range of $F$ values are given in the text table below.

| 1981 |  |  | 1982 |  |  | 1983 |  |  |
| :---: | :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Catch | $\bar{F}_{3-10}$ | Spawning <br> stook | $\bar{F}_{3-10}$ | Catch | Spawning <br> stock | $\overline{\boldsymbol{F}}_{3-10}$ | Catch | Spawning <br> stock |
| 44264 | 0.12 | 373000 | 0.10 | 47300 | 484000 | 0.10 | 49300 | 481000 |
|  |  |  | 0.20 | 90400 | 455000 | 0.20 | 86070 | 412622 |
|  |  |  | 0.30 | 129600 | 427000 | 0.30 | 112800 | 354000 |

In estimating TACs for 1983, some assumption has to be made about recruitment in that year,as there are no data from which it can be measured. Accordingly, a highly conservative value of the lowest value ( $250 \times 10^{6}$ ) recorded in the VPA has been used. This results in the values given above of catch and spawning stock biomass in 1983, provided the fishing mortality rate is maintained at the same level in both years.

### 5.5 Clyde Herring

5.5.1 The fishery in 1981

Landings in the years 1972-81 by Scottish and a few Northern Irish vessels are given in Table 5.7. The landings in 1981 of 2135 tonnes were slightly above the recommended TAC for that year, and sampling
evidence suggests that the landing of overweight boxes may have further increased the actual landings by between $10 \%$ and $15 \%$. There were reports of illegal landings from this fishery, but no data are available to quantify this aspect. An additional estimated 7 tonnes were caught as by-catch in the sprat fishery.
Reports of the fishery indicated that fishermen experienced some difficulty in catching their weekly quotas from the opening of the fishery on 15 June until the end of July, but the TAC was taken earlier than expected by 4 September. There were also reports of discarding of small herring during June and July.
Catches in numbers (spring and autumn spawners combined) for the period 1967-81 are given in Table 5.8. The data for 1981 have been raised to take account of the percentage overweight in the boxes on a monthly basis. In 1981, 2- and 3-ringed herring (1978 and 1977 year classes, respectively) predominated in the landings, and 4-ringers (1976 year class) were also well represented. In addition, there were reports of discarding of small herring, but no measure of the extent of this was available.

### 5.5.2 Tagging experiments

The updated recapture data for the tagging experiment carried out in the Clyde in May-June 1980, in which approximately 7000 externally tagged herring were liberated, are given in Table 5.9. As can be seen from this table, there were again tag returns in 1981 from the Irish Sea and N.W.Ireland area, although, unlike 1980, none from the former area immediately before and during the spawning season. In addition, there were two returns from the South Minch in the winter and one from southwest of Ireland (from a catch of recently spent fish in November). As was the case in 1980, however, most of the returns from this experiment were from within the Clyde. The recovery of two Clyde tagged herring from the South Minch indicates some interchange with this area, a feature not shown in the two previous years because of the closure of Division VIa to directed herring fisheries. These data coupled with the tag return data for other areas adjacent to the Clyde, suggest a rather complex mixing of stocks within the Firth of Clyde. However, if there are directed fisheries in the Manx and Mourne areas as well as in Divisions VIa and VIIb, c in 1982, a proposed tagging in the Clyde in May-June 1982 may assist in quantifying the various relationships between the stocks in these areas.

### 5.5.3 Basis for stock assessment

The 1981 returns of herring tagged in the Clyde in 1980 support the earlier conclusion that herring from a number of different spawning stocks are present in the Clyde, and that some emigration takes place. The proportion of tag returns from outside the Clyde increased from 1980-81. The only period of the year with a significant number of returns in both years is July-September, the period of the Clyde fishery. In this period, the proportion of tag returns from outside the clyde increased from $2.3 \%$ in 1980 to $6.5 \%$ in 1981. This is consistent with a low level of emigration.

Nevertheless, a year and more after tagging, the majority of tag returns still come from the Clyde itself. If one assumes that the likelihood of a tag being reported is not significantly lower outside the Clyde, then this indicates that most of the fishing mortality on the population of Clyde herring (at least those present at the beginning of the main fishing season) takes place in the Clyde itself, and not when the fish emigrate, either temporarily to spawn or permanently. Hence, although recruitment to the Clyde autumn-spawning population comes from outside the Clyde, the population itself has a degree of continuity. This conclusion is also supported by the consistent difference in mean length at age between Clyde herring and those in the adjacent areas, which was the basis for one of the main arguments for managing the Clyde herring as a separate unit, when this question was first considered in 1978 (C.M.1978/ H:67, revised).
Since most of the fishing mortality on the Clyde population appears to be generated in the clyde, the Working Group considered it justifiable to carry out a VPA in order to estimate recent changes in $F$, and to provide estimates of recruitment to the population for comparison with recruitment fluctuations in neighbouring stocks. Since there was evidence of a change in the proportion of spring- and autumn-spawners in the clyde around 1969 (C.M.1978/H:67, revised), the VPA was carried out for the years 1970-81. The results are discussed in the next section.

### 5.5.4 Virtual Population Analysis (VPA)

The VPA on the Clyde herring was carried out with a value of natural mortality of 0.1 in all ages and the following exploitation pattern derived from a trial analysis.

| Age | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $F$ as a proportion | 0.6 | 1.4 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 |
| of F on the older age groups | 0.6 | 1.4 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 | 1.0 |

In all runs of the analysis, the value of $F$ on the oldest age group was assumed to be 0.5 in all years.
Using these input parameters a VPA was carried out using values of $F$ in 1981 ranging from 0.2-0.8 (where $F$ is defined as $F$ on age groups 3-9). The results are summarized in Tables 5.10 and 5.11 , which give, for each value of input $F$, the weighted mean values of $F$ on 2-10 ringers and estimated numbers of $0-g r o u p$ recruits at 1 January each year.

The Working Group had little evidence on which to select the most appropriate value of input $F$ in 1981. The introduction and enforcement of a TAC in 1979, however, which reduced the catch to $50 \%$ of that in the previous year, had probably reduced fishing mortality. In Table 5.l0, the largest decrease in $F$ on all age groups from 1978-79 occurred using low values of input $F$ in 1981. High values of input $F$ in 1981, furthermore, indicated a sharp increase in $F$ on 2 -ringers between 1980 and 1981, a change which was not supported by any increase in nominal fishing effort. The Working Group, therefore, considered that the fishing mortality rate in 1981 was probably near the lower end of the range of trial values. The results from a final analysis, using an input $F$ of 0.3 in 1981, are given in Tables 5.12 and 5.13.

The estimates of F, given in Table 5.12, fluctuated between 0.36 and 0.67 over the period 1970-78 and decreased to 0.32 in 1979 when the TAC regulation was first introduced.

Estimates of recruitment to the Clyde population given in Table 5.13 indicate a mean level of $26.7 \times 10^{6}$ 0-ringers over the period 1970-78. Estimates for 1979 and 1980 are likely to be underestimates because they do not include a contribution from discarding of small fish, which was known to have taken place in 1980 and 1981.
The large year classes in the Clyde population were those of 1969, 1971, 1973, and 1976. Tests of correlation between Clyde recruitment estimates and those in adjacent stocks (Manx, Mourne, Division VIa north, Division VIa south and Division VIIb, c) showed no evidence of a clear relationship with any stock in particular.
5.5.5 State of the stock and management considerations.

The results of the VPA given above together with the tag returns in 1980 and 1981 support the earlier conclusion that autumn-spawning herring in the clyde are drawn from all the adjacent stocks. On the evidence available, the fishing mortality rate in the Clyde is unlikely to be higher than about 0.3 in 1981. If this is correct, then the present level of TAC advised by ICES (2 500 tonnes in 1982) would be at approximately the correct level to stablise the fishing mortality rate on the Clyde herring population.
6. HERRING IN DIVISIONS VIa (SOUTH) AND VIIb, C
6.1 In the preceding section of this report, the parameters adopted in splitting Division VIa into two sub-areas were explained and the justification for adopting the combination of areas finally chosen. The boundaries of this sub-area are shown in Figure 5.1.

### 6.1.1 Catch data

The catches of each country allocated to this area in the period 1970-80 and the preliminary estimates of catches in 1981 are given in Table 6.1. The total international catch in 1981 of about 26000 tonnes was about 4000 tonnes less than in the preceding year despite the lifting of the closure for the southern part of Division VIa. This resulted from a large drop in Irish catches, which was only partly compensated by the increased catches of Federal Republic of Germany and the Netherlands.

### 6.1.2 Catch in numbers at age

The estimated numbers at age caught in this area in each of the years 1970-81 are given in Table 6.2. Catches by the Federal Republic of Germany had not been sampled in 1981, and the age composition of these were estimated by assuming they were comparable to those of the Netherlands. French catches were treated similarly. These catch data show much greater stability during this period than those from Division VIa (north) and in most years show a higher proportion of older fish. As in Division VIa (north), however, the main contribution to the 1981 catches was made by the 1978,1977 and 1976 year classes. 1-ringed fish were more poorly represented than in any year since 1972.

### 6.1.3 Larval surveys

In the past, the larval survey data for this area have not been completely satisfactory in that the surveys have covered only the northern part of the total distribution of spawning and only the early part of the total time of hatching. In 1981, Ireland started to do larval surveys in this area and, as a result, in conjunction with the Scottish surveys, rather good coverage was obtained of the total area and time of hatching. This, however, is of no help at the present time, as the only way to convert these data to estimates of parental stock size is by a regression technique which demands a fairly long series of comparable data. It is hoped to continue these surveys on the 1981 scale for a number of years, at the end of which a new regression can be utilized in this way. In this one, the 1981 index was lower than in any year since 1977.
As in Division VIa (north), a preliminary VPA was run for this area to give a first estimate of spawning stock biomasses, and from these a regression between larval abundance and spawning stock was estimated. From this regression, the 1981 larval abundance index was converted to spawning stock biomass, and this was used to estimate the input $F$ for a new VPA starting with the 1981 data.

### 6.1.4 VPA outputs

Using the catch at age data given in Table 6.2 and an input $F$ of 0.34 derived from the 1981 larval index, a VPA was run. The resulting Fs, stock in numbers and spawning stock biomasses are given in Tables 6.3 and 6.4 , respectively. In this area the preliminary VPA outputs did not suggest that in recent years the $F$ on 2 -ringers was lower than on older fish, so a constant $F$ on all age groups $\geq 2$ was input. The outputs of Tables 6.3 and 6.4 show a rather stable exploitation rate in this area since the mid-1970s, and a rather stable spawning stock biomass but at a level of only about a half of that in the early 1970s.

Using the spawning stock biomasses given in Table 6.4, new regressions were calculated with the larval indices. The larval index for 1972 is obviously discrepant and the data for that year were omitted. The parameters and the regression calculations are given in Table 6.5 . The correlation coefficient is not as high as in Division VIa (north), probably due to the poorer quality of the larval data, but it is highly significant, and the estimates of spawning stock from the regression show a satisfactory degree of agreement with those derived from the VPA, which gives some confidence in the stability of the regression. It should be noted, however, that a rather high proportion is contributed by the intercept. This regression is shown in Figure 6.1. The same comments as made in paragraph 5.2 about the use of data, starting from 1981 in estimating the regression, also apply in this case.

### 6.1.5 Recruitment

As stated earlier, the catches of l-group fish in this area in 1981 were lower than they had been for several years, and this might suggest that recruitment as 2-ringers in 1982 will be poor. The strength of this year class from the VPA is, however, highly dependent on the input $F$, which cannot be measured in any objective way. It was merely chosen to be compatible with levels encountered in other recent years.
The Scottish research vessel surveys in February-March 1981 and 1982 covered only a small but a constant part of this area in both years. Since the proportion of this area covered is small, the data from these
surveys cannot be used to measure the size of this year class, but They would support the evidence from the VPA that this year class is likely to be very small in relation to the preceding one.

### 6.1.6 Management advice

In the previous report of the Working Group, estimates of mean weight at age were given for Divisions VIa (south) and VIIb, c, which suggested that the values were rather higher than in Division VIa (north). The values given in that report fluctuated considerably amongst the older fish, and to get a more rational series these values were used to calculate a smoother series using a von Bertalanffy equation derived from them. These values, which are given in Table 6.6, were used in calculating predicted yields in 1982 and 1983. TACs were calculated over a range of Fs using the parameters given in that table. The stook in numbers data are taken from Table 6.4. Recruitment in 1983 was set at $54280 \times 103$.

Yield per recruit and a spawning stock biomass per recruit curve were estimated for this stock and are shown in Figure 6.2. The yield per recruit curve has no maximum.

7. IRISH SEA HERRING (DIVISION VIIa)
7.1 Introduction

TAC for the North Irish Sea for 1981 was set at 3800 tonnes. The reported catch from the North Irish Sea was 4385 tonnes (Table 7.1). Actual catches probably exceeded this because of dumping of small fish at sea, overweight boxes, and unreported catches. Reported catches were allocated to Manx and Mourne stocks on the basis of vertebral counts, gonad condition, and place of capture as described in Doc. C.M.1979/H:6. 2945 tonnes were allocated to the Manx stock, and 1440 tonnes to the Mourne stock (Table 7.2). The two stocks are considered separately below, and general recommendations for the North Irish Sea are given in Section 7.4.

### 7.2 Manx Stock

7.2.1 The fishery in 1981

The number of vessels participating in the fishery showed a marked reduction from 115 in 1980 to 67 in 1981 (provisional figure for 1981).
The fishing pattern was voluntarily regulated by daily quotas per boat recommended by a representative port committee; a short week of four fishing days was worked. The TAC was taken by 15 September, i.e., earlier than the statutory closure of the fishery on 21 September. Some
fishing over the spawning ground was observed in the closed season, but it proved impossible to trace the landings, which were unrecorded. There was discarding at sea of small herring, but this cannot be quantified.
The low TAC in 1981, fluctuating prices and demand, and availability of herring elsewhere, affected the number of boats fishing at different times and the proportion of the total catch taken in different parts of the fishing season. The seasonal change in fishing pattern from 1980 to 1981 is indicated in the text table below.

Percentage of total catch taken in different months

|  | June/July | August | September and later |
| :---: | :---: | :---: | :---: |
| 1980 | 24.2 | 21.0 | 54.8 |
| 1981 | 29.4 | 35.0 | 35.6 |

### 7.2.2 Estimates of fishing mortality and stock size

Catch in number of fish at each age is given in Table 7.3. VPAs were applied to these data, with a range of input For 1981. Fs for terminal ages in earlier years were taken as those given by mean Fs in the VPA adopted in 1981 (C.M.1981/H:8). There is no direct independent evidence available on which to base a choice of input Fs for a VPA. The Working Group considered, however, that the low TAC and catch in 1981, the smaller fishing fleet, and the early closure of the fishery, indicated an appreciably lower $F$ than that for 1980 . It was also considered that the change in seasonal fishing pattern was likely to generate an $F$ on age group 2 higher than that on older age groups, which are not fully represented in the early catches. The high proportion of 2 -ringed herring in the total catch lends support to this view. VPA with input Fage $2=0.4$ and $F_{\text {age }} 3-8+=0.3$ gave results consistent with the conclusions reached by the Working Group in 1981, i.e., that the stock size was low in 1980 and that $\mathrm{F}_{1980}$ was similar to that in 1977 (C.M.1981/H:8). VPA with $\mathrm{F}_{1981}=0.3$ is given in Tables 7.4 and 7.5 . The results indicate a spawning stock biomass at spawning time of 8100 tonnes.

### 7.2.3 Larval survey

A tow-net survey was carried out over the spawning ground and adjacent areas. A relatively large number of larvae was caught in the first week of October. The larvae were all less than 10 mm , nearly all had prominent yolk sacs and were recently hatched. Data from such surveys in recent years (Table 7.6) are very variable. A proposed follow up survey for older larvae was frustrated by bad weather.

### 7.2.4 State of the stock

There was a modest increase in estimated spawning stock biomass at spawning time in 1981 compared to that in 1980 , but the stock biomass is still low (see text table below) and is heavily dependent on recruitment.

| Spawning stock biomass at spawning time (tonnes $\times 10^{-3}$ ) |  |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1971 | 1972 | 1973 | 1974 | 1975 | 1976 | 1977 | 1978 | 1979 | 1980 | 1981 |
| 29.0 | 26.5 | 26.3 | 20.8 | 13.5 | 10.6 | 7.6 | 9.8 | 9.1 | $5.5^{\text {3F }}$ | $8.1^{35}$ |

3 Inefficient estimates

Recruitment in the next few years will be derived from low levels of spawning stock and is likely to be poor, particularly that of the 1980 year class. Projections made forward to 1983 from present VPA estimates are very uncertain, since they depend on two unknown values for recruitment and on the catch level and pattern in 1982. The projections given in the text table below assume recruitment at $30 \times 10^{6}$ l-ringed fish in 1982 and 1983. This is equal to the lowest level indicated by VPAs carried out by the Working Group, i.e. that for l-ringed fish 1965. The projections give the possible spawning stock biomass in 1982 and 1983 at different levels of $F_{1982}$, with $F_{1983}=F_{1982^{\circ}}$

### 7.3 Mourne Stock

7.3.1 The fishery in 1981

The total nominal catch of the Mourne stock in 1981 was 1440 tonnes, made up of 295 tonnes selectively fished by gill-nets over the Mourne spawning grounds, and 1146 tonnes taken as a component of the Isle of Man fishery outside the l2-mile Irish coast limit (Table 7.2). The
total catch was $26 \%$ lower than in 1980, largely as a result of the reduction of the North Irish Sea TAC (see Section 7.1) and a general decrease in effort in the Mourne area because of lack of market demands. As a result, in 1981 the selective gill-net fishery on the spawning grounds did not take the whole 400 tonnes allocation.
7.3.2 Catch in numbers by age

Total catches by weight of Mourne herring were converted to numbers at age by using data from samples of the catch landed in Northern Ireland and the Republic of Ireland. The age composition of the catches since 1971 is given in Table 7.7. The predominant age group in 1981 was the 1978 year class.

In 1981 some data on discards at sea of juvenile herring taken as a by-catch in the Northern Ireland Nephrops fishery were collected. From sample data in this fishery it was estimated that approximately $1.9 \times 10^{6} 0$-group herring were discarded at sea by vessels landing at Northern Ireland ports.

As Northern Ireland's by-catch data could not reliably be extrapolated to the Republic of Ireland's Nephrops catch due to differences in mesh size, this figure, therefore, is most probably an underestimate of total 0-group catch. However, in the absence of similar data for earlier years, no 0-group catch was included in the VPA.
The mean weights at age used to calculate the stock sizes are based on Northern Ireland and the Republic of Ireland's data and are given in the text table below.
Age(w.r.)
Weight (g) $\quad \frac{1}{106} \quad \frac{2}{169} \quad \frac{3}{205} \quad \frac{4}{224} \quad \frac{5}{249} \quad \frac{6}{263} \quad \frac{7}{273} \quad \frac{8}{280} \quad \frac{9+}{312}$

### 7.3.3 North Irish Sea - Young herring survey

A young herring survey in the northwestern Irish Sea was carried out in February 1982. This survey was similar to those carried out in February 1980 and 1981. The average number of l-group herring taken per hour haul (based on 35 stations) was 770 compared with 830 in 1981 and 108 in 1980. This would indicate that the abundance of the 1980 year class was similar to that of the 1979 year class. The vertebral counts of these herring were 56.81 , which would suggest that they belonged mainly to the Mourne spawning component.

### 7.3.4 Virtual Population Analysis

Although no direct data on effort are available, there is indirect evidence to suggest a reduction in $F$ between 1980 and 1981. The catch of Mourne herring was reduced from 1953 tonnes in 1980 to 1440 tonnes in 1981, there was a marked reduction in market demand for herring owing to availability of supplies from other areas, e.g., Division VIa, and fewer boats participated in the fishery. It was, therefore, concluded that $F 81$ would have been significantly lower than $\mathrm{F}_{80}(=0.3)$.

Input $F=0.2$ was chosen for age groups 2 and over; the input value for l-group fish in 1981 was adjusted to produce a recruitment for year class 1979 of $45 \times 10^{6}$ (the lowest value from the VPA of the previous Working Group); this gave a value of $F=0.08$, which is in accord with last year's conclusion that $F$ on l-ringers would be approximately $1 / 3$ of $F$ on the older age groups. The input value of $F$ for the oldest age group in 1980 and earlier years was taken from
the mean weighted value of F for age groups 2-6 and estimated from the VPA of the previous Working Group (Table 7.8). Stock sizes and biomass were derived both for 1 January and at spawning time and are given in Table 7.9.

The results of the VPA indicate that spawning stock biomass increased in 1981 for the fourth year in succession (see text table below).

Spawning stock biomass at spawning time, tonnes

| $\frac{1976}{3100}$ | 2800 | $\frac{1978}{3300}$ | $\frac{1979}{3800}$ | $4300^{3}$ | $\frac{1981}{7}$ |
| ---: | ---: | ---: | ---: | ---: | ---: |

\# Inefficient estimates

### 7.3.5 State of the stock

The yield per recruit and spawning stock biomass per recruit curves dependent on the 1981 exploitation pattern are shown in Figure 7.3.
In making a prognosis, the Working Group assumed that the mean arithmetic recruitment from the VPA in the period 1974-78, i.e., $63 \times 10^{6} 0$-group fish, was appropriate for the 1980 and 1981 year classes. This value was used as input for projections, together with stock size at 1 January 1981 from the VPA with input $\mathrm{F}_{81}$ on age 2 and over of 0.2 . Stock changes and yields indicated by the projections are given in the text table below.

It must be stressed, however, that because of the assumptions made for both 1982 and 1983 the predictions for the latter year are extremely tentative. Furthermore, the projections for 1983 were rendered even more uncertain because of possible changes in the exploitation pattern resulting from the re-introduction of $a$ directed selective fishery on the spawning grounds.

### 7.4 Management Considerations <br> 7.4.1 TAC

The fishery in the $N$.Irish Sea exploits a mixture of Manx and Mourne herring in the area west and southwest of the Isle of Man for a large part of the fishing season. The Working Group, therefore, recommends that a single TAC be set for herring in the N.Irish Sea, rather than separate TACs for Manx and Mourne stocks, because catches cannot be allocated to stock until all relevant biological and statistical data are available. It is important that the fishing effort applied to take the TAC should not be concentrated on either the Manx stock or the Mourne stock. The impact on each stock will depend on the seasonal and spatial distribution of the fishery. We take as an example a TAC of 3800 tonnes based on the yield from $F=0.15$ applied on each stock, which would give a theoretical catch of 1900 tonnes of Manx herring and 1900 tonnes of Mourne herring. If about two-thirds of the TAC were taken in the mixed fishery, this could result in a catch of about 1300 tonnes of Mourne herring and l 000 tonnes of Manx herring, since the estimated Mourne stock biomass (at the beginning of the season) is higher than the Manx stock biomass. The balance of the TAC could be taken by selective fishing of 600 tonnes Mourne stock on their spawning grounds off the Mourne coast, and 900 tonnes of Manx herring taken as they approach the Manx spawning ground east of the Isle of Man. The estimated effect on stock sizes is given in the text table below. Effect of fishing at $F=0.15$ on stocks in N. Irish Sea

| 1982 |  |  | 1983 |  |
| :---: | :---: | :---: | :---: | :---: |
| Total <br> stock <br> biom. | Spawn. stock <br> biom.at <br> spawning | Catch | Total <br> stock <br> biom. | Spawning stock <br> biomass at spawning |
| 16.0 | 11.35 | 1.9 | 18.6 | 13.5 |
| 19.7 | 11.9 | 1.9 | 26.6 | 17.7 |

The effort available for selective gill-net fishing over the Mourne spawning ground is limited, and in any case it is considered undesirable to increase the catch on this spawning ground until the impact of the resumption of this fishery after the closure between 1978 and 1980 can be fully assessed. If a larger part of a TAC were taken late in the season as the herring approach their respective spawning grounds, the effect could be to increase effort and $F$ on the Man stock. At $F=0.15$, the expected spawning stock at spawning time in 1982 would be 11900 tonnes of Mourne herring, which is near the peak value in 1972, and 11350 tonnes of Manx herring, which is higher than any value since 1975. The effect of management options which entail fishing at values of $F$ lower and higher than $F=0.15$ can be seen in the text table in paragraph 7.2.4 for Manx stock and in the text table in paragraph 7.3.5 for Mourne stock. All estimates must be treated with extreme caution because of the uncertainties introduced by assumed levels of recruitment, and $F$ generated in 1982.

A TAC of 3800 tonnes is the same as that set for 1981 and represents a relatively cautious management. It would be prudent to examine data from the 1982 fishery before considering management for 1983. If, however, it is essential to make a provisional recommendation, it is considered that the TAC for 1983 should be the same as that for 1982. In each year, the part of the TAC allocated to the selective directed herring fishery over the Mourne spawning ground should be clearly stated.

### 7.4.2 Other conservation measures

Management of the N.Irish Sea fishery in the past has included measures to reduce fishing mortality on the spawning stock by closure of the fishery from the Saturday nearest to 21 September until the Monday nearest to 16 November, except for a small directed gill-net fighery on the Mourne spawning ground, prohibition of directed herring fishery in nursery areas, and a minimum size regulation. These measures should be continued in 1982 and 1983.

## 8. NORTH SEA HERRING TAGGING EXPERIMENT

The Working Group took note of the report from the Planning Group (C.M.1982/H:3) and endorsed its proposals. It wishes to stress the importance of obtaining more information on the state of the stock in the northern North Sea. The results of such a tagging experiment should help to check the use of larval abundances, which are presently the only estimate of stock size used, and also to evaluate the acoustic biomass estimates.

It is recommended that this experiment should be implemented in 1983 as envisaged. The problems of developing a system for monitoring commercial catches should be further studied, and the opportunities arising from a tagged herring population in 1983 be used in further development. This should be done with a view to a longer term tagging, programme being developed later.
The Working Group also indicated its support for the work being done in the Irish Sea and Clyde. Those countries taking catches of these stocks should be encouraged to monitor catches for microtags in order to improve the estimates of stock mixing, stock size, and fishing mortality.

## 9. RECOMMENDATION

In view of the importance to the assessment of herring stocks in Division IIIa (and adjacent waters), the Working Group recommends that a workshop on stock components in herring landings from this area be established well in advance of the next meeting of this Working Group and of the Working Group on Division IIIa Stocks. The workshop should attempt a separation of landings into springand autumn-spawned components for as many years back as the available material allows.
The workshop should also consider the exchange of stock elements between Division IIIa and the Baltic-Belt Seas, preferably in cooperation with the members from the Working Group on Assessment of Pelagic Stocks in the Baltic.
