# REPORT OF THE WORKING GROUP ON INDUSTRIAL FISHERIES 

Copenhagen, 5-10 March 1987

#### Abstract

This document is a report of a Working Group of the International Council for the Exploration of the sea and does not necessarily represent the views of the Council. Therefore, it should not be quoted without consultation with the General Secretary.

### 1.2 Terms of Reference

At the Statutory Meeting in 1986, the Council decided that (C.Res.1986/2:5:6) the Industrial Fisheries working Group (Chairman: Mr N.A. Nielsen) will meet at ICES headquarters from 5-10 March 1987 to:
a) estimate monthly quantities and quarterly geographical distribution and size composition of by-catches of herring, cod, haddock, whiting, mackerel, and saithe taken in the fisheries for Norway pout, sandeel, and sprat in the North Sea and adjacent waters and report them to the relevant assessment working groups;
b) consider the report of the ad hoc Multispecies Assessment Working Group;
c) assess the status of the stocks of the target species in the industrial fisheries, i.e., sprat in sub-area IV and Division IIIa and Norway pout and sandeel in Sub-area IV. Data should be made available and assessments carried out for Norway pout and sandeel in Divisions VIa and IIIa;
d) provide quarterly catch-at-age and catch and stock mean weight-at-age data and information on the relative distribution at different ages by quarter for North Sea stocks for 1986 as input for the Multispecies VPA.

### 1.3 Data Deficiencies

The problems of obtaining biological samples from a major part of the Danish industrial landings and from the by-catch in the Swedish consumption fishery again in 1986 hampered the collection of proper age, length, and weight data, especially in the sprat landings. The species composition of the Danish landings is provided by the Inspectorate, while the species compositions from the Swedish landings for reduction also depend on biological samples.

The Working Group would like to stress the need for continuous time series of biological data from the catches, both in respect to the single-species assessments undertaken by this Group and to multispecies assessments.

## 2 TRENDS IN THE INDUSTRIAL FISHERIES FOR SANDEEL, SPRAT, AND NORWAY POUT IN THE NORTH SEA AND DIVISION IIIA

### 2.1 Trends in the North Sea Fisheries

Table 2.1 presents the industrial landings for the years 19741986. The design of the table follows the same pattern which was introduced, described, and discussed in the previous Working Group report (Anon., 1986a).

An overall decline in total annual landings has been observed since 1974. The figure for 1986 of $1,141,000 t$ just slightly exceeds the minimum level of $1,033,000 t$ recorded in 1985, despite the fact that sandeel landings reached a maximum of $851,000 \mathrm{t}$.

In recent years, there has been a continuous decreasing trend in landings of sprat, Norway pout, blue whiting, and Annex $V$ species, whereas landings of sandeel have remained at a comparatively high level since 1984.

### 2.2 Trends in the Division IIIa Fisheries

Updated figures provided by members of the Working Group were available for 1985 and 1986 , as shown in Table 2.2. To some extent, the table reflects similar recent trends as in the North Sea fisheries, notably in the landings of sprat. As observed in the North Sea, the catch of Norway pout was low in 1985 and 1986. over the past three years, herring landings have been at the comparatively high level of more than $100,000 t$ which is nearly twice the long-term mean. The majority of the herring catches are taken in the small-meshed fishery for clupeoids.

## 3 BY-CATCHES IN THE INDUSTRIAL FISHERIES FOR SANDEEL, NORWAY POUT, AND BLUE WHITING IN THE NORTH SEA

Annual by-catches of the major Annex $V$ species, haddock, whiting, and saithe are presented in Table 3.1. Despite the fluctuations in estimated landings of each species over the years, there has been a decreasing trend in annual landings of the three species combined (Table 2.1).

In the previous report, maps showing by-catch of Annex $V$ species in the Norway pout and blue whiting fisheries were presented by statistical rectangles for the fourth quarter of 1984 and the first and second quarters of 1985. Although data were available in the files of the working Group, it was not felt appropriate to extend the sequence any further as the value of such detailed
information might be of rather limited use to the relevant working groups which meet shortly after. Members of these working groups bring forward these data themselves in the form they require.

The estimated species compositions of the Norwegian fisheries for Norway pout and sandeel are presented in Tables 3.2 and 3.3, respectively. Along with reduced annual landings in the Norway pout fishery in recent years, a shift towards blue whiting becoming the predominant species has taken place. Saithe has usually been the major Annex $V$ by-catch species. In the sandeel fishery, by-catch of other species amounts to only a tiny fraction.

## 4 NORWAY POUT

### 4.1 Landings

## North Sea

The landings by country for the years 1957-1986 are shown in Table 4.1.1. In 1986 the total landings amounted to $174,400 \mathrm{t}$. This figure is the lowest since 1969 and $11 \%$ less than in 1985.

Table 4.1.2 shows the landings by month in 1984-1986. Compared to 1985, the reduction in 1986 took place in the first three quarters, while a small increase was observed in the fourth quarter.

## Division VIa

Landings by country are given in Table 4.1.3. Except for Faroes and Scotland, neither of whom had any landings, data were not available for 1986.

## Division IIIa

Table 4.1 .4 shows the landings by country for the years 19711986. The landings in 1985 and 1986 are the lowest on record and only $35 \%$ and $20 \%$, respectively, of the average landings in the period 1971-1984.

### 4.2 Eishing Effort and Catch per Unit Effort

## Danish CPUE

The catch per unit effort of different size categories of vessels participating in the fishery for Norway pout (defined as trips consisting of more than $70 \%$ Norway pout and blue whiting by weight) are given in Table 4.2.1. The data were extracted from logbooks from a large proportion of the landings. In 1986, the data represented $73 \%$ of the landings (see Table 4.2.2). The data differ from those presented in last year's report because this year, the actual number of fishing days was used as a measure of fishing effort instead of the length of the trip. Except for
vessels above 300 GRT, the CPUE increased slightly from 1985 to 1986.

## Norwegian CPUE

Table 4.2 .3 presents the CPUE in hectolitres/days fishing/mean GRT in the fishery for Norway pout and blue whiting for 19761986. Corresponding data for the directed fishery for Norway pout (defined as landings containing at least $70 \%$ Norway pout by weight) are given in Table 4.2.4. Compared to 1985, both sets of data show a reduction of CPUE in the first quarter of 1986 and a slight increase in the third and fourth quarters.

The weighted annual means of these two series are shown in figure 4.2.1. In both series, the mean dropped from a level of 1.5-1.6 hectolitre per fishing day per mean GRT in 1982-1984 to a level around 0.9-1.0 in 1985-1986.

## Total Danish and Norwegian effort

Danish and Norwegian effort data were standardized to a vessel size of 200 GRT and combined using the methods outlined in the 1985 report.

It was assumed that the relationship between CPUE and GRT of the Danish data (Figure 4.2.2), could be described by the equation:

$$
\text { CPUE }=a_{\text {year }} x\left(G R T-G_{0}\right)^{b}
$$

where $b$ is a constant and a year depends on the gear. Inspection of Figure 4.2.2 shows that ${ }^{\text {a }}$ Curve through $(50,0)$ gives the best fit to the points. The log cPue values were analyzed using a general linear model (GLM in SAS) and a year and b were estimated. The analyses were performed for a numbeleał different $G$ values and $a G_{0}=50$ GRT was chosen since this gave the lowest residual error in ${ }^{\circ}$ the model. The results are given in Table 4.2.5.

The relationship between CPUE and GRT was then used to standardize both the Norwegian effort data (Table 4.2.6) and the Danish effort data to a vessel size of 200 GRT (Table 4.2.7). Compared to the average in the period 1982-1984, the total effort was reduced by $29 \%$ and $43 \%$ in 1985 and 1986 , respectively. This reduction took place mainly in the second and third quarters.

### 4.3 Natural Mortality

In its previous report, this working Group adopted an annual value of natural mortality of 1.6 from Bailey and Kunzlik (1984). This estimate was obtained in the period $1935-1955$ prior to the commencement of the fishery. Bailey and Kunzlik (1984) also reported an increase in $M$ with age in unexploited stocks, and it was recommended that an increase in $M$ with age should be considered by the Multispecies Working Group.

The latest report of the Multispecies Assessment Working Group contained the following estimate of the average natural mortality rate in 1978-1982:

| Age | $0^{1}$ | 1 | 2 | 3 |
| :---: | :---: | :---: | :---: | :---: |
| $M$ | 0.9 | 2.1 | 1.3 | 1.0 |
| ${ }^{1}$ Only third and fourth quarters. |  |  |  |  |

These estimates consist of two parts: predation mortality and residual mortality. The latter was inferred by assuming the predation mortality caused by predators not accounted for in the MSVPA to be distributed on species and ages in the same way as predation mortality caused by the tive predators dealt with in the analysis.

In the light of the evidence of increasing natural mortality with age caused by, for example, spawning stress, the working Group decided to retain the $M$ from last year of 1.6 for all ages as input to the VPA.

### 4.4 Catch at Age and VPA Results

The oatch in numbers at age by quarter is shown in table 4.4.1. Data for 1986 were available from Denmark and Norway. These data were combined and raised to the total landings.

As the total effort in the fourth quarter of 1986 was at the same level as the effort in the fourth quarter of 1985 (see Table 4.2.7), a preliminary VPA was run using the same input values of fishing mortality as last year. This, however, produced marked differences between the relative year-class strengths of 1 -groups estimated by VPA and by the IYFs. A second VPA was then performed in which the input Fs were tuned to produce year-class strengths in accordance with estimates obtained from a regression of VPA estimates of the 1976-1983 year classes against IYFS indices (Figure 4.4.1). This produced the fishing mortalities and stock sizes shown in Tables 4.4 .2 and 4.4.3. The biomass and spawning biomass time series are shown in Figure 4.4.2.

A comparison was then made between the unweighted average yearly fishing mortality of ages 0-4 and the total effort in the Danish and Norwegian fisheries (Figure 4.4.3). Assuming a linear relationship between $F$ and effort, the average 1986 fishing mortality comes out a bit lower than expected. Plotting total CPUE against average stock biomass gives the same result (Figure 4.4.4). The Working Group, however, agreed to retain the input $F s$, as increasing them would result in even lower estimates of biomass and thereby give a poorer fit to the linear CPUE and biomass relationship in Figure 4.4.4.

### 4.5 Research Vessel Surveys

Norway pout abundance indices from research vessel surveys are shown in Table 4.5. Indices for the 1986 year class were obtained from the English Groundfish Survey (EGFS) as O-groups in the autumn and the International Young Fish Survey (IYFS) as 1-groups in the following February. The distribution of Norway pout below 15 cm in the IYFS in 1987 is shown in Figure 4.5.1. As prelimi-
nary exchange tapes with 1987 IYFS length frequency data were available to the Working Group from 6 of the 8 countries participating in the IYFS in 1987, a more accurate calculation of the 1group index was obtained using preliminary age/length keys. The Working Group arrived at an index of 3,236 instead of the preliminary value of 3,273 presented in Table 4.5. The slight deviation of $1.14 \%$ was considered to be insignificant and has not been taken into account in further calculations.

Although the abundance of the 1986 year class was higher than that of the 1985 year class in both the EGFS and IYFS, the EGFS showed an increase of only $112 \%$ compared with $168 \%$ in the IYFS. The 1986 EGFS index was only $10 \%$ of the mean for the 1977-1985 year classes. In contrast, the 1986 index from the IYFS was $119 \%$ of the long-term mean.

Both surveys indicate that the 1986 year class is stronger than the weak 1985 year class, though the evidence from the two surveys are conflicting as to the degree of the increased strength.

The plot of the IYFS 1-group index vs the EGFS o-group index (Figure 4.5.2) suggests the 1986 point to be an outlier, which suggests that either the EGFS underestimated the abundance or the IYFS overestimated the abundance of this particular year class. It is suspected that the EGFS may not give a true estimate of ogroup Norway pout abundance since, at the time of the survey, some of the fish may still be in the pelagic stage of development and not available to the bottom trawl.

### 4.6 Weight at Age

The mean weights at age by quarters for age groups 0-4 are shown in Table 4.6.1.

The contribution by weight of each age group in each quarter to the total catch is shown in Table 4.6.2. In 1986, the 1 -groups made up $49 \%$ of the total catch by weight. This is somewhat less than the long-term 1-group mean between 1979-1985 of $65 \%$. The ogroup contribution of $22 \%$ taken entirely in the fourth quarter is much higher than the long-term mean of $4 \%$.

### 4.7 Catch Prediction

An updated SHOT estimate was made using data from 1974-1986. The updated formula is very similar to the one used last year. The new one is:

$$
Y(t)=0.309 Y(t-1)+0.0697 R_{1}
$$

where $Y(t)$ is yield in year $t, R$ is the estimate of recruitment from the 1 -group IYFS index (year class $t-1$ ) and $Y(t-1)$ is yield in year $t-1$. The "hangover" coefficient of 0.309 is based on the average proportion by weight of 2 -group and older fish in the catch between 1979-1986. A plot of the actual and predicted catches using the SHOT estimate is shown in Figure 4.7.

At the working Group meeting in March 1986, the predicted catch
for 1986 using the SHOT method was $200,000 t$. This compares with an actual catch of $175,000 \mathrm{t}$ in 1986 , $13 \%$ less than predicted. If fishing patterns and fishing level remain similar to those in previous years, the predicted catch for 1987 is $275,000 t$.

The working Group further attempted to predict a catch in 1987 based on the assessment presented in Section 4.4.

Two catch predictions were made using the standard ICES prediction program. In the first, it was assumed that the quarterly fishing mortality in 1987 would be equal to that of 1986. This gave a predicted catch of $235,000 \mathrm{t}$ in 1987. In a second prediction, the quarterly fishing mortality in 1987 was assumed to be the average of 1985 and 1986. This gave a total catch in 1987 of $320,000 \mathrm{t}$.

The Working Group could not find a preference for either of the two predictions since the effort in 1987 could not be predicted.

## 5 SANDEEL

### 5.1 Landings in 1986

## North Sea

Landings increased in 1986 to $851,000 t$, which is the highest catch ever recorded. The landings in 1986 were $18 \%$ higher than the mean landings in the most recent decade of $720,000 t$. The data are given in Table 5.1.1. Table 5.1.2 shows the catch by month for Denmark, Norway, and the UK. It shows that catches for each month were higher in 1986 than in 1985 and 1984, especially in July and August. The fishing season for sandeel is very concentrated with $40 \%$ of the catch taken in June and $94 \%$ taken from April to July. UK (Scotland) landings from the Shetland fishery were reduced $30 \%$ from 1985 to 1986 to the lowest level since 1973.

The landings in 1986 by month and area are given in Table 5.1.3 and landings by area for the period 1972-1986 are shown in Table 5.1.4. The standard areas used by this working Group for sandeel are shown in Figure 5.1.

Table 5.1.4 shows that the high 1986 catch is a result of high catches in almost all areas. However, the catch in Areas $2 B$ and 3 increased markedly (see Figure 5.1).

## Di.vision VIa

Scottish landings from Division VIa again increased, rising from $18,600 \mathrm{t}$ in 1985 to $24,469 \mathrm{t}$ in 1986 (Table 5.1.5).

## Division IIIa

The landings from Division IIIa are given in Table 5.1.6. Landings of sandeel from Division IIIa were $67,000 t$ in 1986 , which is more than double the average catch in 1976-1985. The high catch in this area compares with the very high catches in the adjacent North Sea Areas 2 B and 3 .

### 5.2 Fishing Effort

Fishing effort data were available from Denmark, Norway, and UK (Scotland). Danish effort data were only available for the years 1982-1986. Before 1982, there were no effort data for the southern area. The northern area is covered by Norwegian CPUE data of about $40 \%$ of the total international catch. Table 5.2.1 summarizes the coverage for the southern and northern areas.

Effort data for the Norwegian fishery are given in Table 5.2.2. The Danish cPUE data were supplied for a number of vessel groups. Firstly, data were analyzed in order to standardize effort according to vessel size using similar analyses as for Norway pout in Section 4.2.

Figure 5.2 shows the CPUE (tonnes/days fishing) in the first half of the year in the southern area for each vessel group. Separate symbols are used for each year.

It was decided to fit a multiplicative model to the data

$$
\operatorname{CPUE}(y, G R T)=a_{Y} \times \operatorname{GRT}^{b}
$$

where $y=$ year and GRT $=$ gross registered tonnage.
The CPUE for the largest vessel group (above 300 GRT) in 1986 seems to be higher than the CPUE Jevel for that group in earliex years. This is probably due to an increase in the number of very large trawlers of about 800 GRT in this category. It was, therefore, decided to exclude 1986 from the estimation of the multiplicative model.

The results of the analysis of variance are shown in Table 5.2.3. It appears that the annual effects and the power term are significant and good explanatory variables.

The estimates are:

$$
\begin{gathered}
\text { CPUE }=a_{Y} \times \text { GRT } 0.52 \\
a_{82}=3.11 \\
a_{83}=2.77 \\
a_{84}=3.28 \\
a_{85}=2.72
\end{gathered}
$$

The estimated fishing power function was then used to standardize the fishing effort to a $200-G R T$ vessel by multiplying the fishing days in each category with the appropriate factor.

## Southern area

The standardized number of fishing days for each half-year period since 1982 was calculated for the Danish data. The fishing effort data were raised to the total international catch and the results
are shown in Table 5.2.4. It appears that fishing effort in 1986 was reduced to the 1982-1983 level after the relatively high level of fishing effort in 1985.

## Northexn area

The number of fishing days for each vessel group in the Danish fleet was standardized to a $200-G R T$ vessel. The Norwegian fishing effort is given as the total number of fishing days for the fleet together with the average GRT of the fleet. This effect is also standardized to a 200 -GRT vessel. The two series are shown in Table 5.2.5. The gatoh per fishing day differs significantly for the Danish and Norwegian fleets. This could not be explained, but is probably due to differences in the definition of number of fishing days as well as actual differences in CPuE. In order to combine the two sexies, it was decided to scale the Danish cpue for 1982-1986 to the mean value of the Norwegian data. The combined CPUE was then used to calculate the total international effort. It is seen from Table 5.2.5 that the fishing effort increased markedly in 1986 compared to the years 1982-1985.

## Shetland

In the shetland area, the number of days fishing by scottish boats decreased $36 \%$ to the lowest level since the fishery began (Table 5.2.6). For the first time, Danish landings were reported from this area, and effort was allocated on the basis of scottish catch and effort data (Tables 5.4 .3 and 5.2.6) for the relevant months and is shown in Table 5.2.7. Including Danish effort, the number of days fishing in the shetland area was reduced by $21 \%$, compared with the previous year, to the lowest level since 1979 (Tables 5.2.6 and 5.2.7).

Division VIa
Fishing effort for Division VIa is given in Table 5.2.8 and shows an increase of $12 \%$.

### 5.3 Natural Mortality

The 1986 Industrial Fisheries working Group adopted values of $M$ at age for sandeels which were consjistent with the values determined as an 11-year mean (1974-1984) by the ad hoc Multispecies Assessment working Group (Table 5.3). These values were also in general agreement with annual values of $M$ determined in other ways (i.e., catch curve analysis from the early years of the fisheries).

The current working Group similarly decided to adopt the most recent MSVPA values of $M$ at age (Anon., 1987) which are given in Table 5.3 as 5-year means (1978-1982). In particular, it was decided to use these values for the $0-$ and 1 -groups and to adopt, for the older age groups, a smoothed MSVPA value. The 1987 Industrial Fisheries Working Group values of $M$ at age are shown in Table 5.3. The Working Group felt justified in adopting the increased values of $M$ at age (small increases for ages $\geqslant 1$ ) as the 1986 MSVPA values now take account of predation by "other" predators such as seabirds, seals, and additional fish stocks
(e.g., Raja spp. and Western stock mackerel). The division of $M$ between the two halves of the year is similar to the previous year's partition, i.e., exclusively in the second half for 0group, approximately 5:1 for 1 -group, and $2: 1$ for older ages for the first and second half years, respectively.

### 5.4 Catch at Age and VPA

### 5.4.1 Catch at age

## Southern and northern areas

Data on catch and age were supplied by Denmark, Norway, and UK (Scotland). The Norwegian catches in the southern areas were allocated using Danish data. The Faroese catches were assumed to have been taken in the southern areas in the second quarter and were allocated using appropriate Danish data.

The catch in numbers at age for the years 1980-1985 are given by month or quartexs in Tables 5.4.1-5.4.3. The catches were dominated by 1 -group sandeel in both the northern and southern areas.

The catch of o-group in the second half of 1986 was low in the southern areas, whereas the catch of o-group in the northern areas was on the same level as in 1974-1982.

## Shetland

Danish catches in the shetland area (Table 5.4.4) were allocated to numbers at age using $u k$ (Scotland) data for March, June, August, and september. UK (Scotland) catches in the Shetland area (Table 5.4.3) showed significant numbers of O-group (58\%) to be present.

A revision of the Shetland catch-at-age data base was made and is shown in Table 5.4.12. The revision was necessary due to changes made in the UK (Scotland) procedure for raising data from samples to catches over the Shetland area. Formerly, samples taken on the basis of ICES statistical rectangles were pooled and raised according to the total catch from the entire area. Lately, samples have been raised to the catch from the statistical rectangle from which they were taken and the data summed over all rectangles. UK (Scotland) catch in numbers at age raised in this way has been reported to the Working Group since 1984. To be consistent, the Shetland catch-at-age data have now been revised for the period 1974-1983. The effects of revision are shown in figure 5.4.1 using results from VFA on both sets of data (1974-1985) incorporating the 1986 Industrial Fisheries Working Group values of M and input $F$ (Anon., 1986a). It is apparent that revision has little effect on anything other than recruitment in 1974 and total stock biomass in 1975.

## Division VIa

Catch in numbers at age for the years 1980-1986 is given by quarter in Table 5.4.5. The catch in 1986 was predominantly O-and 1-group.

### 5.4.2 Input fishing mortality

For each area, the effort data were used to calibrate the VPA.

## Southern area

From earlier VPAs, it was noted that the fishing pattern on the 1 - and 2 -group sandeel in the first half of the year seemed to alternate in two consecutive years when a good year class appeared. In the first year when the "good" year class was 1group, the fishing mortality was only moderately higher on the $2-$ group than on the 1 -group. However, in the second year when the "good" year class had become 2 -group, the fishing was concentrated on this one, thus giving a much higher (factor of 5) fishing mortality on the 2 -group than on the 1 -group. This phenomenon appeared in 1978-1979, 1982-1983, and 1984-1985. The year 1986 was similar to the first year in such a pair of years showing a very high catch of 1 -group. The fishing pattern in the first half of 1986 was, therefore, estimated as the average fishing pattern for the "first years" 1978, 1982, and 1984. The estimated fishing was:

| Age | 0 | 1 | 2 | 3 | 4 | 5 | 6 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $F$ | 0.35 | 0.60 | 0.60 | 0.60 | 0.60 | 0.60 | 0.60 |

A trial run was used to estimate the biomasses in the period 1982-1986 using points in 1982-1985 to fit a linear regression between CPUE and biomass as of 1 January. The CPUE data are found in Table 5.2.4 and the plot is shown in Figure 5.4.2.

Only four points are available and only a rough estimate of the 1986 biomass can be obtained. It was decided to tune the VPA to a 1986 biomass of 2 million $t$. This value is supported by the calculated fishing effort in 1986 (see Table 5.2.2). This value is lower than the fishing effort in 1982 and 1984, which is in agreement with the lower 1 -group mortality in 1986 compared with 1982 and 1984.

## Northern area

The Danish and Norwegjan effort data were combined to a series of effort data covering the period 1976-1986. The data are shown in Table 5.2.5. The coverage jn 1976 and 1977 were, however, limited (see Table 5.2.1) and it was decided to use only data from 19781986. The fishing pattern for the first half year was estimated from the average fishing mortality in the period 1972-1981. This period was chosen because catches were on the same high level as in 1986. The fishing pattern for the first half year was estimated to be:

| Age | 0 | 1 | 2 | 3 | 4 | 5 | 6 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| F | - | 0.50 | 0.65 | 0.65 | 0.65 | 0.65 | 0.65 |

The biomass as of 1 January was estimated from a trial run and plotted against the CPUE. The regression through the origin was estimated and the 1986 biomass was calculated using the observed 1986 CPUE. The VPA was tuned to this biomass of $400,000 t$ as of 1 January 1986, and the corresponding plot is shown in Figure 5.4.3. Except for the data point for 1979, the plot shows a good linear relationship.

## Shetland area

Fishing effort (days absent) was used to estimate appropriate input $F$ values for the second half of 1986 . Converged values of $F$ (1974-1982) from a trial VPA run were correlated with effort, and input $F$ values were established using the relationship obtained and 1986 effort data. F for the second half of each year was significantly correlated with effort in the same period for the years 1974-1982 (Figure 5.4.4) and resulted in a predicted input $F_{0}$ of 0.060 for the second half of 1986 . F ${ }_{1}$ in the first half of each year (1974-1982) was significantly correlated with effort in the relevant periods (Figure 5.4.4) and predicted an $F_{1}$ value of 0.14 for the first half of 1986 . To obtain this, an input $F_{1}$ of 0.055 was used in the second half of 1986. similarly, the weighted mean $F_{2-5}$ in the first half of each year was significantly correlated with effort in the relevant periods (1974-1982) and predicted a weighted mean $\mathrm{F}_{2-5}$ of 0.17 in the first half of 1986. To obtain this, an input $F$ value of 0.019 was used for all ages $\geqslant 2$ for the second half of 1986 .

## 5.4 .3 VPA results

VPAs were carried out separately for each assessment area using the values of $M$ given in Section 5.3.

Long-term mean values of weight at age were used in the calculation of stock biomass and spawning biomass.

## Southern area

Catch-at-age data used as input to the VPA are shown in Table 5.4.6. The estimated fishing mortalities are given in Table 5.4.7 and estimated stock sizes in Table 5.4.8. The time series of total biomass, effort, and fishing mortality are shown in figure 5.4.5.

The total biomass of sandeel in the southern North Sea is estimated to have been increasing during the 1970 s and has varied around 1.6 million $t$ since 1982 . The biomass has, however, alternated between 1.2 million and 2.0 million $t$ every second year because of the strong 1981, 1983, and 1985 year classes.

Fishing mortality ( $\vec{F}_{\mathcal{F}}$ 4, Eirst half) has varied between 0.4 and 0.5 since the mid- $\overline{9}^{9} 70 s$. Apparently fishing mortality decreased
in 1986 to 0.3. It should, however, be borne in mind that the assessment in the southern area is based on a relatively short time series of effort data.

## Northern area

Catch-at-age data, estimated fishing mortalities, and stock sizes are shown in Tables 5.4.9, 5.4.10, and 5.4.11. Total biomass, effort, and fishing mortality are shown in Figure 5.4.5. The total biomass recovered in 1986 to a level of $400,000 \mathrm{t}$, similar to that in the 1970s. The estimated biomass in the period 19811985 was around $250,000 \mathrm{t}$.

Fishing mortality has shown considerable variation from year to year between values of 0.3 to 0.8 . Fishing mortality is estimated to have been increasing since 1983 and was close to 0.9 in 1986.

Fishing mortality varies abruptly from year to year in the northern area. A possible explanation for this is the indicated co-variation with the fishing mortality in the southern area (see Figure 5.4.5). When fishing mortality in one year is high in one area, it tends to be low in the other area. This was to be expected because the fleet has a limited effort to allocate to each area.

The general concept of two stocks being fished by one fleet can also explain the varying fishing mortalities in the northern area. The stock size in the northern area is $1 / 4$ of the stock size in the southern area and annual redistribution of fishing effort between these two areas will cause a more fluctuating fishing mortality in the northern area than in the southern area.

## Shetland area

Catch-at-age data used in the VPA are given in Table 5.4.12. Estimated values of fishing mortality are given in Table 5.4.13 and stock size in numbers and biomass in Table 5.4.14. It was noted that the weighted $F_{(2-5)}$ in the first half of 1986 compared to the first half of $19 \overline{8} 5$ is an apparent contradiotion to the decrease in effort in this period.

The results indicate that $F$ during 1985 and 1986 was much lower than the levels of 1981 and 1982. Total stock biomass is much reduced from the peak of 1984 (Figure 5.4 .6 ) and spawning stock biomass has also fallen since 1985 (Figure 5.4.6). This is a result of the lessening influence of the good 1981 and 1982 year classes. The high proportion of spawning stock biomass to total biomass ( 0.76 ) in 1986 reflects the poor 1985 year class (the lowest since 1974) and a level of recruitment in 1986 which was no better than average. This suggests that the spawning stock biomass will continue to fall in 1987, but the level of total stock biomass in 1987 will depend largely on the level of recruitment in 1987.

## Comparisons with previous years and all stooks

Comparisons of the absolute levels of biomass in the 1986 and 1987 assessments are difficult because of the use of revised levels of natural mortality. In addition, the data base for the

Shetland stock has been revised. As seen in Figure 5.4.1. this revision has not had a large impact on the estimated stock sizes.

A comparison of the long-term trends in the southern stock shows similarities between the 1986 and 1987 assessments. The stock size as of 1 January 1986 was estimated to be about 2 million $t$ in both assessments. The 1982 year class has, however, been revised downwards considerably in the 1987 assessment which gives lower stock sizes in 1984 and 1985.

The 1987 assessment in the northern area suggests generally a lower stock size of the individuals but a higher recruitment in recent years compared to the 1986 assessment.

The 1986 assessment pointed to a decrease in biomass of the Shetland stock since 1983. The 1987 assessment suggests a steeper decline after 1984. The general biomass trends are, however, similar in the two assessments.

### 5.5 Weights at Age

These are available for 1986 from the North Sea areas, Shetland, and Division VIa [UK (Scotland) data] and are shown in Tables 5.5.1-5.5.4.

### 5.6 Catch Predictions

Since reliable estimates of recruitment to the sandeel stocks are not available, predictions of the catches in 1987 were not made.

The stock size in the southern area in 1987 is similar to the estimated stock sizes in 1985 and 1983, dominated by a strong 2group. Thus, there is no reason to expect catches below the 1983 and 1985 levels of 400,000-500,000 $t$. The catches in the northern area are likely to decrease from the high 1986 level. The spawning stock is estimated to be very low and the catch will depend strongly on the recruiting year class.

The moderate recruitment to the sandeel stock in the shetland area in recent years will probably result in a further decrease in the biomass. It is, therefore, likely that catches will remain at the present low level in 1987.

## 6 SPRAT IN DIVISION IIIa

### 6.1 Landings

Table 6.1 shows the landings by areas and country from 1974-1986. The figures are based upon data provided by working Group members and have no official standing.

In 1986, landings declined to about 20,000 $t$, including landings from Norwegian fjords being $2 / 3$ of the 1985 figure, and representing the lowest figure in the 13 -year period shown in the table. Danish landings were reduced by about $80 \%$, while Swedish
landings increased by perhaps $16 \%$. In the latter case, insufficjent sampling introduced some uncertainty regarding actual industrial landings of sprat both in 1985 and 1986.

Norwegian landings from the fjords along the west coast of Norway declined by about $75 \%$.

### 6.2 Fishing Effort

No data were available to the working Group.

### 6.3 Catch at Age and VPA

No catch-at-age data were available.

### 6.4 Research Vessel Surveys

### 6.4.1 Acoustic surveys

A summary of the earlier acoustic estimates of the sprat stock was given in the 1986 Working Group report. In 1986, surveys were carried out in August and september by Denmark and sweden (Kirkegaard et al., 1987), and in November by Norway (Aglen, 1987). The biomass estimates from these surveys, less than 2,000 $t$, indicate that the stock is still at a low level.

### 6.4.2 International Young Fish Surveys

Final indices of 1 -group and $>2$-group sprat from the 1987 survey were available to the Group. The distribution of the 1-group sprat is shown in Figure 7.4.2 and the indjces are given in Table 6.4. The 1-group index of 1,830 in 1987 indicates that still another weak year class is recruiting to the stock.

In contrast, the index of older sprat $(16,543)$ is the highest on record. This high index is, however, to a large extent based on one very large catch which accounts for about $75 \%$ of the index. Moreover, the survey in 1986 did not suggest a strong 1985 year class. The index is, therefore, not likely to reflect a proportional increase in the older sprat stock.

### 6.5 State of the Stock and Catch Prediction

The development of the sprat stock in Division IIIa was discussed at the sprat Biology Workshop. A brief discussion can be found in Section 7.7 of this report. All stock indicators such as landing statistics, IYFS indices, and acoustic estimates show that the stock is at a low level. The total landings in 1986 were reduced by $35 \%$ compared with the landings in 1985 and are the lowest recorded since 1974. The acoustic estimates of the stock are very low, and a stock at this low level could not be estimated with the present coverage and design of the surveys. The 1986 year class is indicated to be weak and the stock could not be expected to recover in 1987.

The preliminary landings in 1986 of 18,000 t are the same as the landings predicted by the sHot estimate (Anon., 1986a). A comparison of predicted landings by the SHOT method versus actual landings is shown in Figure 6.5. Assuming no changes in fishing mortality in 1987 and using the index of 1 -group sprat and the preliminary landings in 1986, the same SHOT estimate is obtained as in the previous report:

$$
Y(t)=0.228 Y(t-1)+14.52 R_{1}
$$

Landings in 1987 are estimated at $32,000 \mathrm{t}$, including an assumed level of catch of 0 -group sprat as in previous years.

## 7 NORTH SEA SPRAT

### 7.1 Landings

Table 7.1.1 gives landings of sprat by nation and reporting areas as shown in Figure 7.1. The landings in 1986 were about $17,000 t$, a reduction of $33,000 t$ compared to 1985 and the lowest recorded catch since 1950.

A major part of the catch, about $10,000 t$, was taken by Denmark in Sub-division IVb east, and about 4,000 $t$ was taken by England, mainly in the Thames estuary.

Table 7.1 .2 shows the 1986 catches by quarter for Denmark and the UK, accounting for nearly the total catch. About $80 \%$ was taken in the first and second quarters, and in comparison with 1985, a relatively small proportion was taken in the fourth quarter of 1986.

Landings of sprat from Division VIa (Table 7.1.3) in 1986 were only 509 t, a marked decline from previous years.

### 7.2 Fishing Effort

No effort data were available.

### 7.3 Catch at Age

The sampling problems which were described in last year's report continued in 1986. Catch-in-numbers-at-age data were only available for English sprat catches, of which $98 \%$ were derived from the Thames area, and from the very modest Scottish landings mainly taken in Firth of Forth and Moray Firth. As neither can be taken is being representative of the total North sea catch of sprat, about $75 \%$ of which is taken in the eastern part of the North Sea, the Working Group decided not to attempt any construction of an age distribution such as was done in last year's report.

Multispecies Working Group in continuing the MSVPA data set even if no age composition data from the sprat catches are available. It will be attempted to construct an age composition using recruitment survey information in connection with reported catch-at-age data. The Multispecies Working Group must be made aware of the possible errors in this procedure.

### 7.4 Research Vessel Surveys

### 7.4.1 Acoustic surveys

Most of the North Sea and Skagerrak-Kattegat was covered by Norwegian acoustic surveys during November 1986. Data from the area north of 60 N were, however, excluded because of bad weather and poor sampling. The surveys were primarily aimed at herxing, but sprat was included in "mixed" echo-integrator values. The echo fraction (EF) of sprat was calculated from trawl samples as:

$$
E F=\frac{\sum_{1} L_{1}^{2} \times N_{1} \text { (sprat) }}{\sum_{1} L_{1}^{2} N_{\text {al }}(\text { total })}
$$

where $N_{1}=$ no. sprat length $I_{1,} N_{\text {l }}=$ no. all species length $L$, and averaged within each of $10^{1}$ sub-areas. The sprat echo fractions ranged between 0.02 and 0.68 , lowest in the skagerrakKattegat and the northwestern North sea and highest in the western central North Sea. The sprat integrator values were converted to biomass by applying:

$$
\mathrm{TS}_{\mathrm{kg}}=-8.7 \log \mathrm{~L}-19.6 \mathrm{db} \quad \text { (Anon., 1983) }
$$

and to numbers by applying:

$$
T S_{\text {ind }}=20 \log L-69.8
$$

where $L$ is length.

Figure 7.4.1 shows the estimated biomass of sprat by statistical rectangle. The vast majority of the biomass was 1986 year class. Samples showed that the 1986 year class had a modal length of 4-5 cm in most areas. The total biomass was estimated to be in the order of $20,000 t$. Due to imprecision of acoustic surveys when the stock biomass is low and the broad survey grid particularly in the coastal areas, this survey can be taken only as indicative of the poor state of the sprat stock.

In January-February 1987, Scotland conducted a survey for sprat in coastal areas, including Moray Firth and Firth of Forth. Sprat occurred together with juvenile herring, and the highest concentrations were found in the firths. No abundance estimates were available to the working Group.

### 7.4.2 International Young Fish Surveys

Preliminary data from the IYFS in February 1987 were available to the Working Group based on the compilation of 530 hauls. Distribution of sprat by statistical rectangles was presented as no. /hr both for fish $<10 \mathrm{~cm}$ and for total sprat (all length groups).

The distribution of the former group ( $<10 \mathrm{~cm}$ ) is shown in figure 7.4.2. Compared with 1986, the catches per hour are in general very much higher in 1987 and there is a tendency of high concentrations closer to the shore.

The 1987 1-group index for Division IVb was 809 or more than 11 times the 1986 index. Indices since 1972 are shown in Table 7.4, and it appears that the 1987 index is of the same order of magnitude as the average in the 5-year period 1976-1980, when landings were still high.

The 1987 index for "sprat all ages" was calculated from available preliminary data on the number of sprat (all length groups) per 1 hr haul relating to 142 sampled rectangles. This index was 1,500 which is substantially higher than that for 1986. The index for "sprat all ages" was dominated by a very high catch of 1986 yearclass sprat in one square outside Division IVb (35F5). This square contributed substantially to the total North Sea index for all age groups. The abundance of old sprat is, however, still poor since $90 \%$ of the index of "sprat all ages" is attributable to 1-group sprat.

### 7.4.3 Discussion

The acoustic survey (Section 7.4.1) in November 1986 indicates that o-group sprat occurred mainly in the western part of the North Sea (Figure 7.4.1). The 0-group was distributed in the upper water layers and the modal lengths were mainly $4-5 \mathrm{~cm}$.

The IYFs in February 1987 showed a very different distribution. Nearly all 1986 year-class sprat were found at that time in the southeastern North Sea (Figure 7.4.2). In areas of high concentration, the 1986 year class had a modal length of $7.0-8.5 \mathrm{~cm}$.

It seems unlikely that differences between November 1986 and February 1987 can be explained by a large shift in distribution and an average individual length increase in winter of about 4 cm . It should be noted that the IYFS is based on the use of a GOV bottom trawl having a mesh size of about 36 mm , except for the cod end which has a small-meshed liner. For this reason, it seems possible that a small-sized (4-5 cm), pelagically-distributed component of the 1986 year class could occur unrecorded by the IYFS.

Similar sized o-group sprat have been observed during previous winter surveys (e.g., Aglen and Iversen, 1980; Iversen et al., 1981). The origin of these small sprat remains unknown, and although very abundant in some years, their contribution to the fishery of 1 -year-olds the following season is not known. The Group, therefore, found no basis for assuming higher recruitment from the 1986 year class than that indicated by the IYFS 1 -group
index, but draws attention to the fact that this index might neglect one component of the stock.

### 7.5 Predation Mortality

The Multispecies Assessment Working Group has provided a new set of natural mortality estimates for sprat (Anon., 1987). The new values are higher than the ones previously reported, mainly due to adding more predators such as seabirds, seals, and the western mackerel stock to the MSVPA model. The new values, the values previously reported, and the $M$ values used by this Working Group in earlier years are given below:

|  | $\mathrm{M}^{\left(\mathrm{M}_{1}+\mathrm{M}_{2}\right)}$ |  |  |
| :--- | :---: | :---: | :---: |
|  | This | MSVPA | MSVPA |
| Age | WG | 1986 | 1987 |
| 0 | 0.8 | 0.35 | $0.76^{1}$ |
| 1 | 0.8 | 0.77 | 1.20 |
| 2 | 0.8 | 1.44 | 1.87 |
| 3 | 0.8 | 0.46 | 0.81 |
| $4+$ | 0.8 | 0.56 | 0.93 |

${ }^{1}$ only third and fourth quarters.
The new $M$ values are in better conformity with earlier analyses of $M$ found to be 0.8 on fully-recruited age groups and very close to the values used in VPA runs for all age groups except the 1 and 2-groups.

The Working Group noted, however, that the marked differences in values of $M$ for the 1 - and 2 -groups still persist. In the 1986 meeting, the Group could not find a biological explanation for a selective prediction on these age groups if they were equally exposed to the predators. A selective predation could, however, be explained by different distribution of 1 - and 2 -group sprat in relation to the distribution of the main predator whiting.

Distributions by age from the IYFS surveys were analyzed and these suggest that 2 -group whiting and 2 -group sprat are more overlapping than 2 -group whiting and 1 -group sprat. The Group felt that the difference in natural mortality between 1 - and $2-$ group sprat could reflect a difference in exposure of these age groups and that a further study of the distribution of predators and prey should be encouraged. The charts will be made available to the Multispecies Working Group.

### 7.6 ICES Sprat Biology Workshop

The terms of reference for the Sprat Biology Workshop were discussed at the 1986 meeting of the Working Group. The Group stressed the need to concentrate on subjects of relevance to assessment problems. The Sprat Biology Workshop met in Bergen 4-7 November 1986. A first draft report of the Workshop was presented to the working Group. Although this report had not yet been for-
mally adopted by all Workshop participants, it formed the basis for the discussion.

It was noted that during periods of low abundance, sprat are only found in concentrations in some coastal areas. This is also the present situation as illustrated by Figure 7.4.2. The Workshop found that the concentration areas are unlikely to constitute separate stock units, since discrete spawning locations cannot be identified and the larvae are distributed over a wide area. All characters examined (growth, meristics, and genetics) demonstrated large variability, and no basis for stock separation was found. Differences appeared related to very small groupings, transient in nature.

The Workshop analyses, therefore, gave no basis to establish stock units of a more permanent character needed for fisheries management. Although the present system has little biological justification, no alternatives can be suggested.

The Workshop provided a comprehensive description of the changes in abundance and distribution of sprat since the early 1960s. It is clear that a significant decrease in spawning stock size and in recruitment occurred in the northwestern North sea between 1978 and 1980. In the central North sea, there is evidence of a progressive decline in the population some years later, with a concurrent shift in the centre of abundance towards the southern and southeastern North sea. In the Skagerrak and Kattegat, a series of weak year classes in the 1980 also resulted in a marked stock decline in this area.

The increase and subsequent decrease in sprat abundance apparently occurred almost simultaneously over a large area reaching from the North sea via skagerrak/Kattegat into the Baltic. This lod the Workshop to suspect that the fisheries were unlikely to be the major cause of the stock decline. Evidently, environmental changes in the Noxth sea took place during the period of reduced sprat abundance, and although the Workshop was unable to identify the relationship, it was felt that the observed stock fluctuations are likely to be linked to longer-term environmental changes. Corten (1986) expressed similar views and found that the decline in the sprat stock was not directly related either to the changes in the herring stocks or to fishing.

The Workshop described the occurrence of bimodal $I_{1}$ distributions and noted the presence of exceptionally smallo-group sprat, varying in relative importance by area and time. It seems possible that sprat larvae may overwinter without laying down a recognizable otolith ring. Consequently, age readings become unreliable. The origin of such small o-group sprat was discussed by the Workshop and further by the present Working Group based on the recent observation of small 1986 year-class sprat in the North Sea.

### 7.7 State of the Stock and Catch Prediction

As outlined in Section 7.3, catch-at-age data are not available and an assessment of the stock cannot be based on a VPA.

All indicators of stock size indicate low abundance. The 1986 total landings of sprat from the North Sea were only $16,000 t$, a record low since the early 1950s. The 1986 landings were half that predicted by the SHOT estimate, but as noted by the working Group (Anon., 1986a), these estimates have overestimated catches in recent years. The acoustic survey in November 1986 indicates that the total stock biomass in the North Sea remains low. This is further supported by the results of the IYFS in February 1987 in which 2 -group and older sprat were scarce (Section 7.4).

The index of recruitment from the same survey (1-group, Division IVb, Table 7.4), based on sprat $<10 \mathrm{~cm}$, is substantially higher than the previous index and also somewhat higher than the average index during the 1980 . This indicates that the 1986 year class appears to be improved compared to recent year classes.

According to the IYFS, the stock situation at the beginning of 1987 is characterized by a total dominance of $6-8 \mathrm{~cm} 1$-group sprat with a distribution restricted to the southeastern North sea. It is, however, noticed that the small sprat, about 4 cm , observed in the acoustic survey in November were observed only in the northern part of Divisjon IVb during the IYFS (see section 7.4.2).

It is noticed that the SHOT method has overestimated the actual catches in 1983 and onwards by about $68 \%$ on average (Figure 7.8). This implies that fishing mortality has been reduced since the period 1976-1983. The introduction of the sprat box, enforcement of strict by-catch rules, as well as a diversion of effort to the more abundant herring stock in the North Sea corroborates the opinion that a reduction in fishing mortality has occurred.

The basic assumption of a constant fishing mortality in the SHOT method is, therefore, not fulfilled, and the Group decided that the present SHOT equation could not be used for catch predictions in 1987. In this situation with changing fishing mortality and no catch-at-age data for 1985 and 1986 , it was not possible to improve the SHOT estimate using the updated time series.

The recruiting year class is indicated to be considerably stronger than the 1985 year class and the fishing possibility in 1987 will be improved compared to 1986 . The stock of 2 -group and older will, however, be at a low level, and the fishable stock will be largely dependent on the 1986 year class.

8 CHANNEL SPRAT (Divisions VIId,e)

### 8.1 Landings

The nominal catches of sprat for Divisions VIId, e for 1976-1986 are shown in Table 8.1.1. In 1986, the only country to report catches from one area was the UK (England and Wales), whose catch of $1,084 t$ was only $36 \%$ of that reported in 1985 and $14 \%$ of the long-term mean for 1976-1985 for all countries. The fishery was mainly prosecuted in Lyme Bay by pelagic trawlers. Most of the catch was taken in December ( $38 \%$ ), though significant catches were also taken in October ( $30 \%$ ), November ( $18 \%$ ), and September (13\%) (Table 8.1.2). This corresponded closely with the pattern
of catches in the previous ten years.

### 8.2 Fishing Effort

As stated in last. year's report, there is no time series of fishing effort data in the area. Catches have declined significantly in 1986, and in the absence of any further evidence, it must be assumed that fishing effort has not increased and may even have declined.

### 8.3 Research Vessel Surveys

No research vessel surveys were conducted durjing 1985-1986.

### 8.4 Catch at Age

The age compositions of the catches for the seasons $1966 / 1967$ to 1986/1987 are shown in Table 8.4. The bulk of the catch in 1986/ 1987 consisted of $2 / 3$-group fish of the $1984 / 1985$ year class which accounted for $53.5 \%$ of the catch in numbers, though 3/4group fish of the $1983 / 1984$ year class were still present, making up $31.7 \%$ of the catch. Numbers of $0 / 1$ - and $1 / 2-$ group fish were very small and the indicatjons are that the recruiting year class is very weak.

### 8.5 Weight at Age

Table 8.5 shows the average weight by quarters and by seasons for the period 1973-1986. The average weight at age was only available in the fourth quarter in 1986. The overall average weight was higher than in the equivalent quarter in 1985, partly because the average weight of the $1 / 2$-group to $4 / 5$-group fish was higher and partly because of the high proportion of older fish in the catch.

### 8.6 Percentage Weight in the Catch

The seasonal percentage weight in the catch for the seasons 1976/ 1977 to $1986 / 1987$ is presented in Table 8.6 . In $1986 / 1987$, $50 \%$ of the total weight was composed of $2 / 3-g r o u p$ fish. The continuing importance of the 1983/1984 year class to the fishery is shown by the contribution of $34.8 \%$ by weight of $3 / 4$-group fish to the catch.

### 8.7 VPA and Catch Prediction

In the last report, the Working Group decided that, since the relationship between the Lyme Bay sprat population and those further offshore was not known, a VPA assessment for the Lyme Bay area based only on UK landings should not be carried out. Since then, no additional information on stock identity has been brought forward, and the working Group decided, therefore, not to include a VPA assessment for the stock in this year's report.

An attempt was made to provide a short-term prediction by correlating the catch in number of a year class in year $n$ with the catch of the same year class in year $n+1$. In the absence of effort data, the assumption had to be made that effort was constant over the time period. The following correlations were obtained:

> Age $0 / 1$ to predict age $1 / 2: r=0.105, n=19$
> Age $1 / 2$ to predict age $2 / 3: r=0.241, n=20$
> Age $2 / 3$ to predict age $3 / 4: r=0.759, n=20$
> Age $3 / 4$ to predict age $4 / 5 ; r=0.676, n=20$
> Age $4 / 5$ to predict age $5 / 6: r=0.393, n=20$

The only possibility of prediction from this method is for ages 3/4 and 4/5. Howevex, between the 1976/1977 and 1986/1987 seasons, the mean contribution by these two age groups was only $32.4 \%$ by number and $39.6 \%$ by weight. This, as a method of shortterm forecasting, thus proved unsuccessful. With the gradual disappearance of the 1983/1984 year class from the fishery and the weakness of the following year classes, it is likely that catches in 1987/1988 will be below the level of $1986 / 1987$.
