# REPORT OF THE WORKING GROUP ON THE ASSESSMENT OF NORWAY POUT AND SANDEEL 

Copenhagen, 6-12 October 1993

This document is a report of a Working Group of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council. Therefore, it should not be quoted without consultation with the General Secretary.

### 1.2 Terms of Reference

At the 80th Statutory Meeting it was decided (C. Res.1992/2:8:17) that the Working Group on the Assessment of Norway Pout and Sandeel (Chairman: Mr D. W. Skagen, Norway) should meet at ICES Headquarters from 6-12 October 1993 to:
a) update the description of the historical development of the fleet units exploiting Norway pout and sandeel and the catches of these species and the by-catch species;
b) quantify the species composition of by-catches taken in the fisheries for Norway pout and sandeel in the North Sea and adjacent waters;
c) resolve the age compositions of the 1990 catches to allow the time series of catch-at-age data to be maintained;
d) assess the status of Norway pout and sandeel in Sub-area IV and Divisions IIIa and VIa and advise on the need for any management measures, taking into account the outcome of the meeting of the Working Group on Methods of Fish Stock Assessment;
e) provide the data requested by the Multispecies Assessment Working Group;
f) provide information on the industrial fish stocks (Norway pout and sandeel), their age structures, their stock distributions, and their fisheries on an ICES statistical rectangle basis, in order to allow the Working Group on Ecosystems Effects of Fishing Activities to quantitatively evaluate the effects of industrial fisheries in the ecosystem;
g) prepare for the transfer of the Group's work to area-based Working Groups in 1994.

In addition, in a letter dated 20 December 1992 from the Chairman of ACFM, referring to the 1992 ACFM consultations held on 23 September 1992, working groups were requested to "evaluate and comment upon,
the quality and adequacy of the fishery and sampling data upon which their assessments are based", "evaluate, and comment upon, the quality of their assessments" and express their consensus views on appropriate management advice for any of their stocks, pointing out any concerns and developments in the stocks and fisheries which they feel ACFM should address.

### 1.3 Sources of Data

### 1.3.1 Denmark

The Danish industrial landings are defined as all landings taken by fisheries using mesh size smaller than 32 mm and landed with the purpose of being converted to fish meal and oil.

Catches landed for human consumption, almost all taken by gears of mesh size equal to or greater than 31 mm , but for some reason (e.g. quality or price) used for reduction, are not included in this description.

The objectives of the Danish sampling scheme are:

- To collect data needed for estimation of the total landings taken in the Danish small meshed industrial fishery by species, statistical square and month.
- To collect information on age and length composition by species, month and area.

The basic sources of information are stored in four data bases:

- Sales-slip database.
- Logbook database.
- Species composition database.
- Biological database.

## The sales-slip database:

For all landings which are sold, first hand buyers are obliged to report to the Ministry of Fisheries (MF) information on target species, quantity, price and area (ICES Division) for each landing. The information is recorded in the MF's Sales-slip Database.

The information on species composition in the industrial sales-slip database is not representative of the true species composition of the landings as only the target species is recorded (e.g. a landing of nominal Norway Pout may, and usually does, contain various quantities of other species taken as by-catch). Therefore, only information on total quantity of all species landed from each main area (ICES-Division) is used from this database.

## The logbook database:

For the North Sea the general rule deals with vessels with an overall length of 17 m or more. In the Skagerrak and Kattegat the minimum length of vessels is set at 12 m . The logbooks contain information at least on a daily basis about, e.g., catch-data, catch-position (statistical rectangle), species and quantity. Information from these logbooks is recorded in the Logbook Database in the Ministry of Fisheries. The logbook information is used to estimate the relative distribution by ICES statistical rectangle of the landings identified as having been taken by the small meshed industrial fishery. In addition, catch per unit of effort is obtained from catches and fishing day according to this database.

The landings used in this relative distribution are those in which the species composition is consistent with those species typically landed for industrial purposes.

## Species composition database:

The industrial landings are sampled for species composition on a routine basis by the Fishery Inspectors. One standard sample of 10 to 15 kg is taken from each landing sampled. The samples are sorted by species and total weight by species and the position of capture (ICES statistical rectangle) is recorded. The data are stored in the Species composition database in the Ministry of Fisheries. The total number of samples of landings in the North Sea, Skagerrak and Kattegat in the years 1989 to 1992 are given in the text table below.

Before the data are used to calculate the landings by species a quality check is carried out using information from research and commercial vessel surveys, historical data, the biological database (see below) and informal contacts in the most important port.

The species composition of landings by other nations in Danish ports is also estimated and included in this database.

## Biological database:

Separate biological samples from industrial landings are taken on a routine basis by the Fishery Inspectors and handed over to The Danish Institute for Fisheries and Marine Research (DIFMAR). The sample size is about 10 kg . After sorting the sample by species the total weight by species, length composition and mean weight by length group are recorded. Otoliths are collected for age reading. The data, together with information on catch position, are stored in DIFMAR's Biological database.

The total number of samples taken in the North Sea, Skagerrak and Kattegat in the years 1989 to 1992 are given in the text table below.

Number of landings from the North Sea, Skagerrak and Kattegat sampled in the period 1989 to 1992.

|  | 1989 | 1990 | 1991 | 1992 |
| :--- | ---: | ---: | ---: | ---: |
| Species com- <br> position data- <br> base | 1,388 | 1,162 | 824 | 1,109 |
| Biological <br> database | 178 | 64 | 307 | 422 |
| Total number <br> of samples | 1,566 | 1,226 | 1,131 | 1,531 |
| Landings <br> ('000 tonnes) | 1,322 | 960 | 1,207 | 1,376 |

## Estimation of landings by species:

The total industrial landing by month and ICES Division or Sub-area are calculated using the sales-slip database. The landings are allocated to statistical rectangle using the relative geographical distribution from the logbook database of landings identified as having been taken by the small meshed industrial fishery. The output is industrial landings by statistical rectangle and month.

The relative species composition by statistical rectangle and month is estimated using the information in the species composition and biological data base. An average composition by rectangle is estimated taking the mean of all samples from that rectangle. If more than one sample is taken from the same landing, a mean composition of the landing is calculated and treated as one sample.

After calculation of average composition by rectangle a new average composition is calculated taking into account the species composition in all neighbouring rectangles. This is done by taking the mean species composition of the rectangles and all 8 surrounding rectangles.

The total landings by species, statistical rectangle and month are calculated using the estimated species composition and total landings by rectangle and month.

The reason for possible discrepancies between the species composition in the biological database and that in the logbook database is: 1) that the species composition in the logbook is based on a subjective estimate and, 2) that
there is a general tendency by the fishermen to underestimate the contents of protected by-catch species.

## Estimation of the Fishing Effort

For effort calculation purposes, the number of fishing days is calculated as the number of days on which any fishing has taken place according to the logbook.

### 1.3.2 Norway

The term "industrial fisheries" in the Norwegian context refers to fisheries for Norway pout and sandeel by small meshed trawl, i.e. using mesh sizes ranging from 16 to 50 mm . In the sandeel fishery, a mesh size less than 16 mm may be used between 1 March and 31 October.

The current monitoring system for sampling landings caught by small meshed trawl aims at a representative sampling of the landings from the fisheries for Norway pout and sandeel, to provide data for informational and assessment purposes.

The main objectives of the current system are, through random sampling of the trawlers and their landings:
i) to obtain a geographical coverage of the fishing grounds on an annual/seasonal basis;
ii) to determine and record the species composition;
iii) to collect biological samples of the main species to allow estimates of age frequency and mean weight at age.

This has been achieved by establishing a sampling system at fish meal plants receiving industrial landings from the North Sea. In each port a person is appointed by the Institute of Marine Research on a part-time basis and is requested to sample two landings of Norway pout and one of sandeel per week.

A standard sample size of 50 kg is extracted from various parts of the landings in buckets of 10 litres. After sorting the sample, the number and weight of all species are recorded as well as the length distributions of the main species (Norway pout, sandeel, blue whiting, herring, horse mackerel, saithe, cod, haddock and whiting).

The species composition is calculated by unweighted arithmetic means, by quarter for the Norway pout fishery and by month for the sandeel fishery.

The general species composition in the Norway pout fishery demonstrates that the major components were

Norway pout ( $65 \%$ ), blue whiting ( $20 \%$ ) and herring (5\%), as an average of 1991 and 1992.

In the sandeel fishery, sandeel constitutes about $95 \%$ of the landings.

## Classification of landings

Norwegian official fishery statistics identify landings from industrial trawlers, i.e., trawlers using smallmeshed gear, by codes for species which make up at least $70 \%$ of a landing by weight. The codes commonly used are D12 for Norway pout, D13 for blue whiting and E 02 for sandeel. In cases where none of these codes are appropriate, the code is M02. Landings labelled D12, D13 and M02 are all officially reported to ICES as Norway pout when derived from the North Sea east of longitude $0^{\circ}$ or from the Skagerrak.

Effort data are derived from logbook records of landings containing at least $70 \%$ by weight of either Norway pout or sandeel.

### 1.3.3 Scotland

With the continuing decline in the amount of effort in the Division VIa sandeel fishery, there has been an associated decline in the sampling coverage of landings from the fishery. The landings are generally sampled as part of routine market-sampling operations which rely on a sampling team being present in Shetland when a landing from Division VIa is made. Relatively few boats are involved in the fishery so landings are relatively infrequent; hence the decline in coverage. Arrangements are also made for the meal-plant operators to retain samples for subsequent collection, but this is a less reliable method of sampling. The samples are used for both age determination and species composition. Effort data are obtained from logbooks, but with boats fishing in Division VIa and then having to sail to Shetland to land the catch, the added steaming time has distorted the effort data. In addition, a small proportion of landings from the Division VIa fishery are made into foreign ports, particularly in the Faroes, so it is not possible to sample these landings. In recent years the few Scottish boats fishing for sandeel in the North Sea have landed virtually all of their catch into Denmark, so no samples have been obtained from these catches.

### 1.4 Quality of Data

The working group noted and discussed the 'Report of a Meeting between the European Commission and Norwegian Authorities to Evaluate and Describe Measures Relating to Monitoring and Control of Industrial ByCatches in the North Sea - Bergen, 21-25 June 1993'.

### 1.4.1 Sampling coverage

### 1.4.1.1 Denmark

To illustrate the geographical coverage of the Danish sampling scheme in relation to that of the fishery for Norway pout and sand eel combined, the number of samples and the total Danish catch by rectangle and quarter in 1992 are compared in Figures 1.4.1.1a,b,c and d. It can be seen that catches were sampled from all but the least productive rectangles, with those from the most productive rectangles being most heavily sampled. The sampling intensity is approximately 1 sample ( 10 kg ) per 1000 tonnes of the two species landed.

### 1.4.1.2 Norway

Figure 1.4.1.2 shows the geographical distribution of the total landings of Norway pout in 1992 as per mille proportions per rectangle, together with the corresponding numbers of samples. A total of 63 samples were taken for 106,000 tonnes of Norway pout landed in that year, giving a sampling intensity of 0.6 samples of 50 kg per 1000 tonnes landed. The same is illustrated for sandeel in Figures 1.4.1.3a and b. In this case, a total of 27 samples were taken for a total of 89,000 tonnes landed, giving a sampling intensity of 0.3 per 1000 tonnes landed. The sandeel season in 1992 was very short, ending in early July.

### 1.4.2 Sources of bias

### 1.4.2.1 Samples

The manner of sampling by Denmark, Norway and Scotland has been described in Section 1.3. Possible sources of bias identified in these procedures are:
i) The catch in a vessel may be poorly mixed and heterogeneous. Fish at the surface of the hold may consist predominantly of those from the last haul, those which tend most readily to float upwards as a result of the motion of the ship, or those which the crew wish the inspector to see first. These effects could bias species compositions and biological measurements if samples are only taken from the top of the hold. Composite samples formed from subsamples drawn from evenly spread locations in the bulk of the catch would be preferable when possible. However, it may also be an advantage to sample from the last haul because the catch is better preserved and the source area is better known.
ii) Samples collected visually could be biased towards the species composition expected in the catch, or towards the more prominent individuals. A sampling procedure which does not
involve human choice of fish should be arranged if possible to minimise bias. The volume of each sample should be sufficiently large to make the inclusion of the larger fish in the catch possible. Since fish greater than about 40 cm are mostly removed from industrial catches nowadays, the sample volumes in use were felt to be adequate.
iii) The use of inspectors to draw samples for the purpose of collecting scientific samples could cause biases depending on the perceived likelihood of prosecution. The use of large volume samples when infringement of by-catch regulations is suspected may unduly weight those events.

### 1.4.2.2 Choice of sampling unit

A number of alternative sampling units can be considered, e.g. landings without regard to vessel, landings stratified by vessel, landings at given times and landings at given tonnage intervals. Depending on local circumstances, there is considerable potential for biases towards e.g. large vessels, different sea areas, different species according to the fishing habits of different skippers, etc. Ideally, each unit sample weight of fish within a given sampling stratum should have an equal probability of being sampled, given the sampling rate chosen for the stratum.

### 1.4.2.3 Treatment of data

Bias can arise in both the Danish and Norwegian systems for processing data because catch composition and total weight are not estimated for the same sampling units. This is mainly because the sampling of all landings to estimate composition is not at present practicable, and because randomisation cannot be perfect. The biases will depend on local circumstances but can be expected when there is a poor match between samples and landings with respect to statistical rectangles, fishing intentions of vessels, timing and perhaps other factors. These effects could possibly be reduced when calculating averages by weighting samples in relation to the proportion of the total catch which they appear to represent, but this would be unsatisfactory if many samples are missing. Data smoothing processes for composition data, e.g. the Danish system of averaging over sets of 9 adjacent rectangles, could be exacerbating mismatches between composition and tonnage measures, although it has the advantage of helping to reduce the problems of missing values for composition in some rectangles, and composition samples drawn from catches taken in more than one rectangle.

Problems of bias of a different kind can arise if the main species in catches are falsely declared in order to avoid fishery regulations.

### 1.4.3 Sampling variance

The variance of estimates of catch weights by species appears to be difficult to estimate using theoretically derived formulae because of the difficulties in linking qualitative and quantitative measures. If sampling does not effectively cover the fishing fleet and its activities in space, time and other significant respects, estimates of variance are likely to be too low. Also, any bias present in existing data is likely to lead to biased estimates of variance. Nevertheless, because of the importance of the herring by-catch in the Norwegian Norway pout fishery, Skagen (1993) has studied the variance of estimates of these by-catches by assuming that the proportion of herring in samples is Poisson distributed and that the samples provide a reasonable representation of actual catches. Then, using a Bootstrap re-sampling technique, he obtained a distribution of by-catch percentages as a function of the number of samples, N, taken. During 1992, 63 samples were collected from the Norway pout fishery. This implies that the range between the 10 and 90 percentiles for the proportion by weight of herring is somewhat less than half of the estimated mean value for the year. It was suggested that a modest increase of sampling effort from 1992 levels would be worthwhile. This method shows promise when there is only one species of interest in the by-catch. Extension to a multispecies situation would be complicated by the negative covariance between species' weights in a sample of fixed total weight.

### 1.5 Assessment Strategy

### 1.5.1 Background

Due to the breakdown of the sampling system in 1990, analytical assessments have not been made for the main North Sea stocks at subsequent Working Group meetings because standard VPAs require catch data for every year and season. At the last meeting (Anon., 1992), it was decided to attempt to estimate the missing catches as part of the assessment, rather than to use the very few samples that were available to estimate catches at age. At that meeting, two newly developed assessment models were tested, but neither of them worked satisfactorily at that time. One was a modified XSA, the other a separable VPA, which was specifically designed to handle the case where the catches are very low or zero, but where one survey index is available. For this purpose the separable VPA proved useful, and was used for the Shetland and Division VIa sandeel assessments in 1992 and again this year.

Since the last meeting both the separable VPA (Cook and Reeves, in press) and the seasonal XSA (see Appendix I) have been developed further. For most of the assessments done at the present meeting both programs have been tested, although time constraints prevented a full testing of the Seasonal Separable VPA (SSVPA). The seasonal XSA has the advantage that it can constrain the catches to a specified SOP, and it is also more flexible with respect to the treatment of the survey data. For the Shetland and Division VIa sandeel assessments the Working Group found no reason to change the previous practice.

### 1.5.2 Seasonal Separable VPA

The seasonal separable VPA (SSVPA) was first used at the previous Working Group meeting and is documented in the Working Group Report (Anon. 1992). Since then the method has been developed further, and it now includes an option to down-weight selected ages in the catch or survey data. This is appropriate where these ages are not well sampled or represented in the catches. The current implementation of the SSVPA, and its use in the assessment of industrial stocks is documented in Cook and Reeves (in press). The SSVPA program can still accept only a single research vessel series. However, where more than one series exists, as in the case of Norway Pout in the North Sea, the practice has been to combine the indices using factor analysis (Rosenberg et al, 1992).

### 1.5.3 Seasonal extended survivors analysis (SXSA)

This is a modification of the XSA used elsewhere within the ICES community. The basic theory is the same, but the practical implementation and tuning options are different. It operates on a seasonal basis and at present a half-yearly and quarterly version are available. In the present version, the unknown catches are estimated using estimated catchabilities and stock numbers. It is also possible to treat the current year as the year with unknown catches. This enables a prediction of the catches in the current year, where the information from survey indices is included.

A more detailed description of the method is given in a working paper which is attached to the report as Appendix I

## 2 TRENDS IN THE INDUSTRIAL FISHERIES

### 2.1 Division IIIa

The annual landings from the industrial fisheries for the years 1974-1992 are presented in Table 2.1. Minor revisions were made for sandeel in the period 1982-1989. The total landings have fluctuated between $93,000 \mathrm{t}$ and
$235,000 \mathrm{t}$ without any particular trend. Since 1987 the landings have been below the long-term mean of 160,000 $t$, mainly due to a decline in the landings of clupeoids. The so-called mixed-clupeoid fishery is not included in this table from 1991 onwards because the mesh size in this fishery was increased to over 32 mm . Comparatively low landings in the period 1989-1991 were followed by a marked increase to $148,000 \mathrm{t}$ in 1992, due to an overall increase in landings of all species except sprat.

### 2.2 North Sea

The annual landings from the industrial fisheries for the years 1974-1992 are presented in Table 2.2. For 1992 the landings have been broken down by quarters to indicate the seasonality of the various fisheries. Minor revisions were made for sandeel and sprat in the most recent years. The total landings were at a higher level in the 1970s than in more recent years, and have since then fluctuated without any particular trend, ranging from 1 million to 1.9 million t during the entire period. Landings increased from 1 million $t$ in 1990 to over 1.3 million $t$ in 1991 and exceeded 1.5 million $t$ in 1992. There was an overall increase in landings of all species in 1991, especially sandeel. A further increase in 1992 was due to high landings of sprat and Norway pout.

### 2.2.1 Trends in the industrial sandeel fishery in the North Sea

Looking back at the industrial fishery as it has been performed during the last twenty years in the North Sea, the spatial distribution of the fishery has been rather variable lacking any consistency in trends. This may be related to the fact that the area definitions are not based on any biological criteria with the result that they to some extent divide high density areas in two as happens in the high density area which occurs in the central North Sea during May in most years. A small change in location of the catches causes a shift in the apparent importance from one area to another. The importance of Area 2A (Figure 2.2.1a) is an example. The importance of Area 2A has been highly variable, being the most important area in 1978, 1981 and 1989 and of little to medium importance in other years with Area 1A to a large extent shoring complementary changes (Figure 2.2.1b).

Some general remarks can be made. Looking at the relative importance of each of the sandeel areas as shown in Figure 2.2.1b and c, it can be seen that Area 1A is the area in which the biggest fraction of the yearly catch has been caught in most years. The area of former importance in the southwestern North Sea (Area 4) has since the mid-1980s been of insignificant importance. The area around Shetland became increasingly more important during the 1970s and had its maximum in 1981
and 1982 after which the importance of the area declined with almost no catches in 1991 and 1992. Area 2B was of little importance, except in the mid-1970s, until in 1986, it became one of the most important areas, although there was a significant decline in catches from this area in 1992. Area 1C was only of significant importance around 1980.

### 2.3 Division VIa

The annual landings of Norway pout and sandeel as officially reported to ICES are presented in Table 2.3. The landings of both species in 1992 were well below the long-term average. Norway Pout landings were slightly greater than in 1991, but have remained at a low level. Landings of sandeel were the lowest since 1981 and continue the decline since 1988.

## 3 BY-CATCHES IN INDUSTRIAL FISHERIES IN THE NORTH SEA

Fish suitable for marketing for human consumption may be removed from industrial catches and sold separately. They then count against the relevant Norwegian or EC quotas and are not considered to be part of industrial bycatches.

The annual landings of by-catches of the major protected species haddock, whiting and saithe are given separately in Table 2.2. By-catches of haddock were at a comparatively high level up to 1977, then dropped to the level of the long-term mean of $17,000 \mathrm{t}$ and have since 1983 been below that level. By-catches of whiting were at considerably higher levels in some years, and above the longterm mean of $55,000 \mathrm{t}$ up to the early 1980s. They declined to levels below $20,000 \mathrm{t}$ in the period 19841987 but then increased to a level closer to the long-term mean. By-catches of saithe were at relatively high levels up to 1976, then suddenly dropped to a level of a few thousand tonnes where they have remained ever since.

The distribution of industrial landings by fisheries, and associated by-catches of selected species north and south of $57^{\circ} \mathrm{N}$, based on Danish and Norwegian estimates combined, is shown in Table 3.1. In the north the 1992 figures clearly indicate a sandeel fishery with insignificant by-catches, a fishery for Norway pout with marked by-catches of herring, whiting, blue whiting and other non-listed species and a non-defined category of other species consisting mainly of blue whiting. In the south there was a fishery for sandeel with some by-catches of sprat, herring, whiting and other species, a sprat fishery with some by-catch of herring and a mixed fishery for other species such as herring, sprat, sandeel, Norway pout and others. The break-down of species in the column "other" in Tables 2.2 and 3.1 respectively are presented in Table 3.2.

### 4.1 Landings

Total landings as officially reported to ICES are shown in Table 4.1. In 1992 they amounted to $84,000 \mathrm{t}$. This is a considerable increase on the 1991 total of $49,000 \mathrm{t}$, and has previously only been exceeded in 1985 when the total was $86,000 \mathrm{t}$.

## 5 NORWAY POUT IN THE NORTH SEA

### 5.1 Landings

Annual landings as provided by Working Group members are shown by country in Table 5.1.1. In 1992 the landings were 255,000 tonnes which is an increase of $64 \%$ over 1991 and the highest landings on record for the last 8 years. Table 5.1.2, which contains the landings for 1990 to 1992 by month and country, shows that most of the increase took place from July to November in which months landings almost doubled compared to 1991. The area distribution is shown in Figure 5.1.1.

### 5.2 Fishing Effort and Catch Per Unit of Effort

## Danish effort

Danish CPUE (tonnes per day fishing) by vessel category (Gross Register Tonnes) is shown in Table 5.2.1 for the period 1983 to 1992. CPUE has increased for all vessel categories since 1990 and, with the exception of the 251300 GRT category, is now the highest on record.

In all years the CPUE of the 251-300 GRT vessels has been lower than the CPUE of the 201-250 GRT vessels. The consistently lower efficiency of these vessels may be explained by a low average horsepower which is at the same level as in the 201-250 GRT category. In previous years effort was standardized to a vessel size of 200 GRT by fitting a linear model to $\log$ CPUE versus GRT. In order not to smooth out the consistently lower CPUE of the 251-300 GRT category it was decided to use the raw CPUE values directly as an indication of relative fishing power. The effort was therefore standardized to the 151-200 GRT category by multiplying the quarterly number of fishing days of each vessel category by the average yearly CPUE of that category divided by the average yearly CPUE of the 151 to 200 GRT category. This approach was used to revise the time series of effort data back to 1984.

## Norwegian effort

The number of fishing days and average GRT of Norwegian vessels fishing for Norway pout are shown by
quarter in Table 5.2.2 for the period 1982 to 1992. The effort and mean GRT for the period 1982 to 1991 has been revised. The CPUE now refers to all landings reported as the category Norway pout. The total effort is obtained by dividing the estimated catch of biological Norway pout by the CPUE.

## Combined Danish and Norwegian effort.

The Danish and Norwegian data were combined after the Norwegian data had been standardized to a vessel size of 175 GRT. This was done by fitting a linear model to the Danish $\log$ CPUE by vessel category with GRT as the independent variable:
$\log$ CPUE $=\log \left(a_{\text {year }}\right)+b^{*}($ GRT-50 $)$
For the years 1988 to 1992 b was estimated to be 0.324 . Prior to 1988 a value of $b$ of 0.38 was used (Anon. 1988). The practice of using a constant $b$ over several years was originally introduced in 1985 (Anon. 1985). In the present analysis, $b$ was not found to vary significantly between years. The model was used to standardize the Norwegian data by multiplying the number of fishing days by:

Effort $_{175}=$ Effort $_{x} *[(x-50) /(175-50)]^{b}$
where x is the average GRT of the vessel category. The combined Danish and Norwegian effort is shown in Table 5.2.3. Compared to 1991 total effort increased by $44 \%$ in 1992 and was the highest on record since 1984.

### 5.3 Catch at age

Catch in numbers at age was estimated from Danish and Norwegian samples (Table 5.3.1). The catch at age in 1992 was dominated by the 1991 year class. One year old fish accounted for $72 \%$ of the landings in weight in 1992 compared to $52 \%$ in 1991.

### 5.4 Weight, maturity and natural mortality at age

The mean weight at age in the catch by quarter for 1992 was estimated from Danish and Norwegian data (Table 5.4.1). The mean weight at age in the stock was the same as used in the 1990 report (Anon. 1990). Compared to previous reports the maturity at age 1 was reduced from 0.5 to 0.1 . This follows the recommendation in the 1984 working group report (Anon 1984). Weight at age in the stock, maturity at age and natural mortality at age are given in Table 5.4.2.

### 5.5 Research Vessel Surveys

Updated research vessel indices are given in Table 5.5.1. Two points should be noted:
i) All indices back to 1982 from the Scottish Groundfish survey (SGFS) conducted in August have been re-computed uniformly and in the same way as other roundfish indices derived from the same surveys. Past indices have changed slightly but are believed to reflect changing abundances from year to year more accurately.
ii) In 1992, the net used on the English Groundfish survey (EGFS) conducted in August was changed from a Granton trawl to a GOV type. A correction factor for the 1992 results was estimated by regression analysis of year class numbers as described by Cotter (1993) using data from the English and Scottish GFSs, both being in the same season. Estimation was less accurate for Norway pout than for other species because of the short life span, and because Scottish data were in the form of a combined index representing round fish areas 1,2 and 3 primarily (as shown in the table), rather than being disaggregated to the individual areas as would be preferred for the analysis. Data from the EGFS were available for the three areas individually. To compensate for expected effects on variance, the Scottish and English data were weighted 3 and 1 respectively in the GLM analysis. The selected model was:
$\ln \mathrm{N}=\mathrm{a}$. Age $1+\mathrm{b} \cdot$ Age $2+\mathrm{c}$. Yearclass $+\mathrm{d} \cdot \mathrm{RFA}+\mathrm{GOV}+$ error
where N is the abundance index, Age $1=0$ for 0 -group and 1 for older fish, and Age $2=0$ for 0 -group and (age in years - 1) for older fish. (The use of dummy age variables in this way allows for the reduced availability of 0 -group to the survey.) The SGFS results were arbitrarily designated as $\mathrm{RFA}=0$ for the purpose of the model. All factors were found to be significant ( $\mathrm{P}<-$ 0.04 ) except RFA which was marginal ( $\mathrm{P}=0.057$ ) but retained in the model nevertheless. The GOV net was estimated to fish 3.3 times more effectively than the Granton $(-1+1$ s.e. $=2.0$ and 5.7). The estimate is comparable to those obtained more accurately for cod, haddock and whiting (recently revised with data from EGFS 1993), and the decision was therefore taken to utilise it together with data from EGFS 1992 for tuning the Norway pout VPAs.

In Table 5.5.1 it is notable that the EGFS results for 0 -group in 1992 are double those in 1991, and double again in 1993 to strengths not previously reached since the early 1980s. All three surveys indicate that the 1991 year class was strong as 1 -group in 1992, but the IYFS and the EGFS differ in the relative strengths of the 2 -group in 1993. The relative numbers of the 1990 year class as 3-group in 1993 show the same.

### 5.6 Stock Assessment

Separable seasonal VPA (SSVPA) and seasonal XSA (SXSA) were used to estimate the missing quarterly catch in numbers at age for 1990 and the state of the stock.

The SSVPA was used to fit catch at age data to combined Norwegian and Danish effort data from 1985 to 1992 and to combined EGFS, IYFS and SGFS survey indices. Only catch at age data for 1985 to 1989 and 1991/92 could be used. Because the SSVPA can only use one time series of survey indices at a time the available indices were combined by factor analysis using IYFS, EGFS and SGFS indices for ages 1 to 3 and SGFS for age 0 . The resulting combined index as well as statistics from the factor analysis are given in Table 5.6.1. In the SSVPA the catch data, combined survey indices and effort data were given equal weight as this resulted in similar mean square residuals for each data set. Research vessel catchability was assumed to be constant for 2-year -old and older fish. Output statistics from the SSVPA are given in Table 5.6.2. The estimated selectivities increase with age and season to an extent which is not reflected by the CPUE data. The positive year/season effect residuals and positive research vessel residuals for 1992 suggest that the high research vessel indices are not reflected by the commercial CPUE.

The XSA is able to provide estimates of catches for which the SOP is in accordance with landings. Initially, the model was allowed to weight the various indices automatically by the inverse variance of the catchabilities. However, this procedure resulted in survey indices receiving 10-20 times the weight of the commercial cpue. As this resulted in large negative catch residuals for 1992, it was decided to give equal weight to commercial and research vessel cpue. This option, constraining the SOP of the unknown catches to the actual landings, and a linear model for catchability as a function of time with a 5 year cosine taper was applied in an attempt to estimate the 1990 catch at age data. Output statistics are given in Table 5.6.3. For ages 1 and 2 the $\log$ catch residuals are all negative in 1992 suggesting that commercial CPUE would underestimate the stock.

The XSA and SSVPA log catch residuals versus time are shown in Figure 5.6.1 for ages 1 and 2. For age 1 the catch residuals from both models show corresponding changes over time. Both series show large residuals in 1986 and 1989 and both decline from 1987 onwards.

Table 5.6.4 shows the estimated catch in numbers at age in 1990 from the SSVPA and the SXSA. For age 2 the results from both methods are very alike, but for age 1 the results differ in quarter 1 where the XSA estimates a catch at age $160 \%$ above the estimate from the SSVPA. The Working Group decided to use the catch in numbers estimated by SXSA since these were estimated
taking the observed wight of the landings into account. However, despite the fact that the catches estimated by the SSVPA are not constrained to have the same SOP as the landings, the results are very similar. This could give some confidence in the values adopted.

The results from the SXSA in terms of stock in numbers at age, total biomass and spawning stock biomass are given in Table 5.6.5. After a rapid decline from 370 thousand tonnes in 1984 to 92 thousand tonnes in 1986 the spawning stock biomass has gradually increased to 220 thousand tonnes at the beginning of 1992 (Figure 5.6.1). Quarterly fishing mortalities are given in Table 5.6.6.

Figure 5.6.2 compares the total stock biomass as estimated by SXSA and SSVPA to the stock biomass estimated by VPA at the 1990 meeting of the WG (Anon. 1990). With the exception of the terminal year the results from the SXSA show a close correspondence to the historic VPA. The biomass from the SSVPA is far below the biomass estimated by the two other methods, but shows the same trend over time.

The annual fishing mortality at age 1 is shown in Figure 5.6.3. The SXSA is seen to produce values in the same range as the historic VPA, albeit with less interannual variability, while the SSVPA estimates are consistently higher. Fishing mortality is estimated to have declined from a peak of 0.8 in 1985 to a level around 0.4 in recent years: This pattern is not reflected by the development of fishing effort which increased in 1992 to the highest value on record since 1984.

The sensitivity of the SXSA was investigated by retrospective analysis in which the terminal year was decreased from 1993 to 1989 (Figure 5.6.4). All of these runs produced almost identical values of total stock biomass at 1 January indicating that the results for the terminal year are quite robust.

### 5.7 Catch prediction

The SXSA can also be used to perform a catch prediction one year ahead provided catch at age data are available for all other quarters and years. The fishing effort was assumed to be equal to that in 1992. Using the estimate of the catch in numbers at age in 1990 and the IYFS and EGFS survey indices obtained in 1993 the total landings in 1993 were predicted to increase to 304 thousand tonnes, of which 129 thousand tonnes should be taken in the first two quarters. Preliminary estimates of the actual landings are approximately 68 thousand tonnes in the first two quarters of 1993.

## NORWAY POUT IN DIVISION VIA

### 6.1 Landings

Landings of Norway pout as officially reported from Division VIa are given for the period 1974-1992 in Table 6.1. There have been considerable variations in landings over this period, varying from $38,000 \mathrm{t}$ to $3,000 \mathrm{t}$. Landings in 1992 were relatively low, as in the previous two years.

## 7 SANDEEL IN DIVISION IIIA

### 7.1 Landings

Landings in 1992 are estimated to be about 39000 tonnes (Table 7.1) representing an increase of almost $70 \%$ from 1991. The main part ( 34610 tonnes) was recorded from the Skagerrak. Table 7.1 has been revised and the landings in 1982-89 are not likely to undergo further revision. For 1990-1992 a different method of estimating the Danish species composition has been used besides the one used hitherto. The estimated landings in these years are likely to be revised if the new method is adopted as standard in the future.

Landings in 1993 have not yet been estimated.

### 7.2 Biological Data

Sampling biological data was started in 1992 and continued in 1993. They show amongst other features that the landings do not consist entirely of Ammodytes marinus but also contain species like A. lancea, Hyperoplus lanceolatus and even Gymnammodytes semisquamatus. The second species is even the main constituent in some samples.

## 8 SANDEEL IN THE NORTH SEA

### 8.1 General

### 8.1.1 Landings in 1992 and 1993

Total landings in 1992 show a slight increase from 1991 and reached about $855,000 \mathrm{t}$ (Table 8.1.1). Landings by country show an increase in Danish landings of about 50, 000 t while the Norwegian landings decreased by 40,000 tonnes. Table 8.1 .2 shows that the fishery in 1992 came to an early end suggesting a lack of fishable concentrations of O-group sandeel in the second half of the year. Table 8.1.3 gives the monthly landings in each of the areas shown in Figure 2.2.1a.

Table 8.1.4 shows a substantial difference in development between the two assessment areas. In the northern
area landings went down by about 200,000 tonnes while those in the southern area increased by a similar amount to nearly $670,000 \mathrm{t}$ which is the highest on record.

Figure 8.1.1 shows the distribution of the Danish and Norwegian catches combined by statistical rectangle in 1992. The landings from the new fishing grounds off the Firth of Forth increased further in 1992 to about 60000 tonnes landed in Danish harbours. The exploitation began in 1990 with a catch of about 3000 tonnes and increased to nearly 39000 tonnes in 1991. In those two years the fishery off the Firth of Forth only took place in June.

Final landings figures for 1993 estimated by samples collected for species composition were not yet ready at the time of the Working Group meeting. Preliminary official figures, and data from log-books both point to a reduction of about $40 \%$ in the Danish landings as compared with 1992. As preliminary estimates of the Norwegian fishery do not indicate any major change from the previous year, this would indicate a Danish catch of about $450,000 \mathrm{t}$. One reason for the decrease in Danish landings was a strike in the last part of March and the first part of April 1993.

### 8.1.2 Effort and CPUE

The effort statistics and the estimation of CPUE were discussed by the Working Group and some preliminary revisions of the material were made.

Fishing effort (number of days fishing) are extracted from the fishermen's log-books if the landing is recorded as being more than $70 \%$ sandeel. In recent years the total landings selected in this way have exceeded those estimated from the market samples taken for species composition and presented in the catch tables of the Working Group report by the Working Group members. Discrepancies are thus apparent between catch figures in Table 8.1.2 and the "catch sampled for fishing effort" in Table 8.2.1.3. The misreporting has apparently increased in recent years and represents a bias confined to the second half year. While log-books are obligatory for Danish fishermen they are optional in the Norwegian industrial trawl fisheries. This makes it difficult to estimate the range of the bias so introduced. By-catches on the other hand, are not important in the case of sandeel.

One way to overcome the problem is to extract effort data from only those landings which are represented in the market samples for species composition, i.e. those for which there is evidence that the contents were sandeel. However, time did not permit such corrections to be made the last five years material in time for the Working Group meeting.

Another objection which could be made to the effort data, as hitherto presented, is the way in which they are standardised in order to obtain an estimate of the total international effort.

The Norwegian effort data (Table 8.2.1.2) are presented as the total number of fishing days and a mean GRT calculated by weighting each participating vessel's GRT by its number of trips. To convert the Norwegian CPUE to the standard CPUE corresponding to a vessel size of 200 tonnes, the multiplicative model CPUE $=\mathbf{a}$ *(gtr50)**b was applied to all Danish data (Table 8.2.1.1), assuming that $a$ is dependent on year and season, and $b$ on season only, as originally suggested by the 1985 Working Group (Anon 1985). The ensuing values for $b$ were 0.35 for the first half of the year and 0.24 for the second half of the year. The Norwegian data were standardized to a vessel size of 200 tonnes by applying these values of $b$ to the mean GRT for each year and season.

The Danish effort data (Tables 8.2.1.1 and 8.3.1.1) are treated in 7 tonnage groups: $0-50,51-100,101-150,151-$ 200, 201-250, 251-300 and >300 GRT. Mean CPUEs are calculated for each group and a power function of the form:

$$
\log \mathrm{CPUE}(\text { season,GRT })=\log \mathrm{A}+\mathrm{B}^{*} \log \mathrm{GRT}
$$

is fitted by half-year and assessment area. CPUE for a 200 GRT vessel is then calculated using the parameters obtained and revised versions of which are shown in Tables 8.2.1.4 and 8.3.1.3. However, in order to estimate fishing power differentials between vessel categories, the vessels should ideally fish on the same concentration of fish, i.e. fish in the same place at the same time. This condition is not fulfilled by the routine outlined above and may in part explain the often very large differences in the two parameters estimated from one assessment to another. Figure 8.1.2 clearly shows that the smaller vessels are fishing close to the Danish coast while the larger the vessel the further is the area of action extended westward. A comparison of the vessel categories will thus include not only differences in fishing power but also very significant differences in stock densities and catchability.

The Working Group considered that a better approach would be to calculate efficiency coefficients and apply these to the actual number of days fishing by the respective vessel categories. The coefficients will probably be constant over an appreciable number of years considering the present stability in fleet composition.

A special feature apparent in Tables 8.2.1.3 and 8.3.1.1 is the fact that the CPUE of the vessel category 251-300 GRT is at the same level and often lower than the smaller 201-250 GRT group. The most probable explana-
tion is that, while the mean tonnage in the two categories are 229 and 276 GRT respectively, the mean horsepowers of 914 and 930 HP are only slightly different. This will make the bigger vessels less efficient and influence the fitted curve. Applying the revised method outlined above leaves the categories independent of each other.

### 8.2 Sandeel in the Northern North Sea

### 8.2.1 Fishing effort and CPUE

The effort data have been commented upon in the section above. It should be kept in mind that estimates for the second half-year are rather unreliable due to misreporting of catches. Table 8.2.1.1 giving Danish CPUE data has nevertheless been revised for both seasons and new standard CPUEs have been calculated as shown in Table 8.2.1.4. The low value in 1993 reflects the lower abundance of the 1992 year class. The Norwegian effort data are given in Table 8.2.1.2.

The standard international CPUEs have been calculated as the average of the Danish and Norwegian means weighted by the catch sampled for fishing effort and are shown in Table 8.2.1.3. The figures for 1982-1987 differ considerably from previous reports in which the Danish standard effort was scaled to the average value of the Norwegian time series because the Danish recorded CPUE was higher than the Norwegian CPUE. The Working Group could not accept this reason as being valid and pointed out that differences in the fishing areas of the two fleets could account for different CPUEs in the early period. Table 8.1.4 and Figure 2.2.1 suggest, for example, that the proportional catches in sandeel areas 2 B and 3 have changed over the period in question and that Area 3 has been mainly exploited by Danish vessels.

### 8.2.2 Catch at age

Data were available from both the Danish and the Norwegian fisheries with a satisfactory coverage in the first half of 1992. The second half-year was poorly covered, as usual, but the season was short and the catch only amounted to about $14 \%$ of the total.

Age analyses have probably improved, but there are still appreciable differences between the two sets of national data. The Norwegian data give a higher average age than the Danish and the numbers per tonne are 67,500 and 115,300 for Norwegian and Danish data respectively. Again, geographical differences in the areas fished may be responsible. Catches in number at age are given in Table 8.2.2.1.

### 8.2.3 Weight at age

Mean weights at age for 1992 are shown in Table 8.2.3.1 together with revised data for 1991. The Danish and Norwegian data were combined by weighting by catches in number.

### 8.2.4 Stock assessment

A semi-annual XSA was run using the catch-at-age and effort data described above. The natural mortalities and the maturity ogive given in Tables 8.2.4.1 and 8.2.4.2 are the same as in previous assessments.

The estimates of unknown catches were constrained to give a sum of products equal to the assumed catch in tonnes, with weights at age being the mean values over the years 1989-1991.

Test runs weighting the catchabilities according to their inverse variance gave higher weight to the data from the second half of the year compared to the first half of the year, and also gave high weight to the oldest age groups. Since there is evidence that both the effort data and the age distributions may be more reliable for the first than for the second half of the year, and since the age distribution for the oldest ages is uncertain, the group decided to use the option for manual weighting of the catchabilities. The weighting factors are given in Table 8.2.4.3. The results in terms of stock numbers, fishing mortalities and estimates of unknown catches were not radically different by the two approaches.

The $\log$ catch residuals were generally quite high, but without any particular trend. This underlines the problems with using CPUE in the commercial fishery as the only data for calibrating the VPA, in particular when CPUE may reflect the concentration of fish in limited localities more than the total stock abundance. The results of the XSA are given in Table 8.2.4.3.

Average $F$ over ages $1-2$ is plotted against effort in Figure 8.2.1. The correspondence between F and effort is very poor.

The estimates of recruitment in the most recent years are very uncertain, because each of these is effectively determined by a single CPUE value. For this reason, and because actual catch data for comparison were not available, a prediction for the 1993
catches was not attempted.
For the above reasons, it is also apparent that the assessment will be quite unreliable for the most recent cohorts. The estimate of the state of the stock will therefore always lag behind. This can hardly be improved unless supplementary measures of stock abundance, e.g. by survey indices, become available.

### 8.3 Sandeel in the Southern North Sea

### 8.3.1 Fishing effort and CPUE

The mean CPUE per vessel category, the total estimated international effort and the calculated standard CPUEs revised back to 1987 are shown in Tables 8.3.1.1-8.3.1.3 respectively. After the rather low figures in 1991 the effort increased again in 1992 to the level of 1989 and 1990.

### 8.3.2 Catch at age

Catch in numbers at age were available for the Danish fishery. Catches from other nations were distributed by age using the Danish age distribution. Total catches in number at age are given in Table 8.3.2.1.

### 8.3.3 Weight at age

Weights at age in the catch were obtained from Denmark (Table 8.3.3.1). Weights at age in the stock, natural mortality and maturity ogive were not changed from previous years.

### 8.3.4 Assessment

A seasonal XSA was run on a half yearly basis, with the effort and catch at age data described above. The natural mortalities and the maturity ogive given in Tables 8.2.4.1 and 8.2.4.2 are the same as in previous assessments. The estimates of the unknown catches at age in 1990 were constrained to give a SOP equal to the assumed catch in tonnes, using as weights at age the mean values over the years 1989-1991.

As for the northern stock, test runs weighting the catchabilities according to their inverse variance gave higher weight to the data from the second half of the year compared to the first half of the year, and also gave high weight to the oldest age groups. Again, it was decided to use the option for manual weighting of the catchabilities. The weighting factors are given in Table 8.3.4.1. The results in terms of stock numbers, fishing mortalities and estimates of unknown catches were not radically different and for the run accepted are given in Table 8.3.4.1.

The $\log$ catch residuals were generally quite high, but without any particular trend.

Average F over ages $1-2$ is plotted against effort in Fig 8.3.1. The correspondence between F and effort is generally quite good ( $\mathrm{r}=0.77$ for 1982-1990), the first half of the year for 1991 being an exception. This fairly good correspondence may point to the age distributions as the most important source of the large log catch residuals. This again may possibly be influenced by the fishermen's tendency to remain on the same grounds as long as the
fishery is satisfactory, which implies that strong year classes may be overrepresented in the catches.

The estimates of recruitment in the most recent years are very uncertain, since each of these are effectively determined by a single CPUE value.

For the reasons given above, and because actual catch data for comparison were not available, a prediction for the 1993 catches was not attempted.

### 8.4 Sandeel in the Shetland Area

### 8.4.1 Fishing effort and CPUE

The sandeel fishery at Shetland remained closed during 1992 and 1993, so there was no fishing effort or catch during these years. Standardised effort data for previous years are presented in Table 8.4.1, and catch-at-age data for the commercial fishery are given in Table 8.4.2. Total landings are shown in Tables 8.1.3 and 8.1.4.

### 8.4.2 Research vessel survey data.

The series of annual sandeel surveys at Shetland which started in 1984 was continued in 1992 and 1993. Details of the surveys, and of the calculation of the survey indices, were given in the previous Working Group Report (Anon. 1992). The surveys are conducted in August of each year which means that the indices from the 1993 survey were available to the Working Group. The indices are given in Table 8.4.3.

### 8.4.3 Weights at age.

With no recent commercial catch data from the stock, long-term average weights-at-age from the catch have been used to estimate biomass totals. These are given in Table 8.4.4.

### 8.4.4 Natural mortality and maturity

Natural mortality coefficients, and the proportion mature at age are as used previously. The values are given in Table 8.4.5.

### 8.4.5 Analytical assessment

Seasonal separable VPA (SSV) was used in the present assessment as it can use both commercial and survey data. At present the number of years' catch and survey data must correspond, so the present assessment only used catch data back to 1984. All available survey data up to and including 1993 were used.

Initial runs of the SSV gave equal weighting to commercial and survey catches at all ages. The diagnostics from these runs showed some large residuals on the commer-
cial catch at age 0 , suggesting that these catches were less well sampled than those at older ages. Thus, in subsequent runs, the catch data at age 0 were given a weighting of 0.5 relative to the older ages. There was also a similar pattern in the research vessel catches at older ages $(4+)$, so these were also down-weighted to the same extent. The survey data were given a weight of 0.5 relative to the catch and effort data as the survey has used a number of different vessels, including both commercial and research vessels.

Some diagnostics from the final SSV run are shown in Table 8.4.6. As previously, the catch residuals for the first half of 1987 show a large positive residual at age 1 , with negative residuals at all older ages. This reflects the concentration of fishing effort on grounds where the relatively strong 1986 year class was concentrated, and thus represents a slight violation of the assumption of separability. The research vessel residuals show a suggestion of a shift from positive to negative over time. This may correspond to the shift from commercial to research vessels in conducting the survey.

### 8.4.6 Trends in biomass, fishing mortality and recruitment

Fitted populations since 1984 from the SSV are given in Table 8.4.7, along with spawning stock biomass estimates. This relatively short time series is a result of the constraint on the number of years of data which the program can handle. Trends in recruitment and spawning biomass are shown in Figure 8.4.1a and b. The estimates of the strength of the 1993 year-class, and the 1994 spawning biomass are subject to particularly high uncertainty and this is indicated on the graph. Fishing mortality estimates are given in Table 8.4.8.

The present assessment confirms that the 1991 year class is substantially stronger than any other recent yearclasses, and its maturation at the start of 1993 has reversed the decline in spawning stock, which was at a historic low following a series of very poor year-classes. The first estimate of the 1993 year-class indicates that it may be of moderate strength.

### 8.4.7 Management considerations

The fishery was closed at the start of 1991 as the spawning stock had fallen to a historic low, and there was doubt over its ability to produce a strong year class and thus ensure stock recovery. Since then, the strong 1991 year-class has recruited to the stock. Research into factors affecting the availability of sandeels to seabirds at Shetland (Wright and Bailey, 1993), indicates that in 1991 there was a substantial influx of 0 -group from areas to the south-west of Shetland. In general it seems highly likely that recruitment to the Shetland stock is not wholly dependent upon the amount of larvae spawned at Shet-
land, although the contribution from spawning areas outside of Shetland can vary considerably from year to year.

### 8.4.8 Quality of assessment

The assessment of the current state of the stock is based wholly on survey data and, for years where catch data are available, the fishing mortality is very low. Thus, this assessment is subject to particularly high uncertainty. In addition, the stock is at present dominated by the strong 1991 year-class so estimates of spawning stock are particularly sensitive to values of weight at age and maturity assumed for this year-class. Nonetheless, it is clear that this year-class is very strong and that it should have resulted in a marked increase in the spawning stock biomass, although the absolute level of that increase is uncertain.

### 8.4.9 Other issues

The main sandeel grounds off the south-east coast of Shetland are close to the site of the "Braer" oil spill in January 1993. Monitoring of the effects of the oil pollution have detected some contamination of sandeels, but whether this has had any deleterious effects on the population is as yet unclear. Work on this is still underway.

## 9 SANDEEL IN DIVISION VIa

### 9.1 Landings

Official landings of sandeels from Division VIa are given in Table 9.1 and in Figure 9.1.a. Landings in 1992 showed a further decline to just under 5,000 thousand $t$. This represents a $42 \%$ reduction on the 1991 figure, and is the lowest figure since the start of the fishery in 1980.

### 9.2 Fishing Effort and CPUE

Fishing effort data, in days absent by month, for the period 1981 to 1992 are given in Table 9.2. In recent years boats exploiting this fishery have occasionally landed their catch into the Faroes or Denmark, so the record of effort is incomplete. However, it is apparent that the reduced catches in 1992 were in line with a further decline in effort. As in 1991, the absence of a local processing plant is the main reason for the decline in the fishery.

Due to the low number of fishing trips made in 1992, and to the loss of information due to boats landing abroad, it was not possible to standardise effort to a fixed vessel size. For similar reasons, no correction has been made for the additional steaming time required to land the catch in Shetland. Nominal effort figures were
used for 1992. These are given in Table 9.3, together with standardised effort figures for previous years. The problems arising from this deterioration in the quality of the effort data are addressed in Section 9.6.

In 1992 and 1993 the August survey of sandeels at Shetland was extended to cover the west coast grounds. As there are only two years of data from this survey, and as there were differences in the grounds covered in the two years (due to bad weather), it is not yet possible to use these survey data in the assessment.

### 9.3 Catch at age

Catch at age data by month for 1992 are given in Table 9.4, and catch at age data by half-year for 1983 to 1992 are given in Table 9.5. There are some minor revisions of past data to allow for landings into foreign ports.

In 1992, sampling coverage was once again incomplete, but the 14 samples obtained came from areas/months which accounted for $67 \%$ of the total catch.

### 9.4 Weight at age

In view of the incomplete sampling coverage in recent years, long-term mean weights at age in the catch were used to estimate biomass totals. These are given in Table 9.6.

### 9.5 Natural Mortality and Maturity

Values used for natural mortality and proportion mature at age are as used previously. The values are given in Table 9.7.

### 9.6 Analytical Assessment

The assessment used a semi-annual separable VPA with equal weight given to the catch and effort data. The catches at age 0 were given a relative weighting of 0.5 , to remove some large residuals at this age. As the diagnostics from this run (Table 9.8) show, there are still some quite large residuals at this age, but further downweighting was not considered appropriate as the 0 -group fish are an important component of the catch. The year/season effect residuals for 1992 are not particularly large, suggesting that the problems with the effort data have not caused any additional problems in the assessment. The residual mean-square associated with the effort data is rather smaller than that associated with the catch data, suggesting that it may be appropriate to give more weight to the effort data. In view of the known problems with these data, however, this has not been done.

### 9.7 Trends in Biomass, Fishing Mortality and Recruitment

Figures 9.1a-d show trends in landings, fishing mortality, recruitment and spawning stock. Population estimates from the SSV are given in Table 9.9, along with spawning stock biomass estimates, and fishing mortality is given in Table 9.10. Fishing mortality has always been lower than 0.2 , and has declined steadily since 1989 to its present very low level. The 1991 year-class appears rather stronger than other recent year-classes, but its precise strength is still uncertain. The first estimate of the 1992 year class is also large but this estimate is subject to particularly high uncertainty, and the available survey data do not suggest that it is a strong year-class so this estimate has been omitted from the graph. Spawning biomass appears to be increasing, and the maturation of the 1991 year-class at the start of 1993 should have continued this trend.

### 9.8 Management considerations

Following the previous assessment of this stock, ACFM commented that this stock was virtually unexploited at present. Since then there has been a further decline in fishing effort and landings. With a recent strong yearclass and an increasing spawning stock, there appears to be no reason for concern over this stock.

### 9.9 Quality of Assessment

The low level of landings and effort in this fishery has led to problems in catch sampling. Together with the tendency for some boats to land their catch into foreign ports, this means that there has been a decline in the quality of both catch and effort data in recent years. As fishing mortality is very low relative to natural mortality, it can be seen that this assessment is subject to particularly high uncertainty.

## 10 AREA DISTRIBUTION

### 10.1 Sandeels

The distribution of sandeels is not well shown by national groundfish surveys because they are not caught effectively by the gears used. Instead, an attempt was made to use fish stomach contents to provide indications of distribution. Data on the percentage by weight of sandeels in total stomach contents were available to the Working Group for cod in 1980, 1981, 1982 by quarter, and in 1985, 1986 and 1987 for the first and third quarters only. Preliminary data for mackerel in 1991 by quarter were also available. Except for these mackerel data, the results of the 1991 stomach sampling project were not yet available. Figures $10.1 \mathrm{a}, \mathrm{b}, \mathrm{c}, \mathrm{d}$ and e illustrate the results of the most complete surveys for
cod, those in 1980, 1981, 1985, 1986 and 1987; and Figure 10.1 f illustrates the results for mackerel in 1991.

Worthwhile distributional information is available from both predator species. Stocks of sandeel are revealed around Shetland, Orkney, along the coasts of eastern Scotland, eastern England, Netherlands, Germany and Denmark, as well as in the central and northeastern North Sea. The indications are, however, variable from quarter to quarter and year to year in the maps of cod stomach contents, and one cannot readily say whether this reflects varying distribution of sandeels or varying distribution or eating habits of the cod. The percentages of sandeels in mackerel stomachs in 1991 were generally higher than those for cod in earlier years, suggesting that the mackerel may be the better indicator. Their more patchy and seasonal distribution counts against this, however.

The Working Group did not have time to consider whether the occurrence of sandeels in stomach contents could provide a valid quantitative indicator of stock sizes. The uncertainties would include the effects of the presence of alternative prey for the indicator species, varying stocks of the indicator which would affect competition for food, varying feeding habits and migrational patterns, varying distributions in the water column, and possibly a host of other factors. Since these factors could vary from one sandeel stock to another, there would be reservations about relative stock sizes as well.

XSA stock analysis with input from file:
file.lst
Unknown catches have been estimated
They were estimated so that they conform the SOP
Catcabilities at oldest age have been shrunk towards those of the second oldest age.
with weight of the oldest: . 0
The linear funct. model used for estimating catchabilities A cosine taper over 5 years was applied

CPUE indexes have been weighted using fixed weights

# A seasonal extended survivors analysis (SXSA) with optional estimation of unknown catches at age. 

Dankert W. Skagen<br>Institute of Marine Research<br>P.O.Box 1870<br>N-5024 Bergen - Nordnes<br>Norway

## Theory

The extended survivors analysis (XSA) as developed by Shepherd (ref) on the basis of previous work by Doubleday (ref), is one of several methods for calibrating av VPA with additional measures of relative stock abundance. Given the natural mortalities (m) at age and the catches (C) at age in a year class cohort, the catch equations

$$
N_{1}=N_{0} e^{-z} ; \bar{N}=\frac{N_{0}-N_{1}}{\bar{z}} ; z=m+f ; f=C / \mathbb{R}
$$

where $f$ is the fishing mortality, $z$ the total mortality and $N 0, N 1$, and $N$ are the numbers at age in the cohort in the beginning, and the end of the season, and the mean number in the season, respectively, define the stock abundance at age and the fishing mortalities at age as one-parameter families of unique trajectories. Thus, the stock numbers at age and fishing mortalities at age are defined by specifying either one $f$ or one N at age. In XSA, the strategy is to estimate the N at the end of the last year and season (the survivor number S ).

The additional information (tuning indices $=u$ ) can in principle be any measure related to the stock abundance at age and time by some defined model. In practice, it is usually regarded as proportional to $N$, where the proportionality factor $r(=1 / q$, i.e. the inverse catchability) can be estimated.

The S'es and r's are estimated by minimizing the weighted sum of squares

$$
\sum(\log N-\log (r \cdot m))^{2} \cdot w
$$

taken over all possible entries.
As shown by Shepherd, given $\mathrm{N}(\mathrm{S})$, the estimator for $\log (\mathrm{r})$ for a given age and fleet is the mean of all individual estimates $\log (\hat{1})=\log (N)-\log (\mathrm{u})$.

The estimator for $\log S$ is the mean of all entries for the cohort of

$$
\hat{s}=(\log (v r \cdot \mu)-z) \cdot u r / e^{F}
$$

where the capital letters denote cumulated mortalities from the actual age to the age at survivors stage.
As weighting factor, some measure of the precision of the estimate of $r$ is relevant. Here we use the inverse empirical variance of the $\log (r)$.

If there are several fleets, each fleet will be given a set of r's and accompanying weighting factors. The data for each season from a given fleet are treated as separate fleets, ie. catchabilities are defined by season.

Thus, given the S'es, the r's and the weighting factors can be estimated, and given the $r$ 's and the previous $N$ 's, the $S$ 'es can be estimated. This leads to an iterative procedure, which is repeated until convergence.

When the tuning data are the CPUE in the commercial fishery, the r's at age and season will be inversely proportional to the F at age for the same season, i.e. $1 / \mathrm{r}$ can be used as the selection pattern, the effort being the year factor. This is utilized in estimating unknown catches, by applying these f's to the estimated stock numbers.

## Implementation

The program is written in FORTRAN. It was originally implemented on a UNIX workstation. With a sufficiently small number of years, ages and fleets, it can be compiled and run on a PC with some minor modifications. Two versions are available at present, one for half-yearly and one for quarterly assessments, the main difference being the lay-out of the printout tables. The program used Popes approximation:

$$
N_{1}=N_{0} e^{-m}=C e^{-\omega_{0} / 2}
$$

instead of the catch equations for the VPA.
The communication with the program is through a list file, where options and file names are specified. An example is included at the end of the paper.

In the present version, the stock number related to each tuning index is the mean $N$ for the age, season and year in question. Biomasses are computed for the start of the season specified as the spawning season.

At present, missing catches all have to be from the same year, but may be from different seasons.

## Input files

## General.

All input files must be space separated, pure ASCII files. Concealed tabs and other codes sometimes included by text editors will often lead to problems. In files where data are given by age, all ages from the younges age to the plus age must be included in every record. This includes dummy numbers for the younges age prior to the recruiting season.

## Standard input data:

-catch in numbers at age
-weight at age in the catch
-weight at age in the stock
-natural mortality
-maturity ogive
-effort and corresponding catch at age (tuning file)
The common format for these files is records with:
year season values-at-age
The format of the tuning file is:
year season fleetnumber effort catch-at-age

In addition, this program needs some special files:

## Survivor file:

Lists proposed numbers for the survivors, one cohort per line, which are used to start the iterative process. These values are not critical, but they should be of a reasonable order of magnitude.
The format is:

## Dummy-identification (numeric) Survivor-number update-code

The update code should normally be 1 . If it is set to 0 , the survivor number for this cohort will remain as proposed, and data from this cohort will not be included in any estimation procedures. This may sometimes be useful for the oldest cohorts, or for cohorts which are poorly covered with tuning data.

## Manual weighting.

It is possible to give weighting factors manually, instead of using the inverse variances. A file specifying such weights must be included, since it is read even if it is not used. The format is the same as for tuning data. If this option is selected, it will apply to all fleets.

## Missing catches.

If missing catches are to be estimated, the assumed catch in tonnes and proposed numbers caught have to be given. The proposed numbers are only used to start the process.
The format of the file should be:
year season number-at-age (0..plusage)
If the number specified is -1 , this catch will be regarded as known, and the number given in the ordinary catch in numbers file will be used.

## Special features and options

Estimation of inverse catchabilities.
In the estimate for $r$, the contribution from each age and year is weighted according to the number of entries for that cohort. This is done to reduce the influence of cohorts that are poorly characterized.

There is also an option for tapered weighting, where the $r$ is determined for each year using a weighted mean over the nearest year. If this option is used, it will apply to all fleets and seasons. This weighting is by a cosine function. This option allows for slow trends in the catchabilities. It may be useful if such trends are suspected, either to account for them or to verify this suspicion. Abrupt changes in catchability, e.g due to change of gear in survey, will appear as a gradual change in the estimated catchability. Thus, this option is not well suited for treating this kind of problems.

## Cathability at age.

Shrinkage is not implemented in this model. However, there is an option for taking the catchability at the oldest age as a weighted mean of the value for that age and the age before. Giving zero weight to the oldest implies that the value for the second oldest will be used for both. The use of this option is very often necessary to stabilize the iteration.

## Fitted vs. actual catches.

Fitted catches are the product of the effort and the stock number, divided by the inverse catchability, i.e. the catches that one would expect if the fishing mortalities were separable, the catchability at age representing the selection pattern and the effort the yearly fishing mortality level. There is an option where the catches used in the subsequent VPA are weighted means of actual and fitted catches. This option should probably not be used for routine assessment.

## Options for estimating unknown catches.

As noted previously, the primary estimate of the unknown catches is the fitted catches described above. One may use them as they are, or scale them so that the SOP (the sum of catch at age $*$ weight at age) equals the carch in tonnes given as input.

The estimated of the unknown catches are included in the estimates of catchabilities and survivor numbers, as if they were known. The reason for this is that one would like to have catch estimates which, when entered as known, would lead to the same overall assessment.

## Treatment of the plus group.

In the present version, the plus group is treated dynamically over the years. For each season, the plus group is reduced by the effect of the catches and the natural mortality, the rest is transferred to the next season. If the season is the first in a year, the survivors from the oldest true age the previous year are added to the plus group pool. The starting value is the N estimated from the catch in the first year and season, using the catchability in the commercial fleet for the oldest true age.

A trend in the plus group numbers for which there is no evidence from other observations should be taken as a signal that the assessment is unreliable.

## Catches in the current year.

A potential use of the method is in the situation where survey information exists for the current year. Treatin the catches this year as unknown, gives a prediction of the catches in the current year which takes the survey information into account. An appropriate effort for the commercial fishery should be included in the tuning file, and the unckown catches constrained by this effort.
