## 1 INTRODUCTION

### 1.1 Participation

| H. Gislason (Chairman) | Denmark |
| :--- | :--- |
| J. Lahn Johannessen | Norway |
| P. Lewy | Denmark |
| K. Popp Madsen | Denmark |
| S. Reeves | UK (Scotland) |
| D. Skagen | Norway |

### 1.2 Terms of Reference

At the 78th Statutory Meeting it was decided (C.Res.1990/2:5:10) that the Industrial Fisheries Working Group should meet at ICES Headquarters from 20-27 March 1991 to:
a) assess the status of the stocks of the target species in the industrial fisheries, ie., sprat in Sub-area IV and Divisions IIIa, VIa, and VIId,e and Norway pout and sandeel in Sub-area IV and Divisions IIIa and VIa, and advise on the need for any management measures;
b) consider the report of the Multispecies Assessment Working Group and provide the data requested by that Working group;
c) estimate quarterly quantities and geographical distribution of by-catches of blue whiting, herring, cod, haddock, whiting, mackerel, and saithe taken in the fisheries for Norway pout, sandeel, and sprat in the North Sea and adjacent waters.

In addition, ACFM at its May and November meetings in 1990 asked the Group to consider sandeel stock/recruitment relationships, 'safe' levels of SSB/R for sandeel, the evidence for the separation of the sandeel in the North Sea into northern and southern stocks, and the biological basis for future scientific advice on North Sea sandeel stocks.

### 1.3 Sources of Data

In the minutes from the meeting of ACFM in May 1990, a question was raised concerning the disparity between total landings as reported in Tables 2.2 and 3.2. The difference was due to other species, such as horse mackerel, mackerel, dab, argentine etc., caught as a by-catch in the fisheries. These species were included in the total in Table 3.2 in last year's report. This year they have been removed completely from the table.

Another difference which has caused misunderstandings in the past is the difference between data as officially reported to ICES and data provided by Working Group members. The data officially reported to ICES are total landings and have not been sub-divided into landings of target species and by-catch. The Norway pout landings officially reported to ICES are thus likely to contain a considerable amount of blue whiting. The data provided by Working Group members usually refer to individual species.

### 1.4 Data Deficiencies

In 1990, both the Danish and the Norwegian sampling of the industrial landings in the North Sea decreased to an unacceptably low level. This decrease was par-
ticularly serious in the sampling for age composition. If the Working Group is supposed to provide reliable assessments of the North Sea stocks of sprat, sandeel and Norway pout it is absolutely necessary that the sampling effort is increased considerably.

In Denmark the problems are due to different causes: reorganisation of the sampling scheme, cuts in staff at the Danish Fisheries Institute fishermen refusing to have their catch sampled. The fisheries inspectors employed by the Ministry of Fisheries have in recent years been responsible for collecting most of the samples used for determining the species composition of the landings, while assistants employed by the Danish Fisheries Institute have collected the samples used for determining age compositions. From 1991, the fisheries inspectors are supposed to take over all sampling of the industrial fishery. In 1990, the number of samples collected by the Ministry and used to determine the species composition was at the same level as in previous years (approximately 1,000 samples). However, the total number of samples collected in the North Sea by the Danish Fisheries Institute for age composition declined from approximately 100 in 1989 to 38 in 1990. The number of samples available for sprat, Norway pout and sandeel in 1990 are shown in Table 1.4.1.

In Norway the sampling scheme is also being reorganised. From 1991 people employed by the Institute of Marine Research will collect the samples used to determine both the species, length and age compositions of the catch. Previously these samples were collected and analyzed with respect to species composition by employees from the Directorate of Fisheries. Due to the reorganisation, only very few samples for species, length and age composition were collected in the second half of 1990 (Table 1.4.1).

### 1.5 Re-Arrangement of ICES Assessment Working Groups

Due to the biological and technical interactions, the Industrial Fisheries Working Group considers the move towards area-orientated assessment working groups to be a step in the right direction.

The members of the Group do not, however, agree on whether the inclusion of its terms of reference into a future Sub-area IV Demersal Stocks Assessment Working Group would be an advantage. Some members consider the overlap between the Roundfish Working Group and the Industrial Fisheries Working Group in terms of industrial by-catch to be important, while others consider this to be a minor point and emphasize that the industrial fleet as such does not target on catching roundfish species. The latter members also fear that the agenda of an assessment working group which had to deal with roundfish, flatfish and industrial species would be so large that industrial species would receive less attention than necessary.

If ACFM nevertheless decides to incorporate the Industrial Fisheries Working Group into a future Sub-area IV Demersal Stocks Assessment Working Group, it was felt that the terms of reference relating to sprat should be incorporated into the terms of the proposed Herring (Clupeoid?) Assessment Working Group rather than into those of a Demersal group.

The Industrial Fisheries Working Group has never been able to produce short-term management advice due to the short lifespan of the species considered. The major part of the catch usually consists of 1 -year-old fish which enter the fishery at about the time of the Working Group meeting, making it impossible to predict the catches more than at most one year ahead. The need for having annual updates of the assessments is, therefore, limited, and it may be considered to change to a schedule of meetings every second year. The danger of this approach could be that individual laboratories would give even less priority to collecting a sufficient number of samples. We would strongly warn against this possibility.

When considering the future schedule, ACFM should also consider the needs of other working groups, such as the Multispecies or the proposed Technical Measures Groups.

If the Industrial Fisheries Working Group is to continue its existence, the terms of reference of the Group should be directed towards performing assessment of historic stock sizes rather than on long-term management objectives. The industrial species are all important as food for other commercially-important fish stocks and suffer from a high level of predation mortality. The effect of long-term changes in fishing may only be predicted if species interaction is taken into account. It seems doubtful whether the proposed Demersal Working Group would be the appropriate one to perform such predictions as its terms of reference would not include mackerel and herring. It should, therefore, be considered to include long-term predictions in the terms of reference of the proposed Technical Measures Assessment Working Group.

## 2 TRENDS IN THE INDUSTRIAL FISHERIES FOR SANDEEL, SPRAT AND NORWAY POUT IN DIVISION IIIA, THE NORTH SEA AND DIVISION VIA

### 2.1 Division IIIa

The annual landings from the industrial fisheries for the years 1974-1990 are presented in Table 2.1. The total landings have fluctuated between 92,000 and $229,000 \mathrm{t}$. They increased from a minimum of $92,000 \mathrm{t}$ in 1989 to $112,000 \mathrm{t}$ in 1990.

In the four most recent years the landings have been well below the long-term mean of $172,000 \mathrm{t}$. In 1990, sprat landings continued to be at a very low level, whereas those of Norway pout increased from $6,000 \mathrm{t}$ in 1989 to $27,000 \mathrm{t}$.

### 2.2 North Sea

The annual landings from the industrial fisheries for the years 1974-1990 are given in Table 2.2. For 1990, the landings have been broken down by quarters to indicate the seasonality of the various fisheries. The total landings have varied between 1 million and 1.9 million $t$ with a long-term mean of 1.5 million $t$. The landings decreased from 1.5 million $t$ in 1989 to a minimum of 1 million $t$ in 1990. This was mainly due to a steep decline in sandeel landings from $1,035,000$ t to $590,000 t$, but the landing figures for sprat and Norway pout in 1990 were also rather low compared with the long-term means.

### 2.3 Division VIa

The annual landings from the industrial fisheries for the years 1974-1990 are presented in Table 2.3. The total landings have fluctuated widely between 10,000 $t$ and $54,000 \mathrm{t}$, without any particular trend. The landings decreased from $47,000 \mathrm{t}$ in 1989 to $18,000 \mathrm{t}$ in 1990, which is $2 / 3$ of the long-term mean of $27,000 t$. Over the past decade the fishery for sandeel has been comparatively stable, yielding an average of $52 \%$ of the annual industrial landings. However, the landings of Norway pout have been fluctuating widely, yielding an average of $40 \%$ of the annual industrial landings over the last 10 years. In the same period, sprat landings have only contributed an average of $8 \%$.

## 3 BY-CATCHES IN THE INDUSTRIAL FISHERIES IN THE NORTH SEA

The annual landings of by-catches of the major protected species (haddock, whiting and saithe) in the industrial fisheries are given in Table 3.1. After a
steady decline between 1979 and 1986 to a figure of $24,000 \mathrm{t}$ in 1987, the annual by-catch has more than doubled in the most recent years due to an increase in the landings of whiting.

Maps showing the geographical distribution of industrial by-catches of protected species are available for 1990. They are not published in the present report, but are retained in the files of the Working Group.

The areal distribution of the industrial landings by target species and associated by-catches of herring, haddock, whiting and saithe are shown in Table 3.2 for 1990. By-catches in the sandeel fishery are rather small. By-catches of herring have mainly been associated with the sprat fishery. By-catches in the Norway pout fishery consist of a mixture of herring and protected species. The category 'mixed' indicates that none of the target species was dominating in the landings. In the previous report (Anon., 1990), Table 3.2 included by-catches of other species in the totals. The Working Group was not in a position to revise the figures for 1988 and 1989 during the present meeting and, for this reason, Table 3.2 contains only data for 1990.

## 4 NORWAY POUT IN DIVISION IIIa

### 4.1 Landings

Total landings as officially reported to ICES are shown in Table 4.1. In 1990, the landings were about $42,000 \mathrm{t}$, which is at the same level as in 1987 and 1988 but significantly more than in 1989.

## 5 NORWAY POUT IN THE NORTH SEA

### 5.1 Landings

Landings by country are shown in Table 5.1 .1 for the period 1957 to 1990. The landings in 1990 were $119,000 t$ which is a $17 \%$ decrease compared to 1989. Landings by month and country are given in Table 5.1.2 for the years 1988 to 1990. The proportion landed in the first half of 1990 (46\%) was considerably higher than in 1989 (19\%).

### 5.2 Fishing Effort and Catch per Unit Effort

## Danish CPUE

Table 5.2.1 shows Danish CPUE data by vessel category for the period 1983 to 1990. CPUE data for 1990 are very similar to 1989 except for the smallest vessel category for which the 1990 figure decreased by $34 \%$ compared to 1989.

## Norwegian Effort

Number of days fished and mean GRT of the fishing vessels involved in the Norwegian directed Norway pout fishery are shown in Table 5.2.2. Total effort in 1990 increased by $76 \%$ compared to 1989, mainly due to an increase in the first half of the year.

Total Danish and Norweqian Effort
Danish and Norwegian effort data for 1989 and 1990 were standardized to a vessel size of 200 GRT using methods outlined in last year's report (Anon., 1990).

The Danish CPUE and GRT data were fitted to a GLM of the form

$$
\text { CPUE }=A(\text { year }) *(G R T-G O)^{b}
$$

where $A$ is a year-dependent parameter and $b$ is a constant. $G 0$ equal to 50 was selected as in previous years. The results for 1989 and 1990 were:

$$
\begin{aligned}
& \operatorname{CPUE}(89)=4.238 *(G R T-50)^{0.358} \\
& \operatorname{CPUE}(90)=3.686 *(G R T-50)^{0.358}
\end{aligned}
$$

The model explained $82 \%$ of the variation ( R -squared $=0.82$ ). The results for 1990 are shown in Figure 5.2.

The model was used to standardize effort data for 1989 and 1990 to a vessel category of 200 GRT , using quarterly Danish and Norwegian effort data. As the Norwegian data for 1988 to 1990 include effort directed towards blue whiting, the Norwegian catch was used to estimate a standardized effort figure by dividing the Norwegian catch by the standardized Danish CPUE. The standardized effort data are given in Table 5.2.3.

In 1990, the total standardized effort was $13 \%$ lower than in 1989. Effort in the first half year was higher than in 1989 but in the second half it was lower.

### 5.3 Catch at Age

Catch-at-age data for 1989 were updated (Table 5.3.1). For 1990, very few Danish and Norwegian samples for age composition were available for the first three quarters, and no data were available for the fourth quarter during which $35 \%$ of the landings were taken.

The Danish and Norwegian biological samples are summarized in Tables 5.3.2 and 5.3.3. Quarterly length compositions of catches are shown in Annex 1. The estimated catch in numbers at age for the three first quarters are given in Table 5.3.4. However, as the age compositions are based on an insufficient number of samples, the figures are subject to a large uncertainty and the Working Group, therefore, decided not to proceed with a VPA.

### 5.4 Weight at Age

Mean weight at age in the combined Danish and Norwegian catches are shown by quarter in Table 5.4 for the period 1986 to 1990.

### 5.5 Research Vessel Surveys

Updated research vessel indices are given in Table 5.5. The preliminary IYFS 1group index for the 1990 year class is more than twice that of the 1989 year class. The EGFS 0-group index also indicates that the 1990 year class is stronger than the 1989 year class.

### 5.6 VPA

No analytical assessment was performed due to lack of appropriate catch-at-age data for 1990.

### 5.7 Catch Prediction

A SHOT prediction was performed using recruitment at age 1 from last year's VPA and the RCRTINX2 estimate of the 1989 and 1990 year classes at age 1 (Tables 5.7.1 and 5.7.2). The yield/biomass ratio for 1989 and 1990 was chosen to be at the same level as in 1987 in order to correspond to the estimated level of effort. Table 5.7.2 and Figure 5.7 show that the estimated landings for 1990 are considerably higher than the actual landings. In order to obtain a reasonable agreement between the estimated and actual landings in 1990, the Y/B ratio has to be reduced to 0.3. However, the drop in the $Y / B$ ratio from 0.45 in 1989 to 0.30 in 1990 is not justified by the effort data shown in Table 5.2.3. The problem seems to be that the standardized CPUE decreases from 25.5 t per fishing day in 1988 to 20.4 t per fishing day in 1990 , while the index of recruitment at age 1 at the same time increases from 120 to 450 . Given the discrepancy between the increasing recruitment and the decreasing CPUE and the discrepancy between the actual landings in 1990 and the landings estimated by the SHOT method, there seems to be little justification for any confidence in the predicted landings for 1991.

## 6 NORWAY POUT IN DIVISION VIa

### 6.1 Landings

Landings of Norway pout from Division VIa for the period 1974-1990 are given in Table 6.1. The figures are those officially reported to ICES. In 1990, a total of $3,316 t$ was landed from Division VIa, a substantial drop from the 1989 landings of $28,180 \mathrm{t}$, and the lowest total on record. The average amount landed annually from 1974 to 1989 was 13,704 t.

## 7 SANDEEL IN DIVISION IIIA

### 7.1 Landings

Estimated landings decreased again from 17,200 $t$ in 1989 to $15,800 \mathrm{t}$ in 1990 (Table 7.1). The major part - $15,100 \mathrm{t}$ - was taken in the Skagerrak.

## 8 SANDEEL IN THE NORTH SEA

### 8.1 Landings in 1990

Total landings were heavily reduced in 1990 as compared with the peak year 1989. With a total catch of about $590,000 \mathrm{t}$, the reduction was about $43 \%$ and the 1990 figure is the lowest since 1984.

Table 8.1.1 shows nominal landings by country. The decline is seen in all national landings. Norwegian landings declined by $49 \%$ while the Danish catches went down by about $40 \%$. By areas the reductions are $54 \%$ and $30 \%$ for the Northern and Southern sandeel areas, respectively (Table 8.1.4).

As in the two preceding years, the fishery started in strength in early March due to a mild winter. As shown in Tables 8.1 .2 and 8.1.3, the landings peaked in May and then declined to a very low level in July.

An appreciable increase followed in August together with an increase in CPUE. This seems to indicate that a new year class ( 0 -group) became the object of the fishery, and according to Table 8.1.3, this took place in sandeel areas 2B and 3 (Figure 8.1).

### 8.2 Sandeel in the Northern North Sea

### 8.2.1 Fishing effort and CPUE

Fishing effort data were available for Danish and Norwegian vessels based on log books covering $100 \%$ of the fishing operations.

The Danish CPUE data by half year and vessel category for 1982-1990 are shown in Table 8.2.1.1.

In 1989 and 1990 a power function was fitted to each half year separately:

$$
\text { CPUE (half year, GRT) }=a * \operatorname{GRT}^{b}
$$

The parameters are shown in the text table below and the Danish CPUE standardized to a 200 GRT vessel in the first and second half of the year are shown in Table 8.2.1.3.

|  |  | $\underline{\mathrm{R}-\text { square }}$ | $\underline{a}$ | $\underline{\mathrm{~b}}$ |
| :---: | :---: | :---: | :---: | :---: |
| 1989 | I | 0.99 | 3.19 | 0.50 |
|  | II | 0.68 | 10.34 | 0.22 |
| 1990 | I | 0.92 | 6.03 | 0.29 |
|  | II | 0.77 | 7.87 | 0.28 |

Fishing days and mean GRT for the Norwegian fleet were available for the years 1976-1990 (Table 8.2.1.2).

The standardized international CPUE was then calculated as the average of Danish and Norwegian means weighted by catch. Finally, standardized international effort was estimated as total international catch divided by the standardized international CPUE.

The results presented in Table 8.2.1.3 show a drastic reduction in the total effort in the first half year of more than $50 \%$, while an increase of about $10 \%$ took place in the second half of 1990 as compared with 1989.

### 8.2.2 Catch at age

Due to the breakdown of the Danish sampling system, insufficient data on age composition were available from the Danish fishery (see Section 1.4).

In the first half of 1990, the Danish fleet was responsible for $56 \%$ of the landings. The fishery generally took place further to the east and south than the Norwegian fishery. The catches in number at age presented in Table 8.2.2 were estimated by applying the Norwegian data to the entire catch. However, the coverage of the Norwegian fishery by sampling, in particular for age determination, was poorer than in previous years. Due to the difference in fishing areas, it is also highly questionable to what extent the Norwegian samples may be applied to the Danish fishery. The data presented in Table 8.2.2.1 are, therefore, insufficiently supported by samples and may be seriously in error.

### 8.2.3 Weight at age

The mean weight at age in the Norwegian catch is shown in Table 8.2.3.1. The mean weight at age in the stock (Table 8.2.3.2) is unchanged from previous years.

### 8.2.4 VPA

Due to the lack of age data and since it is by no means evident that the two fisheries will have the same age distribution, the Working Group decided that the available data were insufficient for an analytical assessment.

### 8.3 Sandeel in the Southern North Sea

### 8.3.1 Fishing effort and CPUE

Danish CPUE data were available and are shown by half year and vessel category in Table 8.3.1.1.

Effort and CPUE were standardized to a vessel of 200 GRT using the same procedure as described for the northern North sea in Section 8.2.1.

The parameters of the power curve are shown below, and the results are shown in Table 8.3.1.2. Compared to 1989, there is little change in the total fishing effort recorded in 1990. A noteworthy feature is the low CPUE in the first half year of 1990 - in fact the lowest on record - and the comparatively high value for the second half year. The same pattern was observed in the northern North Sea and indicates a shift to fishing on the early recruits of the 1990 year class. A more detailed description of the CPUE and effort data is given in Section 8.6.

|  |  | $\underline{\text { R-square }}$ | $\underline{a}$ | $\underline{\underline{a}}$ |
| ---: | ---: | :---: | :---: | :---: |
| 1989 | I | 0.92 | 3.50 | 0.51 |
|  | II | 0.44 | 16.72 | 0.13 |
|  | I | 0.84 | 7.03 | 0.30 |
| 1990 | II | 0.91 | 12.85 | 0.23 |

### 8.3.2 Catch at age

Only two biological samples were available from this fishery. The age distribution and mean weight at age in these two samples are listed in the text table below.

| Area | Quarter | Age | 0 | 1 | 2 | 3 | 4 | 5 | 6 | Total |
| :--- | :--- | :--- | :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| 2A | 2nd | N | 0 | 14 | 89 | 1 | 0 | 0 | 0 | 104 |
|  |  | W |  | 8.2 | 13.2 | 17.3 |  |  |  | 12.6 |
| 6 | 2nd | N | 0 | 0 | 10.3 | 14 | 8 | 3 | 1 | 129 |
|  |  | W |  |  | 19.0 | 21.4 | 21.7 | 23.4 | 24.0 | 19.6 |

The working Group decided that this is far from sufficient to convert the catches to numbers at age.

### 8.3.2 Weight at age

The only data available are those presented in the text table in Section 8.3.2.

### 8.3.3 VPA

Due to insufficient data for catch at age and weight at age, no analytical assessment could be done on this stock.

### 8.4 Sandeel in the Shetland Area

### 8.4.1 Fishing effort and CPUE

Fishing effort data for the Shetland area over the period 1977-1990 are given in Table 8.4.1.1. As in 1989, no effort was applied to the stock during the second half of the year due to the closure of the fishery within the 6 miles UK limit.

Using the procedure first used in 1990, the effort data from 1982 onwards were once again standardized to a vessel size of 40 GRT. The revised values for standardized effort are given in Table 8.4.1.2. Relative to the first half of 1989, the 1990 figures show a reduction of $23 \%$ in nominal effort and $39 \%$ in standardized effort. These effort figures are the lowest recorded in the fishery and reflect the fact that only two boats fished the stock for the whole season.

### 8.4.2 Catch at age

Catch-at-age data from the shetland sandeel fishery are given in Table 8.4.2. In 1990, the timing of the recruitment of 0-group fish was such that very few were caught before the closure of the fishery during the second half of the year. 1group fish predominate in the landings, making up more than $47 \%$ of the total numbers. This suggests that the 1989 year class may be of reasonable strength, at least compared with other recent years. This is apparent from the relatively low numbers of 2 - and 3 -group fish in the catch. Numbers of 4 -group fish, originating from the apparently strong 1986 year class, are still quite high in the catches. However, even with the further reduction in effort during 1990, it is possible that effort may have been concentrated in areas where older fish predominate, thus compounding recent problems of changing exploitation pattern.

### 8.4.3 Weight at age

Mean weights at age of sandeels in the Shetland catch are given in Table 8.4.3.1. This year for the first time, the stock weights at age used to calculate biomass totals were semi-annual catch weights at age rather than long-term means. These are given in Table 8.4.3.2.

### 8.4.4 VPA

A semi-annual VPA was performed with input fishing mortalities in the most recent year estimated using the semi-annual tuning program available to the Working Group. Natural mortality rates and proportions mature were the same as those used in preceding reports (Anon., 1989).

In selecting input values for $F$ at the oldest age, the convention used previously (i.e., a value of $F=0.5$ ) was used. It is recognized that this value may be artificially high, but using values chosen from average F over a particular age range produces stock and biomass estimates which are greatly in excess of previous Working Group estimates. Thus, unless further information becomes available, it seems reasonable to continue with the current procedure, and thus ensure consistency in estimates between years.

The closure of the Shetland fishery during the second half of the year was a measure designed to protect the incoming 0-group fish, which used to form the bulk of the catch after the beginning of June. Thus, most effort directed at 1group and older fish took place during the first half of the year, so the VPA has been tuned to catch and effort during the first half of the year. Effort data of sufficient detail to permit standardization are only available for the years from 1982 onwards, so the tuning uses standardized effort data for the period 1982-1990. The closure of the fishery during the second half of 1989 and 1990 meant that no $F$ at age 0 was estimated for these years.

The tuning procedure used the mean $\log$ catchabilities at age to estimate $F$ in the most recent years. Mean $\log$ catchability was estimated as a weighted value with linear down-weighting of older values. Input catch-at-age data are given in Table 8.4.4.1, and the log catchabilities at age and the tuning statistics are given in Table 8.4.4.2.

Estimated fishing mortalities at age are given in Table 8.4.4.3, and values averaged over ages 1 to 3 are shown in Figure 8.4.4.1. These values are plotted against standardized effort over the period 1982-1990 in Figure 8.4.4.2. The estimated numbers of fish in the sea and stock biomass totals are shown in Table 8.4.4.4. The numbers of 0-group recruits (on 1 July) are shown in Figure 8.4.4.3, and the corresponding biomass totals are shown in Figure 8.4.4.4.

The current VPA has resulted in a considerable downward revision of the strength of the 1986 year class, although it still appears quite strong compared to most year classses of the last five years. This revision has also removed the peak in total biomass corresponding to the entry of the 1986 year class, although it should be noted that all historical biomass totals have been revised due to the use of annual measured weights at age rather than long-term mean values. The estimate of the strength of the 1989 year class suggests that it is stronger than the two preceding year classes, but at 25.3 thousand million it corresponds to approximately $81 \%$ of the long-term mean. However, it remains necessary to treat the estimates from VPA with extreme caution due to continuing problems with low fishing effort resulting in slow convergence of the VPA, and with the results largely driven by the values of natural mortality used. Furthermore, doubts over the validity of the assumption of constant exploitation pattern (Section 8.4.2) give further cause to treat the analysis with great caution.

### 8.4.5 Critical size of spawning stock

To give an indication of the critical size of the spawning stock of sandeels at Shetland, the method proposed by Serebryakov (1990a) and investigated by the Roundfish Working Group (Anon., 1991) was used. The method is based on a graph of the type shown in Figure 8.4.5. Starting with the basic stock-recruitment scatter plot, lines are superimposed representing high recruitment ( $\mathrm{R}_{\mathrm{h}}$, $10 \%$ of the recruitment values fall above this line), medium recruitment ( $\mathrm{R}_{\mathrm{me}} \mathrm{m}^{\prime}$ ' $50 \%$ of the recruitment values fall on either sider of the line), high survival (Shigh' $10 \%$ of the points above the line), and medium survival ( $S_{m e d, ~}^{\prime} 50 \%$ of the
points fall on either side of the line). The method as used here assumes that points fall on either side of the line). The method as used heredassumes that egg production is proportional to spawning stock biomass. Using this method, the critical point is the spawning stock at which high survival of eggs and larvae is required in order to produce a high recruitment. This point occurs at the
intersection of the lines corresponding to $S_{\text {high }}$ and $R_{\text {hin }}$. In the case of sandeels at Shetland, the critical point appears $\mathrm{t}_{\mathrm{tgh}}$ be a biomhss of around $20,000 \mathrm{t}$. The current VPA suggests that the spawning stock has now fallen below this level, and with continuing low recruitment seeems unliklely to recover immediately. It should be stressed that this critical point should not be regarded as a "magic number", but should be considered in the context of other aspects of the fishery. In the case of sandeels at Shetland, the stock declining below this critical point, when viewed against a background of declining stock and continuing low recruitment, led to the closure of the fishery.

### 8.5 The Separation between a Northern and Southern Sandeel Stock

At last year's meeting it was discussed to what extent recruitment in the northern North Sea depended upon transport of larvae from the southern part. A working document by Berntsen et al. (1990) considered whether the current system in the North Sea would support such a transport.

Berntsen et al. used a 3-D barocline circulation model as described by slagstad (1987) to model the current system. The water mass was divided into rectangles of 20 by 20 km and vertically stratified into 13 different depth layers. Using the flow of water through the English Channel, Skagerrak and across the northern boundaries of the North Sea as forcing functions, the current field in each depth layer was estimated from the observed changes in temperatures and salinities given by Damm (1989). In the absence of data on wind speed and wind direction, wind forcing was neglected.

Assuming sandeel larvae to be found in the upper 10 m of the water column, the model was used to predict the larval drift from 1 April to 1 July. A number of different hatching areas was considered. In most of these areas (east coast of England, western Dogger Bank, eastern Dogger Bank, Inner Shoal, west coast of Denmark and Lingbank/English Klondyke/West Bank) the larvae remained within the same area throughout the period. The main exceptions were the Shetland area and the Viking Bank where currents transported a major part of the larvae away from the hatching area.

The main drawback of the above model seems to be the lack of wind-generated currents, which are known to be a major factor in determining the current field in the North Sea (Backhaus, 1989). However, realistic modelling of the influence of wind forcing on larval transport necessitates detailed information about the vertical distribution of sandeel larvae. This information does not exist.

Berntsen et al. also tried to use stepwise regression analysis to correlate recruitment in the northern area with the following biological variables: SSB, Spawning stock numbers (SPN) and numbers at age 2, 3 and 4 in the northern North Sea from Table 8.2.4.3 of last year's report and SSB in the southern North Sea from Table 8.3.4.2 of last year's report. In addition, a number of environmental variables were included: Monthly mean wind stress components at Utsira in Aprif, May and June, together with an index of influx of Atlantic water north of 57 N in June.

The initial results showed that the stock numbers at age 3 , together with environmental variables, explained a major part of the variations in recruitment. However, as no reasonable biological explanation could be given for the importance of the 3-group in particular, Berntsen et al. decided to exclude this time series from further analysis.

After excluding the 3 -year-olds, the most important among the remaining variables were the $\mathrm{N} / \mathrm{S}$ component of the wind in May and the spawning stock numbers in the northern North Sea, which together had an R-square of 0.66 . The R-square of any of the other time series were all below 0.10 , and the spawning stock bio-
mass, which takes the recent decline in growth rate into account, was not significant.

Figure 8.5.1 shows the relation between recruitment and southerly wind stress in May. In accordance with expectations, recruitment decreases with northerly and increases with southerly winds. Figure 8.5.2 shows the relation between recruitment (adjusted for the effect of the wind) and spawning stock numbers. Most of the correlation is due to the 1988 point. As recruitment and spawning stock numbers in 1988 to a large extent depend on the choice of terminal fishing mortality in 1989, it may be discussed whether 1988 should be included in the analysis at all.

The Working Group agreed that larvae may, at least in some years, be transported from the southern part of the North Sea into the northern part. The extent of this transport is likely to vary from year to year depending on the strength and direction of wind-generated currents. There is no statistically significant correlation between the spawning stock of sandeel in the northern North Sea and the subsequent recruitment, even if the 1988 point is included (see also Section 8.6.3).

The identity of sandeel stocks in the North Sea is thus by no means certain. Samples from the Continuous Plankton Recorder indicate that sandeel larvae in different stages of development may be found over most of the southern and part of the northern North Sea in the period from April to June (Henderson, 1961; Hart, 1974). The mechanism of drifting and settling of larvae has not yet been described in detail from field observations.

### 8.6 Manaqement Considerations

### 8.6.1 Biological features relevant to management

There are a number of aspects of the biology of the sandeel that are relevant to assessment and management considerations. The main biological features in this context are:
i) Habitat

The sandeel is confined to sandy bottoms, where it spends the major part of its life more or less burried in the substratum. Due to the burrowing habit it requires that the substratum is well aerated and the preferred bottom material is consequently rather coarse sand in areas with comparatively high current velocities.

Because of the habitat requirements, the distribution is mainly limited to the shallower areas of the North Sea and dense concentrations are typically found along ridges and edges of banks where tidal currents provide continuous water renewal.
ii) Availability

The burrowing habit of the sandeel makes it inaccessible to the fishery for periods of differing lengths according to age and size of the fish. Adult sandeel are mainly active in April-June when feeding takes place and in December-January for spawning. The juveniles are available from when they settle on the bottom after metamorphosis until about October. Likewise, the 1 -group is the first to appear in the following spring apparently dependent on the temperature. In the mild winters of 1988 to 1990, the activity began early around the beginning of March and the fishery was well underway about a month later.

In some areas sandeel are available during the season outlined above but inaccessible to the fishery because the ground is too rough for the light commercial sandeel trawl. The total extent of these areas is unclear. Tagging experiments have shown that once settled the sandeel seems to be a quite sedentary fish (Popp Madsen, pers. comm.) These 'protected' components may be of importance for the stock, but their actual size is unknown.

### 8.6.2 The effect of fishing

The impact of fishing upon the sandeel in the North Sea is difficult to ascertain because of the discrete distribution, and the changing availability, Due to the sedentary habit of sandeel, the population within a certain area will be influenced by the local more than by the overall fishing effort. From an assessment point of view it may thus be an advantage to use a high spatial disaggregation.

There are indications that effort changes with CPUE. Changes in Danish CPUE and effort during the fishing seasons of 1989 and 1990 are shown in Figures 8.6.2.1 and 8.6.2.2. The upper curves show the average weekly CPUE in tonnes per fishing day while the lower curves show the weekly effort in number of fishing days.

In both years, CPUE increases rather rapidly from the beginning of March to reach a peak in May. Then follows a more or less drastic decline to a minimum in July. After a second maximum in August the fishery stops by the end of September. The maximum CPUE in May denotes the period when all age groups (except the o-group) are available on the fishing grounds. The decline in June coincides with the disappearance of the older fish and the second maximum with the appearance of the 0 -groups on the banks. The effort increases with increasing CPUE and reacts to decreases in CPUE with a decrease about one week later. Effort is reduced once CPUE starts to decline. In 1989 relatively little effort was expended once CPUE dropped below 25 t per day.

A closer look at the average weekly CPUE by statistical rectangle indicates that the same development takes place within individual rectangles although the development here occurs more rapidly. It is clear that effort is rapidly transferred from a rectangle of declining CPUE to other rectangles giving higher catches per day. The curves in Figures 8.6.2.1 and 8.6.2.2 are consequently giving a picture of the overall development on the fishable grounds. The reduction in effort exerted during the August maximum in CPUE is partly due to a reduction in the number of larger vessels participating in the fishery. In 1990 $44 \%$ of the total effort in the first half of the year was due to vessels of more than 200 GRT against $29 \%$ in the second half.

Norwegian CPUE by individual landings in the Lingbank-English Klondyke area in the first half of 1990 are shown in Figure 8.6.2.3. These data only represent a limited fraction of the landings. The CPUE of the total fleet is not available with the same fine resolution in time. The CPUE sems to have developed in the same way as in the Danish fishery. It may be noted, however, that catches associated with a small CPUE appear throughout the whole season.

The year-to-year variations in CPUE and effort in the total international fishery are shown in Figures 8.6.2.4 to 8.6.2.7 for the northern and southern North Sea. In the northern North Sea the effort seems to some extent to be related to the CPUE. In the southern area no clear relation between mean effort and CPUE seems to be present. This indicates that other factors, such as the price of sandeel, may be important in determining the total international effort.

Due to the above-mentioned points it is reasonable to assume that a part of the
total sandeel stock may be protected from exploitation because:

- The ground is too rough for the use of the sandeel trawl.
- The abundance of sandeel is too low to secure a profitable CPUE.

The impact of the fishery on the stock as measured by the fishing mortality from the VPA will thus - all other assumptions alike - tend to be overestimated and the estimates of stock size will tend to be underestimated.

The main part of a year class appears to enter the spawning stock at 2 years of age and in most years this age group constitutes the major spawning component. The impact of the fishery on the abundance of this age group may be expressed by the exploitation rate of the 0 - and 1 -group (Table 8.6.2.1). Average fishing mortalities for the period 1976-1988 derived from the VPA give the following average exploitation rates at age 1:

$$
\begin{aligned}
& \text { Northern North Sea: } E=F / Z=0.571 / 1.771=0.32 \\
& \text { Southern North Sea: } E=F / Z=0.297 / 1.497=0.20
\end{aligned}
$$

From this it appears that fishing is a minor factor in determining the strength of the recruitment to the spawning stock in the southern North Sea, but may have a larger influence in the northern North Sea.

### 8.6.3 Stock/recruitment relationship

A plot of recruitment versus spawning stock size for the northern and southern North Sea combined is given in Figure 8.6.3.1. Excluding 1987, the figure may give the impression of a linear relationship between spawning stock size and recruitment. The correlation is, however, not statistically significant ( $\mathrm{R}=-$ 0.8, df $=10$ ). A similar plot using the data from the MSVPA key run produced at the 1990 meeting of the Multispecies Assessment Working Group is shown in Figure 8.6.3.2. Again the correlation is non-significant ( $R=-0.06, \mathrm{df}=10$ ). If the 1987 data point is excluded, the correlation becomes statistically significant ( $\mathrm{R}=0.66$, $\mathrm{df}=9, \mathrm{P}<0.05$ ). There is, however, no reason for excluding the 1987 point from the analysis. Plots of recruitment versus spawning stock size for the northern and southern assessment areas separately are shown in Figures 8.6.3.3 and 8.6.3.4. In neither of these is the correlation significant ( $R=-0.38$ and $R=0.01$, respectively, $d f=10$ ).

Therefore, in none of the cases is there any evidence of a significant linear relationship between spawning stock size and recruitment.

### 8.6.4 Management measures

In its reports of 1984 and 1989, the Industrial Fisheries Working Group estimated the $Y / R$ and $S S B / R$ at various levels of fishing mortality. The participants saw no point in repeating these calculations. In the North Sea, sandeel is subject to a high and variable natural mortality. If long-term predictions are needed, changes in natural mortality have to be taken into account. This may best be done by the Multispecies Assessment Working Group.

In the case of the Shetland sandeel, the size of the spawning stock has declined due to a series of low recruitments. However, the fishery does not seem to be implicated in the recruitment failure. The spawning stock has recently fallen to a level at which the historical evidence suggests that high egg and larval survival is required to produce a good year class (see Section 8.4.5) and the fishery has been closed.

In the case of the other North Sea stocks there are no signs of a development in either spawning stock size or in recruitment which gives reason for concern. The development is shown in Figures 8.6.4.1 and 8.6.4.2 based on the VPAs of last year's report. The recruitment in the southern area has fluctuated widely and more than in the northern area, but without any pronounced long-term trend. The spawning stock biomasses are less variable from year to year and, if anything, the trend is towards a slight increase.

As already mentioned in Section 1.5 , the Working Group has no means of predicting next years' catches. There is no correlation between the catch of 0groups in the second half of the year and the catch of 1 -group in the following year $(R-s q u a r e=0.02)$. Although there is no apparent need for introducing management measures or precautionary TACs in the main sandeel fisheries in the southern and northern North Sea, the fisheries should, however, be subjected to continuous monitoring and more research should be directed at the many unresolved problems concerning the biology of sandeel.

## 9 SANDEEL IN DIVISION VIa

### 9.1 Landings

Official landings of sandeel in Division VIa are given in Table 9.1. Landings in 1990 were $24 \%$ lower than in 1989.

### 9.2 Fishing Effort and CPUE

Fishing effort data by month for the sandeel fishery in Division VIa over the period 1980-1990 are given in Table 9.2.1. The total effort over 1990 shows a $17 \%$ reduction when compared to 1989. The 1990 season was also shorter than usual, with boats only fishing from May to August, and with most effort occurring during June.

Standardized effort data are now available for the Division VIa sandeel fishery. These are presented in Table 9.2.2. These values were calculated using the same procedure as that used for the Shetland effort data (Section 8.4.1). These data cover the period 1982-1990. The standardized effort figure for 1990 is $18 \%$ less than that for 1989.

### 9.3 Catch at Age

Catch-at-age data by month for 1990 are given in Table 9.3.

### 9.4 Weight at Age

The mean weights at age of sandeels in the Division VIa catch are given by month in Table 9.4.1. As in the case of the Shetland fishery, the stock weights at age used to calculate biomass totals were semi-annual catch weights at age, rather than long-term mean values which had been used previously (Table 9.4.2).

### 9.5 VPA

A semi-annual VPA was performed using the values of natural mortality, and proportion mature at age given in a previous Working Group report (Anon., 1989). The values used for input $F$ at the oldest age were the same as those in the Shetland VPA (Section 8.4.4), and the comments on the method made there also apply in the case of Division VIa. Previously, the input values for $F$ in the
most recent years have been estimated by tuning to catch and effort data during the second half of the year. However, when this was tried this year, it resulted in very high estimates of mean $F$ for the most recent years. These values were inconsistent with the low effort figures for these years. This overestimation of $F$ appears to be due to a shift in the seasonal pattern of fishing effort, with more effort now being expended during the first half of the year. Previously, distribution of effort between the two halves of the year tended to be fairly even, with slightly more occurring during the first half of the year. During 1990, however, $68 \%$ of the standardized effort occurred during the first half of the year. With this imbalance, tuning on the effort during the second half of the year appears to force an artificially high estimate for $F$ during the first half of the most recent year, and the estimates of $F$ at age in the immediately preceding years then consequently increase. Thus for this analysis, the input values for $F$ at age were estimated by tuning to catch and standardized effort data during the first half of the year, with $\log$ catchabilities and linear downweighting of older data. The use of effort data from the first half of the year for tuning purposes is not consistent with previous methodology, but is more appropriate in this case as it reflects the distribution of effort during 1990 more effectively. However, it is possible that this procedure may have slightly underestimated the $F$ at age values in the most recent years.

Input catch-at-age data are given in Table 9.5.1, with the tuning statistics and log catchabilities at age given in Table 9.5.2. Estimated values of $F$ at age are given in Table 9.5.3, with values of mean $F$ (ages 1 to 3) plotted as a time series in Figure 9.5.1, and against standardized effort in Figure 9.5.2 (adjusted $r^{2}=0.609$ ). Estimated numbers in the sea and biomass totals are given in Table 9.5.4. Trends in recruitment and biomass totals are shown in Figures 9.5.3 and 9.5.4, respectively.

The addition of the 1990 catch data to the information available on the Division VIa sandeel stock has resulted in a downward revision of the estimate of the size of the 1986 year class. Even so, this still appears to be the strongest year class on record for this stock. The present assessment has also resulted in a revision of the estimate of the strength of the 1988 year class to more than twice its previous value. This is not surprising as this would have been the most uncertain of the estimates arising from the previous assessment. Similarly, the addition of an extra year's catch data for the 1989 year class has improved the very provisional estimate of recruitment made last year. The indications from this assessment are that the 1989 year class is quite strong, the VPA giving an estimate of around 51 billion fish, which compares with a long-term geometric average of about 33 billion. However, this estimate is still rather provisional, and with the possibility that $F$ during the second half of recent years may have been underestimated, there are reasons for treating this estimate with some caution. In addition, tuning the VPA on effort data during the first half of the year, before the o-group fish have entered the stock, means that the initial estimate of the strength of the 1990 year class is extremely unreliable and should be disregarded.

The use of measured stock weights at age rather than long-term means has resulted in some changes in the historic trends in biomass totals. This is largely due to relatively high measured weights at the younger ages in 1984 and 1987. These have resulted in a large increase in stock biomass relative to that calculated by the previous Working Group (Anon., 1990). In 1987, this increase has been sufficient to counterbalance the decrease in numbers suggested for that year by the current assessment. The current estimate of spawning stock biomass is about $79,000 \mathrm{t}$, a decline from the two preceding years, but still above the geometric mean of $49,000 \mathrm{t}$. The current assessment has resulted in a slight upwards revision of estimates of mean fishing mortality since 1983. The 1990 value appears to be one of the lowest recorded since the fishery began in 1980.

## 10 SPRAT IN DIVISION IIIa

### 10.1 Landings

The landings for the period 1974-1990, as provided by the Working Group members, are shown in Table 10.1. The Swedish data from 1982 onwards have been revised. Due to increasing difficulties in allocating the catches to areas, the revised Swedish data are only given for the whole of Division IIIa. The landings are still at a very low level, and slightly below those of the two previous years.

### 10.2 Research Vessel Surveys

The IYFS index for 1-group and total sprat for 1991, together with the indices from previous years, are shown in Table 10.2. This year's indices are still at a very low level.

### 10.3 State of the Stock and Catch Predictions

According to the IYFS indices, the stock is still at a low level, and there are no signs of improvement in the recruitment.

A SHOT estimate was performed using the IYFS index at age 1 as recruitment index, and a Y/B ratio of 0.772 up to and including 1985, and 0.6 for the more recent years. The estimated catch for 1991 is $9,200 t$, which implies a minor increase from 1990 (Table 10.3).

## 11 SPRAT IN THE NORTH SEA

### 11.1 Landings

The preliminary figure of $76,100 \mathrm{t}$ for the landings of sprat in 1990 is slightly above last year's figure. The landings reached a minimum in 1986. Since 1988, they have remained at around $80,000 \mathrm{t}$.

Table 11.1.1 shows the landings by area and country. Table 11.1.2 shows landings by area and quarter, but includes only landings where such data were available. The catches in the Norwegian fjords are included in Table 11.1 .1 but not in 11.1.2. The main fishery ( $83 \%$ ) took place in Division IVb east, and mostly in the third and fourth quarters.

### 11.2 Catch at Age

Quarterly catch-at-age data are shown in Table 11.2 for those quarters and areas where aged samples were available. The data are based on very few fish ( 376 and 121 for the first and third quarters, respectively).

### 11.3 Weight at Age

Danish data for weight at age in the catch are shown in Table 11.3. These data are partly based on measurements in research catches.

### 11.4 Research Vessel Surveys

### 11.4.1 Acoustic surveys

Acoustic surveys were carried out by Norway and Denmark in June-July in the northern and central North Sea, respectively. From the Danish survey, a biomass of $24,000 \mathrm{t}$ was estimated. In the Norwegian survey, no sprat were found. As in previous years, these surveys are primarily directed towards herring and do not cover the distribution area of sprat sufficiently. Since the estimates are far below the actual catches, they were not used for an assessment.

### 11.4.2 International Young Fish Survey

Preliminary data from the IYFS in February 1991 for sprat $<10 \mathrm{~cm}$, based on a compilation of 425 hauls, are included in Table 11.4. The area distribution is shown in figure 11.4. The preliminary index of 940 is higher than in most of the recent years.

### 11.5 Catch Predictions

The 1988 year class had an exceptionally large IYFS index as 1-year old in 1989. Neither the contribution of this year class in the catches, nor the IYFS index for age 2 in 1990 indicate that this year class should be exceptionally large. To find a substitute for this incredible value, an attempt was made to estimate an age 1 value for the 1988 year class index using the index for age 2 . The correlation between the age 1 and 2 indices was not significant, however; ( $r=$ 0.56 , $\mathrm{df}=5$, excluding the 1988 year class). As was the case last year, the Working Group found the data insufficient to allow any catch prediction.

## 12 SPRAT IN DIVISION VIa

The landings of sprat from Division VIa are shown in Table 12.1. The catch in numbers at age and the mean weight at age are shown in Table 12.2.

## 13 SPRAT IN DIVISIONS VIId,e

### 13.1 Landings

The nominal landings are shown in Table 13.1.1.
There was a slight upturn in the landings in the eastern Channel in the latter part of the year, with some catches being taken from the Poole area in December for the first time in many years. The incoming 1990 year class was predominant in that area, making up $76 \%$ of the samples taken.

In the western Channel, the $1990 / 1991$ Lyme Bay season commenced in July and ended in March. The provisional catch for the $1990 / 1991$ season was $1,562 t$, which is only 334 t more than the very poor catch taken in the 1989/1990 season (Table 13.1.2). In the early part of the $1990 / 1991$ season, the 1988 year class contributed about $62 \%$ to the catch, with the 1989 and 1987 year classes contributing $17 \%$ and $14 \%$, respectively.

### 13.2 Catch at Age

The catch in numbers at. age in the Lyme Bay fishery is shown in Table 13.2.1. The 1988 year class contributed up to $62 \%$ (in numbers) of the catch.

### 13.3 Weights at Age

The mean weight at age for the Lyme Bay fishery is shown in Table 13.3. The mean weight at age in all of the year class was above the long-term average.
