## SUMMARY

This paper provides a report on the combined acoustic survey of herring stocks in the North Sea and ICES division IVaN in June-July 1993. The surveys were carried out by Norway, Scotland, Denmark and Netherlands and covered the period 29 June to 30 July. The results and distributions of herring by age are given for area by 30 Nmile statistical rectangles. The results are expressed in biomass and numbers of fish. In addition data on ichthyophonus infection rates determined from trawl samples obtained on the survey are reported and the infected numbers and proportions of the population are estimated. A discussion of errors in the estimation of abundance is included in the report.

METHODS
Five surveys were carried out during late June and July covering most of the continental shelf north of $54^{\circ} \mathrm{N}$ in the North Sea and $55^{\circ} \mathrm{N}$ to the west of Scotland to a northern limit of $62^{\circ} \mathrm{N}$. The eastern edge of the survey area is bounded by the Norwegian and Danish coasts, and to the west by the shelf edge between 200 and 400 m depth. The surveys are reported individually, and a combined report has been prepared using the data from all five surveys.

## INDIVIDUAL SURVEY REPORTS

## Survey by RV Johan Hort 1-16 July 1993

## Methods

Acoustic data were collected from a 38 kHz Simrad EK500 echosounder. The integrator data were stored and post-processed by a BEI system (Bergen Echo Integrator, Foote et al., 1991). The echo sounder system was last calibrated on 14 February 1993, and then showed no change from the previous calibration of 5 December 1992.

Pelagic trawling was carried out mainly with a large "Åkra" pelagic trawl with approximately $28 \times 28 \mathrm{~m}$ opening, usually with floats on the warps to fish close to the surface. A "Fotö" herring trawl with approximately 20 m vertical opening and 35 m horizontal opening was also used for some hauls. A "Campelen" shrimp trawl was used for bottom trawling. Figure 1 shows the survey track and trawl stations. The distance between transects was $15-18$ nautical miles.

Integrator values were allocated to "herring", to some other categories of fish, and to "plankton/0-group" based on the density and shape of the fish schools, the trawl catches, and the target strength distributions.

From the "herring" category the mean integrator values for herring were calculated for each rectangle of approximately $30 \times 30$ nautical miles ( $30^{\prime}$ in the north-south direction and $60^{\prime}$ in the east-west direction). The computation of number of individuals and biomass per age group was made with a computer program that operates according to the method described by Nakken and Dommasnes (1975).

The following target strength expression for herring was used:

$$
\mathrm{TS}=20 \log \mathrm{~L}-71.2 \mathrm{~dB} \quad \text { ( } \mathrm{L} \text { is fish length in } \mathrm{cm} \text { ) }
$$

Herring estimates were split between North Sea autumn spawners and Division IIIa/ Baltic spring spawners on the basis of vertebral count distributions using the formula (56.5-v)/0.7 as described by Anon. (1993).

## Survey results

Figure 2 shows the herring estimate by ICES statistical rectangles. Table 1 gives numbers and biomass by age groups for North Sea herring and for Division IIIa/Baltic spring spawners, respectively, in each of the areas shown by thick lines in Figure 2.

Total estimates for herring in the surveyed area are:

|  | North Sea autumn <br> spawners, mature | North Sea autumn <br> spawners, immature | IIIa/Baltic <br> spring spawners |
| :--- | :---: | :---: | :---: |
| Number $\mathrm{N} \times 10^{-6}$ | 1629.11 | 6690.40 | 1190.69 |
| Biomass $\left(\right.$ tonnes $\times 10^{-3}$ ) | 322.01 | 569.93 | 148.78 |

In the northwestern part of the investigated area some larger and older herring were found, which may have been Norwegian spring spawners. The quantity of those was negligible, however, and no attempt was made to separate them from North Sea autumn spawners by calculation.

The herring was seen on the echo sounder as small dense schools in the upper 40 m both during day and night. The results of the trawling indicated that there was also some herring in the plankton/0-group scattering layer in-between the schools. However, only in a few instances could this be seen from the echograms, and there may have been some underestimation of the herring for this reason. Only on one occasion was a herring school seen on the sea-bed.

The occurrence of herring infected with the fungus Ichthyophonus is shown in Figure 3. Although the occurrence was high in some samples, those were samples with few fish and in areas with low concentrations of herring. In areas with high densities of herring the infection rate was very low.

## Survey Report RV Tridens 29 June - 16 July 1993

The survey area covered the western North Sea between $54^{\circ}$ and $59^{\circ} \mathrm{N}$ and west of $2^{\circ}$ E. Cruise track and position of trawl stations are shown in Figure 4. Shortage of time prevented sampling of the rectangles south of $55^{\circ} \mathrm{N}$. However, judging from the herring density in the adjacent squares and also from historical data, it is assumed that the abundance of adult herring in these rectangles was low.

## Survey methods

Fish densities were measured by a Simrad EK- 500 system, using a 38 kHz hull mounted transducer. This year, no permission was obtained to calibrate the equipment in a nearby area along the Norwegian coast. However, during a period of very calm weather, the equipment was calibrated in the open sea just prior to the start of the survey. The results of the calibration are presented in Table 2.

Identification of fish traces was based on: a) the shape of fish schools on the echogram; b) the TS distribution; and c) the results of directed trawl sets. Fishing for identification purposes was done using a 2,000 mesh pelagic trawl. Results of the trawl sets are given in Table 3, and length composition of the herring is shown in Table 4.

The area north of $57^{\circ} \mathrm{N}$ was covered by a grid of north/south transects spaced at 15 mile intervals. This survey design was aimed at synchronisation with the Norwegian and Scottish vessels working in adjacent areas. South of $57^{\circ} \mathrm{N}$, the usual pattern of east/west transects was adopted. Ship's speed during periods of calm weather was 12 knots; at wind speeds above 6 BF the speed was reduced to approximately 10 knots. The survey was stopped during the hours of darkness, that was from 2100-0300 UTC, as it was observed that a major part of the herring population would rise to the surface and disappear from the echo sounder (see below).

## Observations

In the northern part of the survey area, most herring were found between $58^{\circ}$ and $59^{\circ} \mathrm{N}$. These were mainly older herring, with a length of about 30 cm . The herring occurred in schools of varying dimensions, and identification of traces by means of trawling was relatively easy. Overall abundance of herring in this area was less than in 1992.

In the vicinity of trawl station 9, a concentration of large herring was observed from 16002300 UTC in order to study the vertical migration at the onset of darkness. It was seen that the schools remained near the bottom until 2100 UTC, and then disintegrated. About two thirds of the herring subsequently rose to the surface, and disappeared from the echogram.

In the southern half of the survey area, a major concentration of herring was found at $56^{\circ} 40 \mathrm{~N}$. Several purse seiners were exploiting the schools in this area. The herring,
mostly three year-olds, had probably moved into the area fairly recently. Earlier, the Dutch fleet had reported a scarcity of herring in the central North Sea in June.

As in last year's survey, some very dense concentrations of 0 -group herring were observed in the open North Sea. The first patch was found at $56^{\circ} 25^{\prime} \mathrm{N}, 1^{\circ} 40^{\circ} \mathrm{E}$. The herring, of about 10 cm length, occurred in very dense bottom schools that were similar in appearance to schools of adult herring. A trawl set for identification purposes yielded $1,200 \mathrm{~kg}$ of these small herring. A similar patch of juvenile herring was found 15 miles south. These herring were observed from late evening, throughout the night, until the following morning. At 2100 UTC the dense bottom schools dissolved, and all herring rose to a depth of 30 m (just above the thermocline) to form a very dense scattering layer that extended over several square miles.

## Data analysis

The procedure for data analysis was slightly changed from last year. Eight sub-areas were identified in which length composition and length/weight were assumed to be fairly uniform (Fig. 5). Within each sub-area, the length distributions of all trawl samples were combined (in some cases after giving certain samples extra weight). The same was done with samples for age/length, weight and maturity.

For each sampling area, the overall mean length of the herring was calculated, and the corresponding TS and sigma values were obtained from the usual formulas:

$$
\mathrm{TS}=20 \log 10(\mathrm{~L})-71.2 \text { and } \sigma=4 \mathrm{pi}^{*} 10 \exp (\mathrm{TS} / 10)
$$

SA-values attributed to herring were averaged by statistical rectangles ( $1^{\circ}$ longitude by $0.5^{\circ}$ latitude). For each rectangle, the total number of herring was found by dividing the mean SA value by the mean sigma for the corresponding sampling area, and then multiplying with the surface area of the rectangle (Fig. 6). The length distribution (in absolute numbers) for each sampling area was found by applying the average \% length distribution for that area to the total number of herring. These length distributions were converted into age distributions by applying the ALKs for the corresponding areas. The summarised results for the entire survey area are presented in Table 5.

## Ichthyophonus

The level of Ichthyophonus infection appeared to be low. Out of a total 1,475 fish investigated, only six specimens appeared to be infected.

## Survey Report for FRV Scotia 10-30 July 1993

## Methods

The acoustic survey on FRV Scotia was carried out using a Simrad EK500 38 kHz sounder echo-integrator. Further data analysis was carried out using Simrad BI500 and Marine Lab Analysis systems. The survey track (Fig. 7) was selected to cover the area at one level of sampling intensity based on the limits of herring densities found in previous years, a transect spacing of 15 nautical miles was used in most parts of the area. On the administrative boundaries of $2^{\circ} \mathrm{E}$ and $4^{\circ} \mathrm{W}$ the ends of the tracks were positioned at $1 / 2$ the actual track spacing from the area boundary, giving equal track length in any
rectangle within the area. The between-track data could then be included in the data analysis. Transects at the coast and shelf break were continued to the limits of the stock and the transect ends omitted from the analysis. The origin of the survey grid was selected randomly with a 15 Nm interval the track was then laid out with systematic spacing from the random origin.

Trawl hauls (Fig. 7) were carried out during the survey on the denser echo traces. Each haul was sampled for length, age, maturity and weight of individual herring. Up to 350 fish were measured at 0.5 cm intervals from each haul. Otoliths were collected with two per 0.5 cm class below 24 cm , and 10 per 0.5 cm class for 24 cm and above. The same fish were sampled for sex maturity and macroscopic evidence of Ichthyophonus infection. Fish weights were collected at sea from a random sample of 50 fish per haul.

Data from the echo integrator were summed over quarter hour periods ( 2.5 Nm at knots). Echo integrator data were collected from 9 m below the surface (transducer at 5 m depth) to 1 m above the seabed. The data were divided into five categories, by visual inspection of the echo-sounder paper record and the integrator cumulative output; "herring traces", "probably herring traces" and "probably not herring traces" all below 50 m , shallow herring schools and shallow schools probably not herring both from above 50 m . For the 1993 survey $68 \%$ of the stock by weight was attributable to the "herring traces" and $17 \%$ to the "probably herring traces" and $16 \%$ to the shallow herring schools. The third category which gave $21 \%$ of total fish was attributable to whiting, norway pout, mackerel, haddock and horse mackerel in that order of importance. Most of these species were either easily recognizable from the echo-sounder record or did not appear to occupy the same area as the herring. The final category of surface schools not allocated to herring constituted $4 \%$ of the total fish biomass. Generally herring were found in waters where the seabed was deeper than 100 m . Similar small schools were found close to the seabed over "hard ground" in shallower water of 70 to 90 m depth. Fishing on these traces consistently gave considerable numbers of Norway pout through the meshes of the trawl. One exception to this was a trawl of stage 5 and 6 herring in 90 m of water north of Orkney.

Two calibrations were carried out during the survey. Agreement between these was better than 0.10 dB . To calculate integrator conversion factors the target strength of herring was estimated using the TS/length relationship recommended by the acoustic survey planning group (Anon., 1982):

$$
\mathrm{TS}=20 \log _{10} \mathrm{~L}-71.2 \mathrm{~dB} \text { per individual }
$$

The weight of fish at length was determined by weighing fish from each trawl haul which contained more than 50 fish. Lengths were recorded by 0.5 cm intervals to the nearest 0.5 cm below. The resulting weight-length relationship for herring was:

$$
\mathrm{W}=1.0810^{-3} \mathrm{~L}^{3.62} \mathrm{~g} \mathrm{~L} \text { measured in } \mathrm{cm}
$$

## Survey results

A total of 45 trawl hauls were carried out, the results of these are shown in Table 6. Thirty-two hauls with significant numbers of herring were used to define three survey sub areas (Fig. 7). The mean length keys, mean lengths, weights and target strengths for each haul and for each sub area are shown in Table 7. 3,206 otoliths were taken to
establish the three age length keys. The numbers and weights of fish by ICES statistical rectangle are shown in Figure 8 along with the number of 2.5 Nm integration intervals. A total estimate of 4,015 million herring or 865,000 tonnes was calculated for the survey area. 766,000 tonnes of these were mature. Herring were found mostly in water with the seabed deeper than 100 m , with traces being found in waters with depths of up to 250 m . The survey was continued to 400 m depth for most of the western and northern edge between $0^{\circ}$ and $4^{\circ} \mathrm{W}$. Herring were generally found in similar water depths to 1992 however, the distributions were characterised by larger numbers of small schools and an absence of large schools in the north of the area. Table 8 shows the numbers, mean lengths, weights and biomass of herring by sub area by age class.

The stock found in the Orkney-Shetland area has a spread of age classes with substantial numbers of six and seven ring fish, a shortage of four ring fish and a similar two ring age class to the one observed in 1992. This confirms the prevalence of older fish seen in previous years with lower recruitment for the current four ring fish. There was no problem with the fishing this year and trace identification was much easier than in 1992, however, the main problems were with small schools found near the bottom with the seabed between 100 and 120 m deep. A depth related division in the catch indicated that with minor exceptions the deeper schools contained only large herring.

In addition to the 866,000 tonnes of herring, approximately 289,000 tonnes of other fish were observed in mid water. Examination of the catch by species (Table 6) shows the difficulty of allocating this between species so this has not been attempted. The dominant part must be considered to be " 0 " group and older Norway pout. The proportions of mature two ring and three ring herring were estimated at $73 \%$ and $74 \%$ respectively. This is a smaller proportion for mature fish than those found in 1992.

## Survey Report for MFV Azalea 14-29 July 1993

## Methods

The acoustic survey on the charter vessel MFV Azalea (14-29 July 1993) was carried out using a Simrad EK500 38 kHz sounder echo-integrator. Further data analysis was carried out using Simrad BI500 and Marine Laboratory Analysis systems. The survey track (Fig. 9) was selected to cover the area in two levels of sampling intensity based on herring densities found in 1991/92. Areas with high intensity sampling had a transect spacing of 7.5 nautical miles and lower intensity areas a transect spacing of 15 nautical miles. The ends of the tracks were positioned at $1 / 2$ the actual track spacing from the area boundary, giving equal track length in any rectangle within each intensity area. Where appropriate the between-track data could then be included in the data analysis. Between track data were abandoned at the westward end of all transects, and on the eastward ends between $56^{\circ} 45^{\prime}$ and $58^{\circ} 00 \mathrm{~N}$, along the coast of the Outer Hebrides.

Thirty-six trawl hauls (Table 9) were carried out during the survey on the denser echo traces. Each haul was sampled for length, age, maturity and weight of individual herring. Up to 350 fish were measured at 0.5 cm intervals from each haul. Otoliths were collected with two per 0.5 cm class below 22 cm , five per 0.5 cm class from 20 to 27 cm and 10 per 0.5 cm class for 27.5 cm and above. Fish weights were collected at sea from a random sample of 50 fish per haul.

Data from the echo integrator were summed over quarter hour periods ( 2.5 Nm at 10 knots). Echo integrator data was collected from 9 m below the surface (transducer at 5 m depth) to 1 m above the seabed. The data were divided into five categories, by visual inspection of the echo-sounder paper record and the integrator cumulative output; "herring traces", "probably herring traces", "surface schools", "other pelagic fish" and "gadoids and others". For the 1993 survey $75 \%$ of the stock by number was attributable to the "herring traces" and $25 \%$ to the "probably herring traces". The third category which was scored was for identifiable surface, or near surface schools, trawl hauls identified these as sprat. The fourth category was for other identifiable pelagic schools, usually mackerel or horse mackerel. Other traces attributable to norway pout, whiting, and haddock were allocated to a fifth category. Most of these categories were either recognizable from the echo-sounder record or did not appear to occupy the same area as the herring. In general, herring were found in waters where the seabed was deeper than 100 m . Small marks, similar to herring marks, but with lower integrator values were seen in the north part of the survey area (north of $58^{\circ} \mathrm{N}$ and east of $5^{\circ} \mathrm{W}$ ). Trawl samples showed these to be made up substantially of norway pout ( $<15 \mathrm{~cm}$ ). In some areas these occurred together with similar herring schools, identification was based on school structure and relationship between size of mark and integrator values. Herring schools were considered as having a higher integrator value for a given size of school. In addition, pout marks were generally considered as being closely in contact with the seabed, while herring schools were more pelagic. Unlike 1992, pout were found throughout the area and sometimes in deeper waters (eg hauls 11, 14 and 29). One trawl sample (haul 5) was dominated by sprat in readily identifiable near surface schools. Four other hauls ( 9,18 , 22 and 27) contained significant quantities of mackerel, Where these occurred with herring, readily identifiable marks could be seen on the echogram. These hauls allowed separation of schools of both species from herring schools.

Two calibrations were carried out during the survey. To calculate integrator conversion factors the target strength of herring was estimated using the TS/length relationship recommended by the acoustic survey planning group (Anon., 1982) for clupeoids:

$$
\mathrm{TS}=20 \log _{10} \mathrm{~L}-71.2 \mathrm{~dB} \text { per individual }
$$

The weight of herring at length was determined by weighing fish from each trawl haul which contained more than 50 fish. Lengths were recorded by 0.5 cm intervals to the nearest 0.5 cm below. The resulting weight-length relationship for herring was:

$$
\mathrm{W}=0.725710^{-2} \mathrm{~L}^{3.06} \mathrm{~g} \mathrm{~L} \text { measured in } \mathrm{cm}
$$

## Survey results

A total of 36 trawl hauls were carried out, the results of these are shown in Table 9. Twenty-one hauls contained more than 70 herring and these hauls were used to define three survey sub areas (Fig. 10). The mean length keys, mean lengths, weights and target strengths for each haul and for each sub area are shown in Table 10. 2,203 otoliths were taken to establish the three age length keys. The numbers and weights of fish by quarter statistical rectangle are shown in Figure 11. A total estimate of 4,187 million herring or 893,600 tonnes was calculated for the survey area. 866,510 tonnes of these were mature. Herring were found mostly in water with the seabed deeper than 110 m , with traces being found in waters with depths of up to 250 m . The survey was continued over the shelf break for most of the western edge of the survey area. Herring were generally found in
similar water depths to 1990 . Table 11 shows the numbers and weights of herring by sub area by age class.

The stock found in the overall area is dominated by $2 / 3$ and six ring fish. This compares well with 1992 where the stock was dominated by two and five ring fish. The three subareas identified were geographically similar to 1992 allowing comparison of the age structures by sub-area. The different sub-areas showed varying age structures. Sub-area III (Shelf break), representing $44 \%$ of the total stock, was dominated by six ring fish $(31.5 \%)$. In 1992 the dominant age classes were four and five ring fish. Sub-area II (south-west Hebrides), ( $46 \%$ of the total stock) contained similar numbers in all age classes between three and six, with the largest year classes being three and four ring fish $(44.9 \%)$. In 1992 a similar structure was identified with similar numbers in all age classes between two and five. Sub-area I (north-east Hebrides), representing $10 \%$ of the total stock, was dominated by two and three ring fish ( $71.7 \%$ and $13.6 \%$ respectively), in 1992 this sub-area was dominated by one and two ring fish. Fishing appeared to be successful and trace identification was straight forward with the exception of some areas west of Orkney containing small schools of herring and gadoids.

The stock estimate shows a substantial increase between 1992 and 1993 (428,600 to 893,600 tonnes). There is no evidence from the age structure of the population that there has been significant recruitment to the stock, the same cohorts appear to be present in similar proportions in 1992 and 1993. Therefore, some discussion of the wide discrepancy in stock estimates is required. The survey area was expanded in 1993 to include the area between $56^{\circ}$ and $56^{\circ} 30 \mathrm{~N}$. Alone this extra area only accounts for $7.3 \%$ of the total stock. The data used in working up this survey were examined exhaustively for potential sources of error. The two calibrations carried out during the survey gave constants within $1 \%$ of each other, both were in close agreement with other calibrations on similar equipment. The fishing during the survey was generally very successful and allowed a good degree of certainty in identifying schools. As has been noted above, in some parts of the area, schools of Norway pout were seen which could be confused with herring. Whenever any potential doubt existed on the identification the fish were assigned to category 5 (gadoids and others). One potential source of error would be misidentification of horse mackerel schools as herring. A substantial part of the stock was found close to the shelf break were horse mackerel are also common. No marks were positively identified as horse mackerel during this survey, however again, where any potential doubt existed the traces were categorised as other pelagic fish (category 4).

The most likely explanation for the high estimate, given no change in the age structure of the population and no evidence of errors in the data gathering process, is simply that more fish were seen in the area this year. There are two factors which may, in part, account for this. Firstly, the 1992 survey found a large concentration of herring close to the southern limit at $56^{\circ} 30^{\prime} \mathrm{N}$ the limit was extended south by $30^{\prime}$ in 1993 possibly including more fish. In both 1992 and 1993 there appeared to be high densities of fish just north of this latitude, particularly near Stanton Bank at approximately $8^{\circ} \mathrm{W}$, which is a known spawning ground ( 95,670 tonnes - $22.3 \%$ of the total - in 1992 and 233,000 tonnes $-26.1 \%$ of the total - in 1993). It is possible that in 1993 fish which were south of this latitude and were missed during the 1992 survey, have moved further north in 1993. Secondly, acoustic surveying, like all survey techniques on patchy phenomena, are subject to sampling precision. Frequency histogram analysis comparing 15 minute echo integrals from Azalea surveys in 1992 and 1993 (Fig. 12) suggests that both years surveys have similar underlying distributions. In 1993 there was a greater number of
large observations, but very similar distributions at the lower values. The largest single 15 minute sample is responsible for approximately $12 \%$ of the total estimate. While this may be considered excessive, it should be noted that this is similar to the contribution of a single large value observed on other acoustic surveys for herring and reported in Anon. (1993b). It should also be noted that in the $1992 \mathrm{VIa}(\mathrm{N})$ herring larval survey, a single station contributed $45 \%$ of the total larval abundance index.

In conclusion, the most likely explanation of the results of this survey is that, firstly, there may have been a greater migration into the area from VIa(S) than in 1992 and, secondly, that due to sampling variance, a greater than usual number of large single sample observations were recorded. It is suggested that in 1994 a higher sampling intensity be used in the southern part of the area to reduce the effects of this variance. It is also hoped that the survey area to the south will be covered by an additional vessel provided by Eire.

## Survey Report RV Dana, 10-23 July 1993

## Methods

The echo integration survey covered the North Sea east of $5^{\circ} \mathrm{E}$ between $57^{\circ}$ and $59^{\circ} \mathrm{N}$, and Kattegat. Acoustic data were collected by a 38 kHz Simrad ES400 echosounder using a towed body mounted transducer. The integration data were stored by the echo analysis system ECHOANN (Degnbol et al., 1990). Figure 13 shows the survey track and areas. Table 12 gives the total area, number of Nm, number of trawl stations mean Sa and TS by area. Distance between transects was about 5-10 nautical miles. Ship's speed during the survey was about 10 knots.

Pelagic trawling was carried out mainly with a Fotö trawl ( 16 mm in cod-end), but also Expo trawl ( 16 mm in cod-end) was used. Trawl hauls (Table 13) were carried out mainly during night (1600-0600). Each haul was sampled for species, length, age and weight. Fish were measured to the nearest 0.5 cm and weighed to the nearest 0.1 g . Otoliths were sampled from herring with 10 per 0.5 cm class above 15 cm . Total 1,453 otoliths were sampled from herring.

Target strength for each length group of herring was estimated by:

$$
\mathrm{TS}=20 \log \mathrm{~L}-71.2 \mathrm{~dB}
$$

and for sprat by: $\quad \mathrm{TS}=20 \log \mathrm{~L}-71.2 \mathrm{~dB}$
gadoids by:

$$
\mathrm{TS}=20 \log \mathrm{~L}-67.5 \mathrm{~dB}
$$

mackerel by
$\mathrm{TS}=21.7 \log \mathrm{~L}-81.5 \mathrm{~dB}$
horse mackerel by: $\quad \mathrm{TS}=20 \log \mathrm{~L}-71.2 \mathrm{~dB}$

## Results

A total of 37 trawl hauls were carried out, the results of these are given in Table 13. The main biomass was found in Kattegat and between $4^{\circ} \mathrm{E}$ and $8^{\circ} \mathrm{E}$ north of $57^{\circ} \mathrm{N}$. A total estimate of 23,299 million herring (Table 14) or $1,340,527$ tonnes was estimated for the
survey area (Table 16). Table 15 shows the spawning biomass by age and area. The mean weight of herring by age and area are given in Table 17.

## COMBINED SURVEY REPORT

Figure 14 shows survey areas for each vessel. The results for the four surveys have been combined. Procedures and TS values are the same as 1992 surveys (CM 1992/H:11). The stock estimates have been worked out by age and maturity stage for 30 min by $1^{\circ}$ statistical rectangles for the complete survey area. These data have been combined to give estimates of immature and mature (spawning) herring for ICES areas VIa north, IVa and IVb separately. The region east of $6^{\circ} \mathrm{E}$ is presented separately and data on a split between North Sea and Baltic stocks is not available. Where the survey areas for individual vessels overlap the mean estimates for each overlapping rectangle have been used. Stock estimates are shown in Table 18 for areas IVa and IVb separately and for area IVab combined for autumn spawning herring and for Baltic spring spawning herring found on the Norwegian side of the North Sea. Table 19 gives the mean weights used to convert numbers to biomass. Figure 15 shows the distribution of abundance (numbers and biomass) of all herring for all areas surveyed. Figure 16 shows the distribution split by age of one ring, two ring and three ring and older herring. Figures 17 and 18 show the density distribution of numbers and biomass of all herring as contour plots.

## Ichthyophonus Infection

Figure 19 shows the prevalence found in samples which were taken during all the surveys and inspected for infection. The samples have been combined using linear interpolation for un-sampled squares. These were assumed to be the mean proportions of surrounding squares with samples (equal weight to each square). The distribution of infection rates for the weighted method is shown in Figure 20. The total numbers infected are shown in Figure 21. In this study the Baltic spring spawning herring are included with the North Sea autumn spawning fish as there was no information on the proportions of infected fish from each population. A total of 148 million fish were estimated as infected, all in ICES area IVa. This is $3.6 \%$ of the total population in this area. The age breakdown of this was estimated using the infected fish found on the Scotia survey for 1992 and 1993 for comparison. Samples were assumed to have equal weight and a single age infection length key was determined by combining all the samples. A single length key was obtained for same area by combining the individual sub area length keys in and weighting them by the abundance for these areas. The infection rate by age for the Orkney Shetland area is given in Table 20. Also included in this table is the number of otoliths sampled and found infected to give an indication of the quality of the estimates at age. It should be borne in mind that column 4 in this table is not derived directly from columns 2 and 3 . Also the assumption that the age at length within the area is homogenous is questionable. However, the biggest changes are for one and two ring fish which show effectively zero prevalence of infection so this problem is not important. The numbers infected are sensibly zero for three years and younger with a rapid rise through four year olds and a peak at five years. The infection rate shows some reduction for older fish but the rise shown for eight and $9+$ is unlikely to be real.

## Precision of Abundance Estimates

It is difficult to get a good estimate of the precision of a single survey. Examination of survey methods (Simmonds and Fryer 1993) indicated that the precision of the spatial
sampling element of a single estimate from a survey of the Orkney Shetland and Buchan area using 40 transects at the $90 \%$ probability level would be about $15 \%$ of the abundance. These simulations are based on data from four annual surveys and were directed at examining survey methods. The precision of the estimates of abundance relied on estimates of variance from these four surveys. The same simulation indicated that the precision of the survey variance, estimated at the $90 \%$ level, is about $140 \%$ of the mean variance. So the precision of the abundance was $15 \%$ but the precision of the variance from the same survey was $140 \%$. Following changes in recent years sampling intensity has been reduced by about $50 \%$. In addition three surveys are carried out covering approximately three times the area. The effects of this are uncertain but the best guess would be to assume that the three surveys of the North Sea stock are independent. The spatial sampling precision of the North Sea estimates for IVa and IVb combined would thus be estimated at the $90 \%$ probability level as being between $7 \%$ and $17 \%$ of the abundance. It should be borne in mind that estimating variance for any survey is likely to suffer from the same precision as above (140\%) and therefore only substantial differences in variance (factors of 2 ) should be regarded as real. In addition other sources of error need to be considered such as; errors due to year on year changes in calibration, errors in estimating fish target strength via length keys, errors due to parts of the population being in unsurveyed areas, errors due to equipment performance and errors due to weather or changing hydrography. It is my view that obtaining good estimates of the variance of surveys for fish populations is very difficult. It is important that comparisons of variance take into account the assumptions that have been made to calculate the variance and the precision of that variance estimate. These must be included in any study before conclusions can be drawn.
