## 1. INTRODUCTION

### 1.1 Terms of Reference

The Atlanto-Scandian Herring, Capelin and Blue Whiting Assessment Working Group (Chairman Mr I. Røttingen, Norway) met at the Institute of Marine Research, Bergen, Norway from 12-18 October 1995 to (C. Res. 1994/2:6:2):
a) assess the status of and provide catch options for 1996 and 1997 for the Norwegian spring-spawning and Icelandic summer-spawning herring stocks;
b) provide any new information on the present spatial and temporal distribution of Norwegian springspawning herring;
c) assess the status of capelin in Sub-areas V and XIV and provide catch options for the winter 1995/1996 and summer/autumn 1996 seasons;
d) assess the status of and provide catch options for capelin in Sub-areas I and II (excluding Division IIa west of $5^{\circ} \mathrm{W}$ ) for the winter 1995/1996 and summer/autumn 1996 seasons;
e) consider further possibilities for the incorporation of biological interaction into the assessments of capelin, herring and cod stocks;
f) assess the status and provide catch options for 1996 and 1997 for the blue whiting stock;
g) update the information on the spatial and temporal distribution of the stock and of the fisheries on blue whiting;
h) for those stocks and/or fisheries where data permit, provide the information required to give advice or guidance on
i) medium-term management objectives (in terms of spawning stock biomass and mortality rates and options)
ii) the appropriateness of control on catch (or landings) and fishing effort,
iii) the potential for multispecies and multi-annual catch options.

In addition, the following relevant paragraphs of the NEAFC request for advice from ICES was passed on to the present working group by the chairman of ACFM:

1) provide quantitative information on the present spatial and temporal distribution of the Norwegian spring spawning herring stock;
2) assess the impact of the Ichtyophonus hoferi disease on stocks of herring (and other pelagic fish);
3) for blue whiting, evaluate the development of the total stock biomass and spawning stock biomass over a three-year period (1996-1998) if at all possible.

## 2. ICELANDIC SUMMER SPAWNING HERRING

### 2.1 The fishery

The catches of summer spawning herring from 19751994 are given in Table 2.1.1. These include an estimate of $2,009 \mathrm{t}$ of discards for the $1994 / 1995$ season. The fishery took place off the southeast coast and $57 \%$ of the catches were used for reduction while $43 \%$ were used for human consumption. Major part of the catches was taken by purse seiners but 1 trawler participated in the fishery. Until 1990 the herring fishery took place during the last three months of each calendar year but in 19901994 the autumn fishery continued in January and early February the following year. Therefore all references to the years 1990-1994 refer to the season starting in October of that year.

| Year | Landings | Catches | TACs | Rec TAC |
| :--- | ---: | ---: | ---: | ---: |
| 1984 | 50.3 | 50.3 | 50.0 | 50.0 |
| 1985 | 49.1 | 49.1 | 50.0 | 50.0 |
| 1986 | 65.5 | 65.5 | 65.0 | 65.0 |

| $1991 / 1992$ | 98.5 | 109.5 | 110.0 | 79.0 |
| $1992 / 1993$ | 106.7 | 108.5 | 120.0 | 86.0 |
| $1993 / 1994$ | 101.5 | 102.7 | 111.0 | 90.0 |
| $1994 / 1995$ | 132.0 | 134.0 | 137.0 | 120.0 |

### 2.2 Catch in numbers and weight at age

The catches in number at age for the Icelandic summer spawners for the period 1975-1994 are given in Table 2.1.1. As usual the age is given in rings where the age in years equals the number of rings +1 . In the first years after the fishery was reopened in 1975 the 1971 year class was most abundant. During the period 1979-1982 the 1974 and 1975 year classes predominated in the catches. During the period 1983-1986 the fishery was dominated by the strong 1979 year class. In 1987 and 1988 the fishery was on the other hand based on a number of year classes ranging from 3-10 ringed herring. In the period 1989-1991 the 1983 year class predominated in the catch. The 1988 year class was also well represented in the 1991 catches and predominated during the 1992 season. In 1993 the age distribution was dominated by the strong 1989 year class although the 1988 year class was also well represented. In 1994/1995 the catches were distributed on 4 year classes, 19881991. The catch in numbers of 2 -ringers has never been higher and yielded some $25 \%$ of the total numbers. The weight at age for each year are given in Table 2.2.1 and the proportion mature at age is given in Table 2.2.2. The most striking feature of these parameters in this stock is that despite an inter-annual variation, the weights at age as well as other biological parameters of this herring stock have remained relatively stable over a wide range of stock size and fluctuations in environmental conditions in Icelandic waters.

### 2.3 Acoustic surveys

The Icelandic summer spawning herring stock has been monitored by acoustic surveys annually since 1973. These surveys have been carried out in NovemberDecember or January, usually after the fishery has been closed. During a survey which took place in November December 1994 no acoustic estimate was obtained, neither for the adults nor the juveniles. Therefore results of the January 1994 survey have been used as a basis for the present assessment (Table 2.3.1). As in last year's report, the TS value of TS $=20 \log \mathrm{~L}-72 \mathrm{~dB}$ was used to calculate the stock estimates. In addition the estimate from a previous survey carried out in December 1992 was used for the 1991 year class ( 3 ringers in 1995). In the absence of any estimates of the 1992 and 1993 year classes they were assumed to be of average abundance (600 million as 1 -ringers).

### 2.4 Stock Assessment

The result of the acoustic surveys together with the catch in number at age were used to calculate initial mortalities for the 1994/1995 season. Results are given in Table 2.4.1 as $\mathrm{F}^{1}$. In this analysis 5-ringers and older have been grouped for estimating the fishing mortality on the oldest herring, whereas the fishing mortality for the younger age groups is calculated for each year class.

As in previous years the estimation procedure from Halldórsson et al. (1986) was used to estimate the stock size in the final year, based on all available acoustic data for the older part of the stock ( $5+$ ringers on 1 January each year). The procedure minimizes the sum of squares of log-transformed rather than untransformed data since there is increased variability in later years coinciding with the increase in stock size.

A series of VPAs were run using varying terminal $\mathrm{F}^{\prime} \mathrm{s}$ on $5+$ ringers. For each terminal F a sum of squares (SSE(F)) of differences between the 5+ from the VPA and acoustic estimates is computed. A plot of these values is shown in Figure 2.4.1. From this series of VPAs it is clear that the best (giving the minimum value of SSE) one to one relation between the acoustic estimates and virtual population analysis is obtained with an input F of about 0.32 . The confidence intervals for the fitted terminal F values $(0.20,0.62)$ are obtained as described by Halldórsson et al. (1986) and Stefánsson (1987) by using the tabled F-distribution to set bounds on the SSE and finding the terminal $F$ values corresponding to these bounds (Figure 2.4.1).

Using the catch data given in Table 2.1.1 and the fitted values of fishing mortalities given in Table 2.4.1, a final VPA was run using a natural mortality rate of 0.1 on all age groups and proportion of natural mortality before spawning as 0.5 . Fishing mortality at age and stock in numbers at age with spawning stock biomass on 1 July are given in Tables 2.4.2 and 2.4.3, respectively, and the standard plots are shown in Figure 2.4.2. The resulting stock trend from VPA is plotted along the acoustic estimate in Figure 2.4.3 and the correspondence with acoustic estimates is shown in Figure 2.4.4.

According to the current assessment the spawning stock biomass was about $530,000 \mathrm{t}$ in July 1994 as compared to the projected spawning stock from last year's assessment of $570,000 \mathrm{t}$. This difference is partly due to lower mean weights by ages than expected and higher catches.

### 2.5 Catch and Stock Projections

The input data for the projections are given in Table 2.5.1. As in previous years a regression of weight increase has been used to predict the weight at age for 28 ringers (using as input weight at age for 1-7 ringers the year before). Data for the regression included, as starting years, the period 1986-1994. For 1 ringers and $9+$ ringers, a simple average of mean weights at age for the period 1986-1994 was used for the prediction. Weights at age for $2-8$ ringers in the catch are thus obtained by using the relation:
$\mathrm{W}_{\mathrm{y}+1}-\mathrm{W}_{\mathrm{y}}=-0.223 \times \mathrm{W}_{\mathrm{y}}+88.99(\mathrm{~g})$
Where $W_{y}$ and $W_{y+1}$ are the mean weight of the same year class in the year $y$ and $y+1$, respectively.

During the 1995/96 fishing season the age distribution will be dominated by the 1988-1991 year classes (5-7 ringers). The exploitation pattern used for the stock and catch predictions takes this into account. This is somewhat different from the average exploitation pattern based on the fishery during 1986-1990 as shown in Table 2.4.1.

As in previous assessment and in agreement with the increased level of recruitment during the 1980s and early 1990 s , an assumed value of 600 million of 1 ringers in 1994 and 1995 has been used. The estimate of 2- ringers in 1994 is derived from the acoustic estimate of 1 ringers in 1993 (the 1991 year class).

Output of the prediction assuming catches corresponding to a fishing mortality rate of $F=0.22$ is given in Table 2.5.2, and projections of spawning stock
 are given in Table 2.5.3.

Yield per recruit calculations are shown in Figure 2.5.1 using the input values in Table 2.5.4.

### 2.6 Management Considerations

A TAC of 110,000 tonnes has been set for the current 1995/96 season. This corresponds to a fishing mortality of $\mathrm{F}_{4-14 \mathrm{w}}=0.22$. Fishing at the fishing mortality rate of $\mathrm{F}_{0.1}=0.22$ during the 1996/97 season would result in a catch of about 115,000 tonnes. The working group points out that managing this stock at an exploitation rate at or near $\mathrm{F}_{0.1}$ has been successful in the past. Fishing at higher fishing mortality rates than $\mathrm{F}_{0.1}$ would give a correspondingly higher short-term yield but would reduce the stock sharply when the effect of the strong year classes presently in the stock has dwindled.

### 2.7 Medium-term prediction

Medium term prediction was carried out for the Icelandic summer spawning herring.

Input data for 1995 was based on the current assessment and short-term projections (sections 2.4 and 2.5). For future years, the same values were used for the selection pattern at age, weights at age and proportion mature at age as in 1995.

A stock-recruitment function of the Ricker form was used to generate recruitment in future years, starting with the 1995 year class which appears as 1-ringers in 1997. This stock-recruitment function was estimated based on available data since 1974. Although data is available for earlier years (Anon. 1995a), this was not used in light of the results in Jakobsson et al. (1993), which indicate that different recruitment functions were applicable in earlier years.

The resulting fitted recruitment function is given along with the input data in Fig. 2.7.1. The parameter estimates are given by $\mathrm{a}=3.576$ and $\mathrm{K}=601.1$. These estimates are quite uncertain due to the variability in historical recruitment. This uncertainty can be estimated if estimation is based on the usual linear transformation of the Ricker function. The resulting table of standard errors and correlation is given by:

|  | $\ln \mathrm{a}$ | $-1 / \mathrm{K}$ |
| :--- | :--- | :--- |
| $\ln \mathrm{a}$ | 0.38 -0.92 <br> $-1 / \mathrm{K}$ -0.92 | 0.00 |

The CV of recruitment around the fitted curve is about $65 \%$ and this is used for generating future recruits with lognormal variation.

For the projections, a lognormal standard error (s.e.) of 0.2 was used for the stock size of $5+$-ringed herring. This is in accordance with Fig. 2.4.1, which indicates that the confidence interval for the terminal fishing mortality may correspond roughly to a (s.e.) of $20 \%$. Since the estimate of fishing mortality is based on assuming a constant selection pattern on the older fish, errors in this estimate will be in the same direction for all age groups. Thus, a single lognormal error on stock size is generated for all $5+$-ringed age groups in the year 1995.

Since there is some more knowledge on the 1 -ringed herring in 1995 than there is on future recruitment (e.g. this year class has not appeared in huge quantities in the fishery or surveys), the CV on this year class is set to 0.4 . The CV for $2-4$ ringers is set so that the CV decreases linearly from 0.4 on 1-ringers to 0.2 on $5+-$ ringers.

Since this stock has been managed at levels corresponding fairly closely to fishing at $\mathrm{F}_{0.1}$, the approach taken is to simulate using an approximation to this strategy. In recent years $\mathrm{F}_{0.1}$ has consistently been estimated at about 0.22 , so this strategy is basically a fixed-F harvesting strategy. A simple catch control law corresponding to fishing at $\mathrm{F}_{0.1}$ was implemented by generating future true stock sizes and perturbing the stock numbers by a CV of $20 \%$ to obtain a simulation of the estimated stock. The catch was then set based on the fixed F strategy. This procedure is an approximation to using a quota based on a fishing mortality estimated with an error which is the inverse of the error in the stock estimate.

The true stock was projected forward in time using a fishing mortality which was perturbed to accommodate the fact that the set catches did not correspond to the true catches at $\mathrm{F}_{0.1}$.

The resulting output is given in Fig. 2.7.2. It is seen that there is very little probability of the harvesting strategy
reducing the stock to low level. There is some probability within this model of the stock increasing to very high levels. This is due to the handling of uncertainty in the parameters of the Ricker curve and variation around the curve and is a consequence of the fact that the present state of the stock is close to or above the historical upper bound.

### 2.8 Comments on the assessment

The XSA method was also attempted for this stock. The resulting VPA summary tables from the usual method and XSA are given in Tables 2.8.1-2. SSB in July 1994 from XSA is given as 553 thousand tonnes, compared to 529 thousand tonnes from section 2.4. There are relatively minor differences between the SSB and recruitment from the two methods. Retrospective plots of the SSB for both methods are shown in Figure 2.8.1. Although both methods show similar retrospective plots, the method described in section 2.4 gives less disagreement between runs made in different years, at least for the latest years. Therefore the method used in earlier assessments has been adhered to.

## 3. NORWEGIAN SPRING SPAWNING HERRING

### 3.1 The Fisheries

### 3.1.1 1994

An initial TAC for 1994 was set at 450,000 tonnes. This was divided into 375,000 tonnes (Norway) and 75,000 tonnes (Russia).

## The Faroes

The Faroese herring fishery took place in June in international waters in the Norwegian Sea. A total of 2,911 t were taken, the mean weight of the herring in the catches was 371 g .

## Iceland

The Icelandic herring fishery took place in June mainly in international waters in the Norwegian Sea. A total of $21,146 \mathrm{t}$ were taken, the mean weight of the herring in the catches was 391 g .

## Norway

The Norwegian fishery started in the beginning of January in the wintering areas of Northern Norway, and $107,433 \mathrm{t}$ were taken in this area in January and beginning of February. The herring then migrated to the spawning areas. On the spawning areas the fishery took place at Møre from the beginning of February to the beginning of March. 74,321 t were taken in this fishery. In the latter part of March and in April there was a
fishery on spent herring ( $32,517 \mathrm{t}$ ) at the start of the feeding migration. In the period May-July there was only a minor fishery on herring. $6,321 \mathrm{t}$ of herring were caught in this period, including $2,648 \mathrm{t}$ in international waters and the Jan Mayen zone in the Norwegian Sea. In autumn the adult herring returned to the wintering areas in Northern Norway, and in the period August December $160,265 \mathrm{t}$ were caught, according to the nominal catch statistics. The mean weight of the herring in the catches varied from 360 g in the prespawning fishery in winter at Møre to 180 g in the coastal summer fishery. Of the total Norwegian catch of $380,767 \mathrm{t}, 70 \%$ was used for human consumption and $30 \%$ for industrial purposes.

## Russia

The Russian herring fishery took place in February to April on the Norwegian coastal banks. A total of 74,400 t were taken, mean weight in the catches was 319 g .

The total catch of Norwegian spring spawning herring in 1994 amounted to 479,228 tonnes.

### 3.1.2 1995

The following TACs were set independently: For the fisheries of Norway and Russia: 650,000 tonnes. For the fisheries of the Faroes and Iceland: 250,000 tonnes.

## The Faroes

The Faroese fishery started in the beginning of May. The first catches were taken in the area north of the Faroes, but later in May the fishery shifted to the north and northeast to the northern border of the Faroese EEZ. The total catch of herring in Faroese waters was about $50,000 \mathrm{t}$. In addition some Faroese catches were taken in international waters in the Norwegian Sea. The total landings of Faroese catches in 1995 amounted to 57,000 t.

## Iceland

The Icelandic fishery started in the last days of April, but only small catches were taken in that month. In May the Icelandic catch was about $139,000 \mathrm{t}$, of which about $3 / 4$ were taken within the Faroese EEZ and the remainder in international waters. In June some 38,000 t were caught, mostly in international waters but also in the Icelandic EEZ. The total Icelandic catch amounted to 170,611 tonnes.

## Norway

The structure of the winter and spring fisheries was the same in 1995 as in to 1994. By 1 May, Norway had caught approximately 310,000 t . In May-June approximately $4,900 \mathrm{t}$ and $2,400 \mathrm{t}$ were caught by Norwegian vessels in international waters and in the Jan

Mayen EEZ, respectively. By 1 October 1995 the total Norwegian catch was approximately $410,000 \mathrm{t}$.

## Russia

The Russian catch in the spawning area in February to April amounted to $92,000 \mathrm{t}$. In addition, $8,000 \mathrm{t}$ of herring were taken in the Lofoten area in September.

## Other nations

Other nations have, as a preliminary figure, reported a catch of $37,017 \mathrm{t}$ of Norwegian spring spawning herring, mainly from international waters.

The total catch of Norwegian spring spawning herring is expected to be 914,000 tonnes in 1995.

### 3.2 Catch statistics

The total annual catches of Norwegian spring spawning herring for the period 1972-1995 (1995 preliminary) are presented in Tables 3.2.1 and 3.2.2. For 1994 there has not been added any amount for discards, private fishery, etc.

### 3.3 The adult stock

### 3.3.1 Acoustic surveys on the spawning stock

In 1995 this survey also included areas of both spawning and spawning migration. Fig 3.3.1 shows the distribution of the herring in the period 15.2-31.3 1995.

The acoustic abundance estimates were converted to biomass using TS $=20 \log \mathrm{~L}-71.9$ and in the text table below the number per year class (in millions) is presented:

| Year class | Total estimate |
| :---: | :---: |
| 1992 | 1792 |
| 1991 | 7621 |
| 1990 | 3807 |
| 1989 | 2151 |
| 1988 | 322 |
| 1987 | 20 |
| 1986 | 1 |
| 1985 | 124 |
| 1984 | 63 |
| 1983 | 2573 |
| Total | 18474 |

### 3.3.2 Acoustic surveys in the wintering areas

The wintering area was acoustically surveyed in December 1994 and January 1995 (Foote and Røttingen 1995). The following estimates (in million individuals)
were obtained, corrected for acoustic extinction and applying a target strength/length relationship of TS=20 $\log$ L-71.9:

| Year class | Estimate <br> Dec. 1994 | Estimate Jan. <br> 1995 |
| :---: | :---: | :---: |
| 1992 | 16 | 47 |
| 1991 | 3708 | 3781 |

### 3.3.3 Acoustic estimates in the feeding areas

In summer 1995 the herring was distributed over wide areas in the Norwegian Sea. At times the herring was distributed in the upper water masses and could not be estimated by traditional echo integrator technique. However, late in the feeding season, in July-August when the return migration to the wintering areas had begun, the herring was distributed in deeper layers and could thus be estimated by the integrator technique. The areas of distribution in July -August 1995 are given in Figs 3.3.2 and 3.3.3. The text table below gives an estimate of the stock (in million individuals) based on the combination of these surveys ( $\mathrm{TS}=20 \log \mathrm{~L}-71.9$ is applied):

| Year class | Estimate |
| :---: | ---: |
| 1994 | 199 |
| 1993 | 167 |
| 1992 | 13144 |
| 1991 | 17228 |
| 1990 | 3309 |
| 1989 | 1356 |
| 1988 | 228 |
| 1987 | 1 |
| 1986 | 1 |
| 1985 | 4 |
| 1984 | 71 |
| 1983 | 1427 |
| 1982 | 10 |
| Total | 37143 |

### 3.3.4 Tagging experiments

The Norwegian tagging experiment on herring, which was initiated in 1975, has been continued, and recoveries from commercial catches have been screened
for tags using tag detectors installed at sea food processing factories. 11.900 tonnes of herring were screened for tags in 1995, and 92 tagged fish were recovered, out of which 64 tags originated from releases in 1987 to 1992. Tags have also been reported from other Norwegian factories, mainly fish meal plants, which use herring entrails from the herring filleting industry in the production. These tags originate from an unknown catch, and have not been used in the assessment. Table 3.3.1 show the number of recoveries and corresponding releases used in the assessment. Due to the expected high F-value on the year classes older than the 1983-year class in 1985-1988, the WG based the assessment on the releases of herring from the year classes 1983-1988. The tagged herring are not aged individually but samples of the age distribution of the catches from which the tagging is done are available. These samples were used for calculating the number of tagged herring from the year classes 1983-1988 last year. However, the lengths of tagged herring were recorded when released, and in the present estimate the number of releases and corresponding recoveries are determined according to the length of the tagged fish when released. This new procedure has to some extent changed the estimated number of releases compared to the data given in the 1994 report.

The total number of screened herring in 1995 is 37.0 million individuals, the number screened of the year classes 1983-1988 is 13.8 million individuals, and $66 \%$ is from the 1983 year class.

From the catch of herring in the Norwegian Sea this summer, Iceland has reported 630 herring tags retained on magnets in Icelandic fish meal plants. A magnet efficiency test carried out at one of the plants gave a magnet efficiency of $47.5 \%$. The herring used in the test experiment was however in very poor condition, which may have caused error in the efficiency estimate. The Icelandic sample was therefore not used in the assessment.

### 3.3.5 Mortality estimates

The mortality Z was estimated by the method previously used (Anon., 1995a; Hamre 1990). The plots of $\ln \mathrm{K}$ against year of release of the sample in Table 3.3.1 are shown in Figure 3.3.4. In order to avoid error of nonrandom mixing, the estimate of mortality was based on the tag releases in 1987-1992 only, which mainly consists of the year classes 1983-1988 (as in last year report). This grouping gives a fit of the points to a straight line with a slope corresponding to a total mortality Z of 0.277 . This is almost the same total mortality estimate as obtained last year $(\mathrm{Z}=0.269)$.

### 3.3.6 Abundance estimate from tagging

Applying the calculated average mortality rate Z of 0.277 for the period 1987 to 1992, the VPA-estimated
mortality for 1993 and 1994 ( $\mathrm{Z}=0.30$ and 0.38 respectively) and a tagging mortality of $40 \%$ (as in last years report) the number of survivals by release in 1995 was calculated and the results are shown in the right hand column of Table 3.3.1. According to this estimate, 22509 tagged herring from the releases 1987-1992 did survive in 1995, and 64 tagged herring were recovered in a screened catch of 13.8 million individuals of the year classes 1983-1988. This gives a stock estimate of 4.85 billion individuals. The 1983 year class accounts for $66 \%$ of the estimate or $3.2 \cdot 10^{9}$ individuals.

### 3.3.7 Natural mortality

Last year the Atlanto-Scandian Herring and Capelin Working Group decided, on the basis of the results from the tagging experiment, to apply an M of 0.23 for the adult stock. Tagging experiments carried out around 1980 indicated an M of 0.13 in this stock. It was argued that the disease Ichthyophonus hoferi may have contributed to the apparent increase in natural mortality. However, the prevalence of Ichthyophonus has now decreased considerably (Section 3.8). In year classes 1988 and younger the prevalence seems to have been low since 1991, therefore the working group decided to change the M value in the VPA from 0.23 to 0.13 for the period 1991-1994 for the year classes 1988 and younger. For the year classes 1987 and older the M value given in last years report ( $\mathrm{M}=0.23$ ) is unchanged. It is pointed out that this value is very uncertain, and thus the absolute values from the VPA of these year classes (and spawning stock) should be interpreted with great caution.

In the prognosis an M of 0.13 is used for 3 years and older herring.

### 3.4 Recruitment

### 3.4.1 Stock estimates of immature herring

The nursery area of the Norwegian spring spawning herring are Norwegian fjord and coastal areas and the southern part of the Barents Sea. Since 1988, when the 1983 year class spawned for the first time, the latter area has increased in importance as a nursery area for the herring. The main part of the data on immature herring are obtained from three different investigation series:

1) Acoustic estimates of 0 -group herring in fjord and coastal areas of Norway (Table 3.4.1).
2) 0-group trawl survey in the Barents Sea in AugustSeptember (Table 3.4.2).
3) Acoustic estimates of immature herring in the Barents Sea (Table 3.4.3).

In last year's report it was stated that there was some uncertainties with the estimates of immature herring
from the Barents Sea due to a possible mixing with other herring stocks (Cheshko-Petschorskaya stock of herring). The Working Group recommended that research should be made on this subject, and in 1995 a joint Norwegian-Russian project has been in operation on this matter (herring sampled during the abundance surveys have been sampled for both genetics and vertebrae number). The estimates for 1995 consist of only Norwegian spring spawning herring.

### 3.4.2 Natural mortality of immature herring

Barros (1995) has shown that natural mortality of juvenile Norwegian spring spawning herring in the Barents Sea is highly variable and strongly age dependent, but the precision of the data allows only estimation of two mortality patterns, "high and low". He has also shown that this mortality is associated with the ratio between the abundance of the capelin stock and that of juvenile cod.

Given the present state of the system (high cod abundance and low capelin abundance), it is therefore quite plausible that both the 1994 and 1995 year classes will suffer a high mortality rate. The derived mortalities for ages 1 and 2 are 1.56 and 0.54 respectively.

### 3.4.3 Assessment of immature and recruiting year classes

## 1991 year class

In 1995 members of this year class were distributed over wide areas in the Norwegian Sea. An estimate on the basis of the surveys in July -August 1995 (Figs 3.3.2 and 3.3.3) gave an estimate of 17.2 billion individuals (text table in section 3.3.3). This is regarded as the most reliable total estimate of this year class. Raised by a natural mortality of 0.13 for 8 months gives 18.8 billion individuals. In addition some of this year class was fished in 1995. The number of this year class fished is only known for the Faroese and Icelandic fishery. In the Icelandic fishery $1 \%$ of the catches consisted of this year class, in the Faroes the percentage was $7 \%$.

Assuming an average of $3 \%$ in all the fisheries up to 1 August 1995 and a total catch of $680,000 \mathrm{t}$, gives approximately 20,400 tonnes fished of this year class. With an average weight of 190 g (as in the Faroese and Icelandic fishery) this indicates that approximately 107 million individuals of this year class is caught in the fishery. The total estimate for this year class at 1 January 1995 is thus set to 18.9 billion.

## 1992 year class

Individuals of this year class probably began emigrating from the Barents Sea in 1994. During the summer 1995 the year class was distributed over wide areas in the
eastern part of the Norwegian Sea from $64^{\circ} \mathrm{N}$ and northwards, and in parts of the Barents Sea.

There have been several acoustic estimates of this year class in 1995. A Russian survey in the Barents Sea in February gave 35,000 million individuals, and a joint Russian/Norwegian survey in the Barents Sea in May gave 8,000 million. A Norwegian survey in the Barents Sea in June also gave 8,000 million. Two Norwegian surveys in the Norwegian Sea in July and August, respectively, gave 13,100 million when combined. A new Norwegian survey in the eastern part of the Norwegian Sea in September gave 8,900 million.

The results from the surveys are given in the text table below. Earlier estimates used by the 1994 AtlantoScandian Herring and Capelin Working Group have also been included in the table. In order to allow comparison of the numbers, the last column contains the numbers by 1 January, if the estimates from the surveys are reduced by natural mortality ( $\mathrm{M} 1=1.56$ for age 1 , $\mathrm{M} 2=0.54$ for age 2 , and $\mathrm{M} 3=0.13$ for age 3 ).

| Time | Area | Acoustic <br> estimate <br> (billion <br> individuals) | Number by 1 <br> January 1995 <br> (billion <br> individuals) |
| :--- | :--- | ---: | ---: |
| May 1993 | Barents Sea | 102.6 | 24.1 |
| May 1994 | Barents Sea | 59.2 | 43.2 |
| February 1995 | Barents Sea | 35.0 | 35.8 |
| May 1995 | Barents Sea | 8.0 | 8.4 |
| June 1995 | Barents Sea | 8.0 | 8.5 |
| July/August | Norwegian Sea | 13.1 | 14.3 |
| 1995 |  | 8.9 | 9.7 |
| September Norwegian Sea <br> (eastern part) 895 |  |  |  |

The estimates from May and June 1995 cover only part of the year class, and are therefore too low.

The estimates from July/August 1995 and September 1995 both are from a highly dynamic situation when the herring was migrating out of the Barents Sea, and it is likely that the herring measured in July/August had migrated further south and out of the area when the new estimate was made in September. Although the surveys in July/August and September probably did not cover the entire distribution area, and the sum of the two estimates may thus to a certain degree be an underestimate, it is felt that this sum (22 billion individuals) is the best estimate of this year class. Raised by natural mortality for 8 months the estimate for 1 January 1995 is 24.0 billion.

This estimate is in accordance with the prognosis of this year class as 3 year olds made in 1993 (24.6 billion), but is only $55 \%$ of the number in the prognosis made last year. In this context, it should be noted that there are considerable difficulties in monitoring the large migratory movements of this year class from the Barents Sea to the Norwegian Sea. In retrospect, it can
be seen that, according to the acoustic estimates, the strong 1983 year class from 2 years old to 3 years old (Table 3.4.3) show an even stronger relative reduction in year class strength compared to the 1992 year class.

## 1993 year class

There have been several acoustic estimates of the Barents Sea component of this year class, but the results are conflicting. The joint Russian/Norwegian survey in May 1994 gave 6,600 million individuals. The Russian survey in February 1995 gave 36,700 million, and the joint Russian/Norwegian survey in May 1995 gave 7,700 million. The Norwegian survey in June 1995 gave 3,200 million, and the joint survey in September 1995 gave 400 million.

The results from the surveys are shown in the text table below, together with the corresponding numbers by 1 January 1996 if the numbers calculated from the different surveys are reduced by a natural mortality of 1.56 from age 1 to 2 and 0.54 from age 2 to 3 .

| Time | Area | Acoustic <br> estimate <br> (billion <br> individuals) | Number by 1 <br> January 1996 <br> (billion <br> individuals) |
| :--- | :--- | :---: | :---: |
| May 1994 | Barents Sea | 6.6 | 1.5 |
| February 1995 | Barents Sea | 36.7 | 23.4 |
| May 1995 | Barents Sea | 7.7 | 5.6 |
| June 1995 | Barents Sea | 3.2 | 2.4 |
| September 1995 | Barents Sea | 0.4 | 0.4 |

In last years report it was stated that the May 1994 estimate was probably an underestimate due to concentrations of small herring in Russian territorial waters which were not covered by the survey. In May 1995 no herring were reported from these waters.

Although the results from the 1995 surveys seem to be contradictory and indicate serious methodological problems, the working group decided to use the May 1995 survey as a basis for the estimate of the 1993 year class on 1 January 1995. The May survey is a joint Norwegian/Russian long time investigation series and the main task is to survey the immature herring stock. The remaining surveys in 1995 were designed primarily for other tasks. The May estimate is reduced by a mortality of 0.54 for 7 months. This gives an estimate of 5,6 million herring as 3 years old.

## 1994 year class

This year class had been estimated as 1 year old herring by using the estimate at 500 million at 1 May (Table 3.4.3) and reducing it by a natural mortality of 1.56 for 7 months and a further natural mortality of 0.54 for one year. In addition the estimate for the fjord areas from December 1994 (Table 3.4.1) is reduced correspondingly and added to the estimate. This gives a
total of 845 million individuals of the 1994 year class as 1 year old herring.

### 3.4.4 Maturity development of the 1991 and 1992 year classes

## 1991 year class

In July - August 1995 approximately $55 \%$ of this year class were classified as immature fish and will probably not spawn in 1996.

## 1992 year class

In August 1995 only a few per cent of this year class was classified as maturing. Taking into account that there also were a considerable number of this year class remaining in the Barents Sea, the total maturity coefficient of this year class is set to $1 \%$.

The following proportion mature at age is applied for 1996:

| Age | Proportion mature |
| :--- | :---: |
| 3 | 0 |
| 4 | 0.01 |
| 5 | 0.45 |
| $6-13+$ | 1.00 |

### 3.5 VPA and Catch and Stock Prognosis

### 3.5.1 Tuning the VPA

Data from the acoustic surveys in the wintering areas in December and January and on the spawning grounds in February-March were available for tuning the VPA, in addition to stock estimates from tagging. It was decided to use these acoustic estimates only for age 5 and older fish, because younger age groups are not completely covered by these surveys. The survey data, catch data and natural mortalities used are given in Table 3.5.1.

During the assessments in 1993 and 1994, the abundance estimates of the 1983 year class from surveys and from the tagging experiments were combined by first estimating a catchability (or availability) coefficient $q_{s}$ for each survey $s$, which is used to scale each survey to the VPA. Popes approximation is used in the VPA. The sum of squares of the deviations between the scaled survey estimates and the corresponding VPA estimates are then computed, and the population number in the final year is then varied in order to obtain the best possible fit.

Mathematically, this can be expressed as follows:
$y$ : year index
s: survey index
$\mathrm{N}_{\mathrm{y}}$ : Stock number in year y
$\mathrm{A}_{\mathrm{y}, \mathrm{s}}$ : Survey index in year y from survey s
$\mathrm{n}_{\mathrm{s}}$ : number of years for which we have an index from survey s
t: last year for which catch data exist
We then minimize $S_{y, s}\left(N_{y}-A_{y, s} q_{s}\right)^{2}$, where $q_{s}=S_{y}$ $N_{y} / S_{y} A_{y, s}$ when $n_{s}>1$, and $q_{s}=1$ when $n_{s}=1$. This is done by varying $\mathrm{N}_{\mathrm{t}+1}$, and using Popes approximation to calculate the population number backwards in time.

However, this approach seemed to give too much weight to the series of acoustic estimates on the spawning areas, because of the high stock number in 1988-1991. Even a small relative deviation from these stock numbers will cause a high sum of squares for the acoustic estimates in 1988-1991. Also, the way the catchability is computed gives most weight to the surveys with the highest absolute values. This causes most of the survey estimates in 1994 and 1995 to be higher than the VPA estimate, as seen from Figure 3.5.1.

Thus, it was decided to also try to minimize the sum of squares of the deviations between the logarithm of the scaled survey estimates and the corresponding VPA estimates, i.e. to minimize $S_{y, s}\left(\ln N_{y}-\ln \left(A_{y, s} q_{s}\right)\right)^{2}$, where $\mathrm{q}_{\mathrm{s}}=\exp \left(\left(\mathrm{S}_{\mathrm{y}} \ln \left(\mathrm{N}_{\mathrm{y}} / \mathrm{A}_{\mathrm{y}, \mathrm{s}}\right) / \mathrm{n}_{\mathrm{s}}\right)\right.$ when $\mathrm{n}_{\mathrm{s}}>1$, and $\mathrm{q}_{\mathrm{s}}=$ 1 when $\mathrm{n}_{\mathrm{s}}=1$. The result of this minimization is shown in Figure 3.5.2. From this figure it is seen that the new method gives a better fit to the survey data in the last years, and thus it was decided to adopt this new method. It should be noted that the catchability for the tagging estimate was fixed to 1 , and not computed. If the catchability of the tagging estimate was estimated in the same way as the other estimates, a minimum could not always be found.

The text table below shows that the new method, as well as the new data, increase the estimate (millions) of the size of the 1983 year class at January 1, 1995.

| Last year in <br> analysis/method | Old | New |
| :--- | :---: | :---: |
| 1994 | 2.040 | 2.814 |
| 1995 | 1.806 | 3.500 |

We then extended the new method to include also the 1988 and 1989 year classes, assuming the catchability to be constant for all year classes. It was decided to exclude the year classes 1982 and earlier and 1984-1987 from this analysis, as they are very weak. The result of this tuning is given in Table 3.5.1. Figures 3.5.3-3.5.5 show the VPA compared to the survey data adjusted by the estimated catchabilities for the 1983, 1988 and 1989 year classes respectively.

The 1984-1987 and 1990 year classes were estimated by averaging the December 1994 and January 1995 estimates of these year classes, scaled with the
catchabilities for these surveys estimated from the tuning. The estimates of all the year classes 1983-1990 at January 1, 1995, are summed up in the text table below.

| Year class | Estimate January 1, 1995 <br> (million individuals) |
| :--- | :---: |
| 1983 | 3457 |
| 1984 | 35 |
| 1985 | 277 |
| 1986 | 30 |
| 1987 | 46 |
| 1988 | 1203 |
| 1989 | 3595 |
| 1990 | 4924 |

### 3.5.2 VPA input and output

The input data to the VPA are given in Tables 3.5.23.5.6. The terminal Fs for the different year classes in the last year were found by tuning the catch at age data given in Table 3.5 .2 to the stock numbers at age given in the text table above. This year the VPA was run for age groups 3-13+. The terminal Fs at oldest age were adjusted somewhat from the values used last year, when the VPA was run for age groups 3-12+, to give reasonable values for fishing mortalities and stock sizes. The VPA program used sets the fishing mortality on the plus group equal to the fishing mortality on the oldest true age group in such a way that the stock number of the plus group in one year may become larger than the sum of the numbers in the oldest true age group and the plus group the year before. Thus, it is difficult to avoid inconsistencies.

In previous years, $\mathrm{F}_{5-10, u}$ has been used as the reference F. In 1994, this reference $F$ will not include the fishing mortality on the 1983 year class. Also, with the very large variability in year-class strength observed in this stock, an unweighted F does not always give a good indication of the development in F. However, we have continued to use $\mathrm{F}_{5-10, \mathrm{u}}$.

The results of the VPA are given in Tables 3.5.7-3.5.11.

### 3.5.3 Input data for the catch and stock prognosis

These data are given in Table 3.5.12. For the adult herring VPA stock numbers at 1 January 1995 have been used (Table 3.5.8). The abundance of the 19911994 year classes is calculated as described in Section 3.4.3.

The weight at age in the stock for 1995 is calculated from biological samples in December 1994 and January 1995. No trend in weight at age in the catch has been detected in recent years and therefore the weight at age in the catch in 1995 has been set equal to the 1991-1994 average. As the stock size is expected to increase towards the level from the 1950s and 1960s in the coming years, a slower growth may be anticipated. The weights at age in the catch data from the 1950s are not comparable to the present values due to a different structure in the fisheries (a larger portion was then taken as spent herring). The Working Group therefore chose the 1960s as a reference period for weight at age in the stock and catch at higher stock sizes. The change in weight at age is made gradual by setting the weight at age in the stock and in the catch in 1997 and later equal to the 1960-1969 average, and setting the 1996 values equal to the average of the 1995 and 1997 values. The maturity at age in 1996 is given in Section 3.4.4. For the years 1997 and later the average maturity at age in the period 1960-1968 was used.

For the prognosis the same flat-topped exploitation pattern as last year was chosen, assuming full recruitment to the fishery at age 5 . A natural mortality of $\mathrm{M}=0.13$ was applied for all age groups.

### 3.5.4 Results of the prognosis

The expected catch in 1995 ( $914,000 \mathrm{t}$ ) indicates that the fishing mortality ( $\mathrm{F}_{5-10, \mathrm{u}}$ ) decreased from 0.23 in 1994 to 0.18 in 1995. This decrease is, however, an artifact caused by the high fishing mortality on age 10 in 1994, in reality there has been an increase. The effects of different levels of $F$ on the catch in 1996 and on the stock and SSB in 1997 are presented in Table 3.5.13.

The assessment shows that the spawning stock biomass will increase from 3.9 million tonnes in 1995 to 4.8 million tonnes in 1996. In 1997, the spawning stock biomass will increase to above 5.5 million $t$ at all levels of fishing mortality in 1996 listed in Table 3.5.13. The total stock biomass ( $3+$ ) will increase from 8.4 million $t$ in 1995 to 10.7 million tonnes in 1996. This increase is due to the strong 1991 and 1992 year classes.

### 3.6 Risk analysis and management considerations

### 3.6.1 Risk analysis

A risk analysis on the spawning stock biomass was performed using the program @RISK with 300 iterations. The time range for the runs was 1 January 1996 to 1 January 2005.

### 3.6.1.1 Input data

The same data as for the short-term prognosis was used.

### 3.6.1.2 Modelling of uncertainty

## Stock data

The uncertainty connected to the initial values of the 1983, 1988 and 1989 year classes were modelled by performing the tuning procedure 30 times, each time drawing each measured value from a normal distribution with standard deviation equal to the standard deviation of the differences between the time series and the tuning vpa series. Data from other year classes were neglected and the 1989 year class was calculated from the two other year classes by keeping the sum equal to the sum in each time series. The final standard deviations for the 1983 and 1988 year classes were 0.08 and 0.167 billion, respectively.

For the younger year classes a coefficient of variation of 0.25 was assumed.

## Maturity ogive

A normal distribution with standard deviation of 0.1 was assumed for the 4 year old fish. The drawn value was kept through each simulation run.

## Natural mortality

A standard deviation of 0.05 was assumed. The drawn value was kept throughout each simulation run.

## Recruitment

All recruitment refers to 3 year old fish. Two different approaches were used:

A Beverton-Holt recruitment function was fitted to the data assuming a log-normal error. Two different cases were applied: Retaining all data (recruitment model 2) and deleting the exceptionally large year classes 1950, 1959 and 1983 year classes (recruitment model 1). The rationale behind the latter approach is that the time series shows that there always has been a period of up to 10 years between years of good recruitment. 1992 was a year of good recruitment, so it is unlikely that another year of good recruitment will occur within the time series used for the simulations.

Also, the method used last year was run. The historical halfvalues in a Beverton-Holt model were calculated assuming a maximum recruitment of 1.5 times the maximum observed recruitment and were drawn with equal probability during the simulations (recruitment model 4). In this case the effect of autocorrelation in recruitment was taken into account by drawing halfvalues from the same number of years after a good year class $(1950,1959,1983)$ as the time from the year in question to 1992 (recruitment model 3).

### 3.6.1.3 Results

The simulation results are compared to a spawning stock level of 2.5 million tonnes, in the text figures below called MBAL.

The figures below show the simulation results for recruitment model 1 using an F -value of fully recruited herring of 0.166 , yielding a mean of the yearly mean catch of 1.02 million tonnes as compared to using a constant catch of 1.02 million tonnes.

In both cases the median increases until 1998 and decreases afterwards. The median is about 2.5 million
tonnes in 2005 in both cases, but the constant catch option exhibits higher variability.

The figures below show the simulation results for recruitment model 2 using an F -value of fully recruited herring of 0.166 , yielding a mean of the yearly mean
catch of 1.13 million tonnes as compared to using a constant catch of 1.13 million tonnes.

For recruitment model 2 the medians in 2005 are above 2.5 million tonnes in both cases, the median for the constant F option being somewhat larger than the
median for the constant catch option. Also in this case the constant catch option shows the larger variability.

The figures below show the simulation results for recruitment model 3 using an F-value of fully recruited herring of 0.166 , yielding a mean of the yearly mean
catch of 0.97 million tonnes as compared to using a constant catch of 0.97 million tonnes.

The medians are in both cases a little higher in 2005 than for recruitment models 1 and 2 . The same difference between the constant catch option and the
constant F option found for recruitment models 1 and 2 applies also here.

The figures below show the simulation results for recruitment model 4 using an F-value of fully recruited herring of 0.166 , yielding a mean of the yearly mean
catch of 1.25 million tonnes as compared to using a constant catch of 1.25 million tonnes.

The median is about the same in 2005 in both cases, but also here the constant catch option exhibits the larger variability. However, recruitment model 4 is the most optimistic one giving a median spawning stock of more than 5 million tonnes in 2005 as compared to about 3.5 million tonnes for recruitment model 2.5-3.0 million tonnes for the more pessimistic recruitment models 1 and 3.

The most striking difference between the two alternative approaches to modelling recruitment is that the recruitment models 1 and 2 give a consistently negative trend for the median spawning stock from 1998 whereas
in the models 3 and 4 the median spawning stock have a slight increase from year 2002. The difference between the approaches is however not large, and both approaches gives the same differences between the constant F and constant catch options.

The reason why the constant catch option seems to give smaller probabilities of maintaining the spawning stock above 2.5 million tonnes throughout 2005 comes probably from the stock decline after year 1998, which is evident in all models. A constant F option will tend to be more conservative in a declining stock situation.

### 3.6.2 Management considerations

The immatures and adults of this stock form a central part of the ecosystem in the Barents and Norwegian Seas, respectively. The herring has an important role as a transformer of the production of zooplankton biomass and energy to a form which is available to organisms at a higher level of the food chain. Thus a large stock of herring, both immature and adults, will utilize larger quantities of plankton (and over wider areas) and be able to support larger fish stocks in the higher food chain levels, than a small stock of herring will do. Seen from this ecosystem point of view the spawning stock should be maintained at a level above 2.5 million t . In the 1950s and beginning of the 1960s the spawning stock was in the order of $5-10$ million $t$ (Table 3.5.11). Further, the MSY level of this stock has been estimated to be about 6 million $t$, and the Working Group has earlier indicated this as a preferable level in a long time perspective.

The prospects for recruitment to the spawning stock are discussed in the present and last years report. The spawning stock is expected to increase strongly in the coming years due to the recruitment of the strong 1991 and 1992 year classes. However, the year classes 1993 95 seem to be weak. Due to these extreme dynamics in the recruitment situation in the coming years, the choice of a harvesting strategy for 1996 (and for the coming years) should not be made on the basis of the short-term prediction table (Table 3.5.13). Rather, the choice should be made on the basis of the medium-term development of this stock and keeping in mind the important role this stock has in the Barents and Norwegian Sea ecosystems.

In the above section on risk analysis the Working Group has put forward possible developments of the spawning stock of Norwegian spring-spawning herring using two different harvesting strategies, i.e., a constant TAC strategy and a constant F strategy presented with the use of four different recruitment models.

An advantage of using a constant TAC is to keep the spawning stock at a relatively higher level over a longer time period, an advantage of using a constant $F$ strategy will be a more cautious harvesting at lower levels of the spawning stock. A combination of these two harvesting strategies should be considered in the management of this stock. Harvesting according to $\mathrm{F}_{0.1}$ but taking no more than MSY needs particular consideration.

### 3.7 Information on the Spatial and Temporal Distribution of Norwegian spring spawning herring

3.7.1 Recorded distribution and migration in 1995
A) Winter 1995

Adult herring: The entire spawning stock was, before the spawning migration commenced in the beginning of January, located in the wintering areas in Ofotfjorden and Tysfjorden in Northern Norway. The spawning took place along the Norwegian coast. In 1995 the spawning grounds were located on the coastal banks from $62^{\circ} \mathrm{N}$ to $70^{\circ} \mathrm{N}$. Very little spawning took place on the historical spawning grounds south of $62^{\circ} \mathrm{N}$.

Immature herring: In winter 1995 the immature stock was distributed in the south and southeastern parts of the Barents Sea. (Fig 3.7.1).

## B) Spring and summer 1995

Adult herring: After spawning the adult stock started their feeding migration to the Norwegian Sea. In spring and summer 1995 a joint investigation series in the Norwegian Sea by research vessels from the Faroes, Iceland, Norway and Russia was coordinated according to an agreed procedure. Thus the migration in the Norwegian Sea could be monitored month by month. A general picture of the migration pattern for the adult herring is given in Fig. 3.7.2.

Immature herring: In spring and summer a large amount of the immature herring recorded in the previous years in the Barents sea (mainly 1992 year class) emigrated from that area.

## C) Autumn 1995

Adult herring: Adult herring were reported off Vesterålen in the latter part of August, and have later entered Vestfjorden. The first herring schools were reported from Tysfjord around October 1. This indicates that the wintering areas which have been utilized since 1987/1988 will be in use in the wintering season 1995/1996 by the older part of the population.

Immature herring: During the joint Norwegian/Russian surveys in the Barents Sea in August/September very little immature herring were recorded. Further, the 1995 year class is the weakest on record since 1987 (Table 3.4.2).

### 3.7.2 Quantitative information on present spatial and temporal distribution of the Norwegian spring spawning herring stock

In September 1995 scientists from Faroes, Iceland, Norway and Russia met in Reykjavik in order to estimate zonal distribution of Norwegian spring spawning herring by the use of a "biomass x time" model (Hamre 1993). The 1983 year class was chosen as representative for the present period and used as an input year class in the model. The following present zonal attachment was estimated:

| Zone | \% |
| :--- | :---: |
| Faroes | 1.3 |
| Iceland | 0.1 |
| Norway | 87.3 |
| Jan Mayen | 1.0 |
| Russia | 6.2 |
| Int. Norw. Sea | 3.1 |
| Svalbard | 0.9 |
| Int. Bar. Sea | 0.1 |
| EU | 0.0 |

### 3.8 Ichtyophonus hoferi disease in the Norwegian spring spawning herring stock

This disease was first observed in herring in the NorthEast Atlantic in the summer of 1991. In a working paper presented by D. Skagen (Trends in Prevalence of Ichtyophonus disease in Norwegian spring spawning herring in the Ofoten area in 1992) to the present Working Group meeting show that the prevalences in this stock are declining (Fig 3.8.1). As in the North Sea herring, the disease appears to be mainly associated with certain year classes. Within each year class, the prevalence declines with time. For the North sea herring , it was shown that a decline like this could be explained by assuming that a fraction of the year class was infected at an early stage in life, giving that part of the year class a higher mortality throughout the following years. The declining prevalence could thus be explained as due to exhaustion of an infected subpopulation. This argument can also be applied to the Norwegian spring spawning herring.

The overall prevalence in the most recent samples is now in the order of $1.2 \%$. This, together with the clearly declining trend in the prevalence in the oldest year classes, indicates that the disease in the Norwegian spring spawning herring, as in the North Sea herring, is fading away. A prevalence of $1.2 \%$ corresponds to an additional natural mortality of 0.05 and 0.025 with a disease duration of 3 and 6 months respectively.

As discussed in last years report, there has been some uncertainties about the estimation of the prevalence of the Ichtyophonus disease in the stock of Norwegian spring spawning herring (Anon. 1995a). Some methods seem to give prevalences in the order of $100 \%$ (Karaseva et al. 1995) In a working paper (Hodneland et al. ) presented to the Working Group the different methods to estimate the prevalence of the Ichtyophonus disease are critically examined. On the basis of the evaluation of the methods given in this working paper, the Working Group concluded that the method applied to investigate the development of the prevalence of the Ichthyophonus (working document by D. Skagen) should be continued.

### 3.9 Comments to the assessment and the predictions

The assessment has changed considerably since last year. The size of the 1983 year class at present has been increased by about $50 \%$, while the size of the 1992 year class as 3 -year-olds has been decreased by $40 \%$. Also, the natural mortality in the predictions has been reduced from 0.23 to 0.13 . Altogether, this increases both the current stock size and the projections for stock size and catches considerably. It is also worth noting that according to this assessment, the spawning stock biomass has been above 2.5 million tonnes from 1988 onwards.

## 4. BARENTS SEA CAPELIN

### 4.1 Regulation of the Barents Sea Capelin Fishery

Since 1979, the Barents Sea capelin fishery has been regulated by a bilateral fishery management agreement between USSR (now Russia) and Norway. A TAC has been set separately for the winter fishery and for the autumn fishery. The fishery was closed from 1 May to 15 August until 1984. During the period 1984 to 1986, the fishery was closed from 1 May to 1 September. From the autumn of 1986 to the winter of 1991, no fishery took place. The fishery was re-opened in the winter season 1991, on a recovered stock. From the autumn 1993 the fishery was again closed. A minimum landing size of 11 cm has been in force for several years.

### 4.2 Catch Statistics

The international catch by country and season in the years 1965-1995 is given in Table 4.2.1. Following the recommendation from ACFM, there was no fishing for Barents Sea capelin during 1995.

### 4.3 Stock Size Estimates

### 4.3.1 Larval and 0-group surveys

Norwegian larval surveys based on Gulf III plankton samples have been conducted in June each year since 1981. The calculated numbers by year (which should be regarded as indices only) are shown in Table 4.3.1. The index this year is 0 . A few larvae only were caught during the larval survey. However, during the joint Norwegian-Russian acoustic survey during September, some few larvae were caught in a Gulf III sampler, showing that some spawning must have taken place during summer in the eastern areas. During the international 0-group survey in the Barents Sea in August 1994 very small amounts of 0-group capelin were detected. An area based index (Table 4.3.1) of 43 shows that the year class 1995 is at the same low level as the year classes 1992-1994. These findings confirm
the present collapse of the stock. The amount of young herring in the Barents Sea is now seen to decrease. As noted previously (Anon. 1995a) this may increase the chances for a high survival rate of capelin larvae next year.

### 4.3.2 Acoustic stock estimates in 1995

September to 1 October. The geographical distribution of capelin is shown in Figure 4.3.1. Table 4.3.2 gives the estimate as numbers by age and length, and the biomass at age. The results are summarized in the text table below (the estimates of the same age groups measured in 1994 are shown on a shaded background).

The 1995 acoustic survey was carried out jointly by two Russian and two Norwegian vessels in the period 13

| Year class |  | Age | Number ( $10^{9}$ ) |  | Mean weight (g) |  | Biomass ( $10^{3} \mathrm{t}$ ) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1994 | 1993 | 1 | 7.1 | 19.7 | 6.7 | 4.4 | 47.4 | 86.8 |
| 1993 | 1992 | 2 | 8.1 | 3.4 | 13.8 | 11.2 | 112.4 | 38.5 |
| 1992 | 1991 | 3 | 1.5 | 4.3 | 16.8 | 16.5 | 25.7 | 71.0 |
| 1991 | 1990 | 4 | 0.4 | 0.2 | 22.6 | 184 | 7.9 | 3.1 |
| Total stock in |  |  |  |  |  |  |  |  |
| 1995 | 1994 | 1-4 | 17.2 | 27.7 | 11.3 | 12 | 193.6 | 199.3 |
| Based on TS value: $19.1 \log \mathrm{~L}-74.0$, corresponding to $=5.0 \times 10^{-7} \times \mathrm{L}^{1.91}$ |  |  |  |  |  |  |  |  |

In comparing the acoustic estimate by year class obtained this year to the estimate obtained last year, one should bear in mind that the relative error is probably large when the capelin abundance is low, both because of fewer trawl stations with large capelin catches (incomplete age sampling) and because the echogram scrutinizing becomes more uncertain.

The total stock is estimated at about 195000 tonnes, the lowest abundance on record, apart from those in 1986 and 1987. About $60 \%$ ( 120,000 tonnes) of this stock is maturing.

The 1994 year class (1-group) consists, according to this estimate, of 7 billion individuals. The mean weight is estimated at 6.7 g , which is the highest on record. Consequently, the biomass of the 1994 year class is about 47 thousand tonnes.

The estimated number of fish in the 1993 year class (2group) is 8.1 billion, as opposed to 3.4 billion in the 1992 year class measured last year. The mean weight at this age is 13.8 g (11.2 g in 1994), and consequently the biomass of the two years old fish is about 112,000 tonnes. The mean weight is the highest recorded apart from that found in 1990.

The 1992 year class is estimated at 1.5 billion individuals with mean weight 16.8 g , giving a biomass of about 26,000 tonnes. The mean weight is at the same level as the preceding year classes. The 1991 year class (now 4 years old) is estimated at 0.4 billion individuals. With a mean weight of 22.6 g this age group makes up only
8,000 tonnes. Only negligible amounts were found of 5 years old capelin.

The text table below shows the number of fish in the various year classes, and their mortality from age 1 to 2 .

| Year: | $85-86$ | $86-87$ | $87-88$ | $88-89$ | $89-90$ | $90-91$ | $91-92$ | $92-93$ | $93-94$ | $94-95$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Year class: | 1984 | 1985 | 1986 | 1987 | 1988 | 1989 | 1990 | 1991 | 1992 | 1993 |
| Age 1, Nos $\left(10^{9}\right)$ | 35.1 | 7.5 | 37.3 | 20.0 | 177.9 | 700.0 | 392.0 | 351.3 | 2.2 | 19.8 |
| Age 2, Nos $\left(10^{9}\right)$ | 3.4 | 1.5 | 28.8 | 17.8 | 177.5 | 574.4 | 196.3 | 53.4 | 3.4 | 8.1 |
| Total mortality $(\%)$ | 90 | 80 | 33 | 12 | .2 | 18 | 50 | 85 | - | 59 |

As there has been practically no fishing on these age groups, the figures for total mortality constitute natural mortality only. In spite of the uncertainties, illustrated by the low value for the 1988 year class and the negative mortality for the 1992 year class, these values probably reflect quite well the trend in predation on capelin. As can be seen from the table, the mortality was high up to 1985-1987, but then a substantial decrease occurred in 1987-1990, probably caused by diminished predation pressure from cod. From 1990 the mortality increased again, back at the level measured before 1986. The negative mortality last year is due to measurement error,
and consequently it is difficult to interpret the value obtained this year. The increase since 1990 is consistent with an increasing stock of cod now preying on the capelin. Estimates of stock in number and weight for the period 1973-1995 are shown in Table 4.3.3.

Historical stock developmentAn overview of the development of the Barents Sea capelin stock in the period 1986-1995 is given in Tables 4.3.4-4.3.13. The methods and assumptions used for constructing the tables were explained in Appendix A to Anon. (1995a).

In that report, also the complete time series back to 1973 can be found. It should be noted that several of the assumptions and parameter values used in constructing these tables are provisional and future research may alter some of the tables considerably. For instance, Mvalues for immature capelin will be calculated using new estimates of the length at maturity and M-values for mature capelin will be calculated taking the predation by cod into account. However, for giving a crude overview of the development of the Barents Sea capelin stock the tables may be adequate.

Estimates of stock in number by age group and total biomass for the period are shown in Table 4.3.4. Catch in number by age group and total biomass is shown for the spring season and the autumn season in Tables 4.3.5 and 4.3.6. Fishing mortality coefficients by age group for the autumn season and natural mortality coefficients by age group for immature capelin are shown in Tables 4.3.7 and 4.3.8. Stock size at 1 January in numbers by age group and total biomass and the mean weight by age group at 1 January are shown in Tables 4.3.9 and 4.3.10. Proportion of mature stock by age group at 1 January and spawning stock biomass at 1 April are shown in Tables 4.3.11 and 4.3.12. Table 4.3.13 gives an aggregated summary.

### 4.4 Management Considerations

In managing the Barents Sea fishery one of the main goals has been to allow a minimum target spawning stock biomass to spawn. In the period 1979-1982, this was set at $500,000 \mathrm{t}$ and later at $400,000 \mathrm{t}$ based on an analysis by Hamre and Tjelmeland (1982). The present maturing component of $120,000 \mathrm{t}$, which will be reduced by predation by cod until spawning, is far below this and other conceivable levels of the target spawning stock. Therefore, there is no room for any fishery in 1996. The 1993, 1994 and 1995 year classes are very poor, and consequently any fishery for capelin in the Barents Sea cannot be expected before at least 1999.

## 5. CAPELIN IN THE ICELAND-EAST GREENLAND-JAN MAYEN AREA

### 5.1 The Fishery and Catch Regulations

The fishery depends for the most part upon maturing capelin, i.e. that part of each year class which spawns at age 3 as well as those fish at age 4 which did not spawn earlier. The size of the immature components is difficult to assess before their recruitment to the adult stock at ages 2 and 3. This is especially true of the 3-group immatures.

The fishery of the Iceland-East Greenland-Jan Mayen capelin has, therefore, been regulated by preliminary catch quotas set prior to each fishing season (JulyMarch) based on the results of surveys of the abundance
of immature 1- (and 2-) group capelin. Final catch quotas for each season have then been set in accordance with the results of acoustic surveys of abundance of the maturing fishable stock, carried out in autumn (OctoberNovember) and/or winter (January/February) in that season. A summary of the above procedure and its results is given in Table 5.1.1.

Over the years, there has generally been no fishery permitted in the period April-June and the season opened in July/August or later, depending on the state of the stock. Due to very low stock abundance there was a fishing ban lasting from December 1981 to November 1983. In addition, areas with high abundance of juvenile 1 - and 2-group capelin (in the shelf region off NW-, Nand NE-Iceland) have usually been closed to the summer and autumn fishery.

The total annual catch of capelin in the Iceland-East Greenland-Jan Mayen area since 1964 is given by weight, season and fleet in Table 5.1.2. The total international catch in numbers during the summer/autumn 1978-1994 and winter 1979-1995 seasons is given by age groups and years in Tables 5.1.3 and 5.1.4 respectively.

### 5.2 Historic Stock Abundance

The annual abundance by number and weight at age for mature and immature capelin in the Iceland-East Greenland-Jan Mayen area has been calculated with reference to 1 August (before the fishing season) and 1 January in the following year for the 1978/79-1994/95 seasons. The results are given in Tables 5.2.1 and 5.2.2 (1 August and 1 January, respectively. Table 5.2.2 also gives the remaining spawning stock by number and biomass in March/April 1979-1995.

The above calculations of stock abundance are based on the "best" acoustic estimates of the abundance of maturing capelin. These are obtained in autumn and/or winter, the "best" in each case being defined as that estimate on which the final decision on TAC was based. Taking account of the catch in number and a monthly natural mortality rate of $\mathrm{M}=0.035$ (Anon. 1991a) the abundance estimates of each age group are then projected to the appropriate point in time. Since the acoustic estimates of the abundance of the juvenile part of the stock are unrealistically low and no information is available on natural mortality rates among such capelin, the abundance of juvenile capelin by number was also back-calculated using the same natural mortality rate as in the case of the adult stock.

The observed annual mean weight by age is used for obtaining the stock biomass on 1 January. With the exception of juvenile capelin, the historic average growth pattern was used for estimating stock biomass of the other components on 1 August, from mean weights observed in the autumn of the same year or in January of
the following year. The remaining spawning stock biomass is calculated from mean weights in January of the same year. It is known that some weight increase takes place in February and March. Therefore, the remaining spawning stock biomass is underestimated by a small margin.

### 5.3 Method of Stock Prognosis

The precautionary TAC should be set at such a level as to open the fishery before the October survey, yet keep it closed when it is likely that fishing will reduce the residual spawning stock below $400,000 \mathrm{t}$. Thus the prognosis procedure needs to predict the fishable stock in the beginning of the season in order to predict the effects of fishing. In order to account for the highly variable year class strength, the procedure needs to predict separately the two major components of the mature stock (ages 2 and 3) in the fall. These predictions need to be done in spring.

Available data usually include acoustic survey estimates of the different age groups in August, October and January. August survey results, used for a number of years in order to predict 2-group recruits, have proven unreliable. This has become apparent by comparing these predictions to later assessments of the same stock components. On the other hand, it has been found that autumn (October/November) acoustic estimates of 1and 2-group abundance are more reliable predictors of fishable stock abundance one year ahead in time. A prediction model was, therefore, developed using the autumn survey data (Anon., 1993a). A summary of the method reads as follows (for denotations see Table 5.3.1 and Fig. 5.3.1):

The maturing part of the 2-group in fall $\left(\mathrm{N}_{2}{ }^{\text {mat }}\right)$ is a part of the survivors of the 1 -group in the previous fall $\left(\mathrm{N}_{1}\right)$, which is measured in October. A regression of the backcalculated maturing 2 -group abundance against the autumn acoustic estimates of 1 -group abundance is used for predicting the abundance of maturing 2-group capelin.

The maturing part of the 3-group in fall corresponds to the surviving part of the year class which did not mature and spawn in the year before. Unfortunately, the surveys of the immature 2-group ( $\mathrm{N}_{2}{ }^{\mathrm{imm}}$ ) in the year before are gross underestimates and will, therefore, not be used. Similarly, the January survey of this year class only estimates the part which will spawn and thus is no indication of what will appear in fall of next year. It is found, however, that maturity at age 2 is inversely related to year class size $\left(\mathrm{N}_{2}{ }^{\text {tot }}\right)$. Hence the total abundance of the 2-group in autumn is an indication of what will appear as 3 -group in the following season. A regression relating the back-calculated total abundance of year classes at age 2 to their abundance at age $3\left(\mathrm{~N}_{2}{ }^{\text {tot }}\right.$ and $\mathrm{N}_{3}{ }^{\text {tot }}$ ) is used for predicting the abundance of 3group capelin.

The data sets comprising all comparisons of numbers by age and maturity, relevant to the prediction model, are given in Table 5.3.1. The mean weight of maturing 2and 3-group capelin in autumn 1981-1994 (year classes 1978-1992) is given in Table 5.3.2. The above regressions are updated as new data become available. A test of their performance is given in Table 5.3.3.

### 5.4 Stock Prognosis and Assessments for the 1994/1995 Season

Calculations of expected TAC for the 1994/1995 season, using the prediction method described in section 5.3 and year classes 1980-1990, indicated a total catch of $1,430,000 \mathrm{t}$, with the usual prerequisite of a monthly natural mortality rate of 0.035 and a remaining spawning stock of $400,000 \mathrm{t}$, if the catch were spread evenly over the period August 1994-March 1995.

Although the model has predicted roughly the same TAC or slightly lower than finally recommended from acoustic assessments of fishable stock abundance in late autumn and/or winter, the series includes the notable exception of the 1989/1990 season. In this case the prediction proved to be optimistic by about one third. In view of this, as well as the short time series it was recommended that a precautionary TAC should not exceed $2 / 3$ of the total TAC predicted for the season, i.e. $950,000 \mathrm{t}$. This advice was accepted by all parties concerned. In addition, areas north of Iceland were closed to the fishery in order to protect the juvenile part of the stock from coming into contact with the summer fishery.

The autumn survey was carried out in the period 25 October - 16 November 1994. Because of ice, the westernmost part of the channel between Iceland and Greenland as well as the Greenland plateau could not be reached. However, no capelin were recorded near the ice border. Weather conditions were quite variable and surveying had to be halted on occasions to wait out storms. The capelin were almost always recorded in scattering layers and in most areas the recordings consisted of a mixture of mature and immature fish.

According to the autumn 1994 survey the estimated fishable/spawning stock was $33.8 * 10^{9}$ fish on 1 November 1994. At that time the observed mean weight in the fishable stock was 16.8 g and the stock biomass, therefore, about $570,000 \mathrm{t}$. Details of this stock estimate are given in Table 5.4.1.

With the usual prerequisite of a monthly natural mortality rate of 0.035 , a remaining spawning stock of $400,000 \mathrm{t}$ and an estimated weight increase of 2.6 g , the autumn abundance estimate indicated a TAC of 165,000 $t$ in the period November 1994-March 1995, if the catch were spread evenly over the period. Counting the catch taken in July-October 1994, this corresponded to a total TAC of about $485,000 \mathrm{t}$ for all of the 1994/95 season.

Clearly, the autumn 1994 assessment indicated a much smaller fishable stock than had been projected and was even well below the precautionary TAC set prior to the opening of the fishery. Due to the continued scattered distribution of the capelin, practically no fishery could be conducted in November and December 1994. A new survey of stock abundance was, therefore, not scheduled until January 1995.

The winter 1995 survey of the spawning/fishable stock abundance stretched over the period 2 January - 16 February. This was both because of difficult weather conditions, especially in January, but also and no less due to the extreme dispersal of the capelin until the spawners began to aggregate near the shelf edge east and southeast of Iceland.

According to the winter 1995 survey, the estimated fishable/spawning stock was $42.1 * 10^{9}$ fish on 15 February 1995. At that time the observed mean weight in the fishable stock was 20.8 g and the stock biomass, therefore, about $875,000 \mathrm{t}$. Details of this stock estimate are given in Table 5.4.2.

The winter 1995 survey was carried out under extremely difficult conditions which necessitated adjustments for effects by aeration and migration. In view of previous experience of evaluating such estimates it is likely that the 1995 spawning and fishable stock of capelin has been underestimated to some, but unquantifiable, extent.

In retrospect, it is clear that the autumn 1994 survey did not register but part of the older year class in the fishable/spawning stock and missed the largest individuals of the younger year class. Similarly, part of the smaller adult individuals seem to be missing in the winter 1995 estimate. The result of an attempt to reconcile these differences is given in Table 5.4.3, where a discounted autumn 1994 estimate of the adult numbers of fish in the $<15 \mathrm{~cm}$ categories have been substituted for those recorded during the winter 1995 survey. This combined estimate indicates a spawning stock biomass of about $925,000 \mathrm{t}$ on 15 February.

Counting the catch already taken, the autumn/winter 1994/95 abundance estimates correspond to a TAC of about $850,000 \mathrm{t}$ for all of the 1994/95 season, or 532,000 t for the 1995 winter fishery. Due to the fact that only $40,000 \mathrm{t}$ of capelin had been taken by 15 February there was practically no possibility of the catch exceeding the above limit in the short time remaining of the winter 1995 season (6-7 weeks). A formal advice on TAC during the winter 1995 season was, therefore, never issued.

### 5.5 The Fishery in the 1994/1995 Season

The summer capelin fishery was opened on 1 July 1994. In the first half of July the fleet was mainly fishing with relatively high catch rates off the eastern north coast of

Iceland at about latitude $68^{\circ} \mathrm{N}$. The fishery gradually moved to the west and was in the latter half of July conducted off the western north coast of Iceland, but with reduced catch rates. By August, the fishery had shifted to the area between the Vestfir_ir peninsula and Greenland, south of Scoresby Sound, where the fleet finally lost contact with the fishable stock.

In spite of intensive search, hardly any fishable concentrations were located during the remainder of the 1994 summer/autumn season. Thus, $218,000 \mathrm{t}$ were taken in July, 89,000 t in August and only 17,000 t during the period September-December. Thus, the total capelin catch in the 1994 summer/autumn season amounted to just under 324,000 tonnes.

Because of extremely difficult weather conditions and scattered distribution of the capelin east of Iceland, practically no catches could be taken until in the second week of February 1995, when the first spawners migrated into and concentrated in the shallower waters off the southeast coast of Iceland. From about midFebruary until 20 March the fishery was quite intensive and only hampered by spells of bad weather and the capacity of the shore-based reduction plants. Towards the end of March, good catches became more sporadic until the end of the season in early April. With the exception of the Greenlandic vessel "Ammassat", which landed only 440 tonnes, the winter 1995 capelin fishery was exclusively Icelandic.

A total of $863,900 \mathrm{t}$ were landed by Icelandic, Norwegian, Greenlandic and Faroese vessels in the 1994/1995 season (Table 5.1.2). About 400,000 t were left and spawned in the spring of 1995 (cf. Tables 5.1.1 and 5.2.2).

The total international catch in numbers by age groups is given for the summer autumn 1994 and the winter 1995 seasons in Tables 5.1.3 and 5.1.4. The length distribution of the catch is given by age groups in Tables 5.5.1 and 5.5.2.

### 5.6 Stock Abundance and TAC in the 1995/1996 Season

The main component of the fishable stock in the 1995/1996 season will be the maturing part of the 1993 year class and that part of the 1992 year class which did not mature and spawn at age 3 in the spring of 1995.

The October 1994 survey gave an estimate of 119.0 billion capelin belonging to the 1993 year class. The winter 1995 assessment gave a total of 33.4 billion mature capelin, belonging to the 1992 year class (Table 5.4.2). Counting the catch and assuming a monthly natural mortality rate of 0.035 this estimate corresponds to 59.8 billion maturing capelin of the 1992 year class when back-calculated to 1 August 1994 (Table 5.3.1).

As stated in section 5.4, the October 1994 survey underestimated the larger individuals of the 1992 year class (size $>15 \mathrm{~cm}$ ). Using the winter 1995 survey estimate of the abundance of these size categories and the October 1994 estimate of the smaller fish ( $<15 \mathrm{~cm}$ ), the back-calculated total estimate of the 1992 year class on 1 August 1994 is 71.4 billion capelin, when account has been taken of fishing and natural mortalities (Table 5.3.1).

After updating the appropriate regressions in the light of new information, the prediction model, described in section 5.3 gives:
a) for the 1993 year class; $\quad \mathrm{N}_{2}^{\text {mat }}=0.66 \mathrm{~N}_{1}$ $+14.4 ; \mathrm{R}^{2}=0.73, \mathrm{P}<0.01$.
b) for the 1992 year class;

$$
\mathrm{N}_{3}^{\mathrm{tot}}=0.39 \mathrm{~N}_{2}^{\mathrm{tot}}-
$$ $12.8 ; \mathrm{R}^{2}=0.67, \mathrm{P}<0.01$.

The resulting predictions of the abundance by number of maturing capelin at ages 2 and 3 on 1 August 1995 are 92.5 and 14.9 billion fish, respectively.

The fishable stock biomass, obtained by multiplying the estimated stock in number by the average mean weight of maturing capelin in autumn, was then projected forward to spawning time in March 1996 with the usual prerequisites of a monthly mortality rate of $\mathrm{M}=0.035$ and a remaining spawning stock of $400,000 \mathrm{t}$. This gave a predicted TAC of $1,202,000 \mathrm{t}$ if spread evenly over the time August 1995 - March 1996 (Table 5.3.3).

The limitations of this model and its historic performance (see Table 5.3.3 and section 5.3 above) indicate that a precautionary TAC should not exceed $2 / 3$ of the total TAC predicted for the whole season: According to this criterion the precautionary TAC for the 1995/96 capelin fishery should be set at $800,000 \mathrm{t}$. Decisions on the final TAC for the 1995/96 season should, as in earlier years, be based on the results of surveys carried out in October-November 1995 and/or January 1996.

The stock prognosis just described was submitted to the May 1995 meeting of ACFM. The resolution of that meeting concurred with the above advice of a precautionary TAC of $800,000 t$ for the 1995/96 season, the final decision to be made when the stock had been surveyed in autumn 1995/winter 1996. This advice was subsequently accepted by all parties concerned and a TAC of $800,000 \mathrm{t}$ set for the first part of the season.

The autumn 1995 stock assessment survey is scheduled to begin on 25 October. Therefore, no further information is as yet available on the actual state of the present fishable stock of capelin in the Iceland-East Greenland-Jan Mayen area.

### 5.7 The 1995 Summer and Autumn Fishery

The season opened on 1 July with the Icelandic fishing fleet taking good catches, especially near the shelf edge north of the Vestfir_ir peninsula. However, it soon became apparent that the catch consisted of slow growing 2-group capelin, especially in the westernmost part of the fishing area. Therefore, this area was temporarily closed to the fishery around mid-July.

On 10 July a Norwegian fishery began in deep water areas the ENE of Langanes with catches consisting mainly of large capelin of the 1993 and 1992 year classes. However, it seems that there was not much capelin in this area and the fishery soon shifted to near the shelf edge north of Melrakkaslétta (around $16^{\circ} \mathrm{W}$ ).

Extensive sampling of the catch around mid-July by Icelandic fishery inspectors revealed that a large part by number of the catch in the north Icelandic area consisted of capelin $<13.5 \mathrm{~cm}$. The fish were full of copepods and were expected to increase rapidly in weight in the next few weeks. The area within the Icelandic EEZ, south of $68^{\circ} 10^{\prime} \mathrm{N}$ to the west of $18^{\circ} \mathrm{W}$, and south of $67^{\circ} 40^{\prime} \mathrm{N}$ to the east of $18^{\circ} \mathrm{W}$ was, therefore, closed as of 19 July 1995. At the time there was much ice in the Denmark Strait, as well as east of Greenland farther to the north, and no fishable capelin concentrations could be found outside of the closed area.

When the fishing ban was lifted on 9 August, the Icelandic fishing fleet searched for capelin in the previously closed area as well as in most of the usual summer distribution area of the fishable stock. No fishable concentrations were located.

In the summer of 1995, Icelandic, Norwegian, Greenlandic and Faroese vessels caught about 82,000, $28,000,1,000$ and 200 tonnes, respectively. All of the catch was taken in July.

### 5.8 Stock Abundance and TAC in the 1996/97 Season

The main components of the fishable stock in the 1996/97 season will be the 1994 and 1993 year classes. As yet the only available information on the abundance of the 1994 year class is the 0 -group and 1 -group indices, obtained in August 1994 and 1995, respectively. An abundance estimate of the 1993 year class as 1-group was obtained in October/November 1994.

The 19940 -group capelin index is one of the highest indices recorded in the past (Table 5.8.1). Further, the August 19950 -group survey yielded an estimate of 189 billion 1-group capelin of the 1994 year class. This is the second highest August estimate of 1 -group capelin on record (Table 5.8.2). The autumn 1994 survey results indicated a strong 1993 year class, but as stated in section 5.6 no new information on the abundance and
maturing ratio of this year class has yet been obtained in 1995.

Although the above information thus indicates good recruitment to the fishable stock of 1996/97, experience has shown that such type of data are erroneous predictors of stock abundance one and a half to two years ahead in time.

Information necessary for predicting year class abundance in the 1996/1997 season, using the method described in section 5.2 , will not become available until after both the autumn 1995 and winter 1996 surveys have been completed. Therefore, even a preliminary advice on a precautionary TAC for the 1996/1997 season, must be postponed, at least until late November 1995.

### 5.9 Closed Areas During the Summer-Autumn Season

In the years 1989-1992 very few capelin seem to have migrated to feed in the central and northern parts of the Iceland-East Greenland-Jan Mayen area. Instead, most of the adult stock apparently stayed in or near the shelf area north of Iceland to feed there together with the immatures. Although on a smaller scale, this is also true for other years since as a rule only part of the fishable stock migrates to feed at high latitudes in summer.

When conducted over the north Icelandic shelf and in the area of the Iceland-Greenland Ridge, a summer fishery, and in part the autumn fishery also, is usually dependent upon mixed concentrations of mature and immature capelin. Such fishery inevitably results in repeated escape of 1-group capelin and the smallest 2group fish, which are generally not retained by the mesh used in capelin seines. While there are no measurements of mortalities caused by escape, it is likely that fishing for prolonged periods on such mixed concentrations can cause mass mortality of 1 -group capelin that goes unnoticed (Anon., 1993a). This was indeed the situation in July of 1995, when the closed area west of $18^{\circ} \mathrm{W}$ only reached $67^{\circ} 45^{\prime} \mathrm{N}$ while fishing was allowed east of that longitude without constraints.

A closure of an area south of $68^{\circ} \mathrm{N}$ from west of $18^{\circ} \mathrm{W}$ and south of $67^{\circ} 30^{\prime}$ from east of $18^{\circ} \mathrm{W}$, within the Icelandic EEZ, would effectively force the initial fishing operations in July and August to take place in deep water areas and to concentrate on fast growing fish with maximum fat content. This area should, therefore, be closed to the fishery during those months.

The October-November surveys will resolve the actual size distribution of capelin within the waters of the north Icelandic shelf and allow the establishment of further area closures, if necessary, on a real time basis.

### 5.10 Comments on the Assessment

The Working Group noted that alternative methods for computing the precautionary TAC should be considered. In particular, an approach which directly uses the relationship between abundance and the proportion mature should be investigated.

## 6. BLUE WHITING

### 6.1 Stock identity and stock separation

Preliminary results of investigations conducted by Russian and Norwegian scientists (Mazhirina, 1993; Belikov 1993; Mork and Gievær 1993) in 1991-1993 indicate that several populations could appear in the spawning area. There were, however, no indications of genetic substructure among the blue whiting from west of the British Isles to Gibraltar.

In 1995 genetic investigations of population structure of blue whiting were continued by Norwegian scientists. It was found that the southern boundary of the separate stock off Northern Norway was located north of Lofoten Isles, and in addition two local populations were identified, i.e. one in a fjord in North-Norway and one in a fjord in West-Norway (Giæver and Mork, 1995).

ACFM also agreed at its November 1993 meeting that the two stocks should be combined for assessment purposes, but that the catch predictions could still be done by area.

The Working Group, ACFM and NEAFC adhere to the idea of a single blue whiting stock. However, it is considered necessary to continue the study of this species' population structure.

### 6.2 Fishery in 1994 and 1995

Estimates of total landings of blue whiting by countries in 1994 from various fisheries by countries are given in Tables 6.2.2-5 and summarised in Table 6.2.1. The total landings from all blue whiting fisheries in 1994 were $455,739 \mathrm{t}$ which is $4 \%$ less than in 1993.

The majority of the blue whiting catches have been taken in the spawning area. The landings in 1994 from the directed fishery increased by $3 \%$ and the industrial mixed fishery decreased by $54 \%$ respectively compared to 1993.

Preliminary data on the blue whiting catches from January-August 1995 were submitted by Working Group members and the total preliminary catch amounted to $380,000 \mathrm{t}$ (Table 6.2.6). Scaling this to the preliminary catch within the same period of 1994, the expected total catch of 1995 will be $470,000 \mathrm{t}$.

Landings from the southern area, i.e. from Spain and Portugal were 29,473 t in 1994 which is $9 \%$ less than in 1993 (Table 6.2.1).

### 6.3 Biological characteristics

### 6.3.1 Length Composition of Catches

Data on length composition of the 1994 catches of the blue whiting stock by ICES-division were presented by Norway, Faroes, Portugal and Spain (Table 6.3.1-4). Length composition of the catches varied over seasons and areas.

Length composition of catches of blue whiting taken by Faroese vessels in 1994 varied in the directed fishery from $20-40 \mathrm{~cm}$, in mixed fishery from $14-26 \mathrm{~cm}$. The Norwegian directed fishery in 1994 was based on blue whiting with length $23-40 \mathrm{~cm}$ and the mixed fishery $19-$ 39 cm . Blue whiting in the length range $12-39 \mathrm{~cm}$ was taken by the Spanish and Portuguese vessels in 1994.

Data on length composition of the catches in 1995 were presented by Norway, Faroes and Russia (Table 6.3.5-8). The bulk of the Norwegian catches in the directed fishery consisted of fish from $22-42 \mathrm{~cm}$ and in the mixed industrial fishery from $13-34 \mathrm{~cm}$. The length compositions from the Russian vessels ranged from 1644 cm , with fish of length $31-33 \mathrm{~cm}$ dominating. Length compositions of blue whiting catches taken by Faroese vessels in 1995 varied from $22-40 \mathrm{~cm}$.

### 6.3.2 Age Composition of Catches

For the directed fishery in 1994 age compositions were provided by Norway and Faroes. These countries accounted for $62 \%$ of the landings. The landings for the directed fishery of Russia, Latvia and Estonia in area Vb and Russia in area IIa and VIa were allocated to catch in numbers by use of Faroese age compositions in the same areas, and the rest of the landings for the directed fishery were allocated to catch in numbers by use of Norwegian age compositions in the same areas (Table 6.3.9).

For landings of blue whiting taken in the mixed industrial fisheries, age compositions were provided by Norway and The Faroes representing $21 \%$ of the landings (Table 6.3.10).

For the landings in the Southern area catch-at-age data for Portugal and Spain were calculated using the age length keys provided by Spain (Table 6.3.11).

The combined age composition for the directed fishery in the spawning area and in the Norwegian Sea, as well as the total mixed industrial fishery, together with the age composition for the landings in the southern area, were assumed to give the total age composition of the
total landings from the blue whiting stock (Table 6.3.12).

### 6.3.3 Weight at Age

Data on mean weight at age for 1994 were presented by Norway, Faroes and Spain. Landings from other countries were assumed to have the same mean weight at age composition when fished in the same area and period as the sampled catches. Table 6.3.13 shows the mean weight-at-age from 1981-94 as used in the VPA run. The weight in the stock was assumed to be the same as in the catch.

### 6.3.4 Maturity at Age

Table 6.3.14 shows the maturity-at-age from 1981-94 as used in the VPA run.

### 6.4 Stock estimates

### 6.4.1 Acoustic surveys

### 6.4.1.1 Surveys in the spawning season

In 1995 during the period 22 March-24 April, Norway and Russia carried out surveys in the shelf edge area to the west of the British Isles for recording of the distribution, and for assessment of the blue whiting spawning stock size (Monstad et al. 1995a). It was the fifth joint survey by research vessels from IMR, Bergen and PINRO, Murmansk. The Norwegian survey was also part of the SEFOS-project (EC, AIR) and hence a numbers of plankton stations were also worked for studies of the blue whiting eggs and larvae. Both vessels operated echo sounders of 38 kHz (EK-500), and a ship-to-ship calibration performed resulted in a 1:1 relationship of the vessels' acoustic instruments.

Separate estimates were made by both vessels and combined on subarea basis. The area was surveyed from the south $\left(48^{\circ} 30^{\prime} \mathrm{N}\right)$ and northwards to the Faroe/Shetland area $\left(62^{\circ} 00^{\prime} \mathrm{N}\right)$, including the Porcupine bank (Figs.6.4 1 and 6.4.2). Blue whiting was recorded along the whole continental slope, with the densest concentrations recorded the 5-6 April near the edge of the northern part of the Porcupine bank. One week later these concentrations had moved approximately 150 nautical miles northwards (Figs.6.4.3 and 6.4.4).

The combined result of the acoustic assessment was a biomass of 6.1 mill. tonnes belonging to the spawning stock, and 0.8 mill. tonnes of immature blue whiting. These represent $45.5 \times 10^{9}$ and $21.9 \times 10^{9}$ individuals respectively.

By numbers one year old blue whiting dominated, especially in the Faroe/Shetland area. Totally, this 1994 year class made up almost $30 \%$ of the stock recorded. Among the adults the 1992 year class was the most numerous one (Fig.6.4.5).

### 6.4.1.2 Surveys in the feeding season

During the international investigations on herring and environment in the Norwegian Sea (Anon., 1995a), blue whiting was recorded by Russia, Norway and Faroes over a rather wide area in June/July and July/August (Figs.6.4.6 and 6.4.7). From the Faroes area the distribution in May/June stretched northwards to $71^{\circ} \mathrm{N}$ between the Norwegian coast and $5^{\circ} \mathrm{W}$, while in July/August it was observed northwards to $74^{\circ} \mathrm{N}$ and westwards to $7^{\circ} \mathrm{W}$. The recordings were mostly of very scattered nature, but some higher concentrations were, however, in both periods found between $62^{\circ}$ and $68^{\circ} \mathrm{N}$ from the Norwegian coast to $1^{\circ} \mathrm{E}$.

Norway, with the R.V."Johan Hjort" from 7/7-2/8 assessed the biomass to 1.8 mill. tonnes (Monstad et al., 1995b), while Russia, with R.V."Prof. Marty" from 6/612/7 assessed it to 2.5 mill. tonnes (Krysov, 1995).

The weighted total length and age composition of blue whiting obtained by the Norwegian, Russian and Faroese vessels are shown on Fig.6.4.8. Totally the 1994 year class dominated and contributed with $45 \%$ in numbers to the stock recorded.

### 6.4.1.3 Discussion

In the text table below the total biomass estimates (in million tonnes) in the spawning area since 1983 are given. The corresponding spawning stock size are given in brackets.

| Year | Russia | Norway | Faroes | Russia+ <br> Norway <br> combined |
| :---: | :---: | :---: | :---: | :---: |
| 1983 | $3.6(3.6)$ | $4.7(4.4)$ | - | - |
| 1984 | $3.4(2.7)$ | $2.8(2.1)$ | $2.4(2.2)$ | - |
| 1985 | $2.8(2.7)$ | - | $6.4(1.7)$ | - |
| 1986 | $6.4(5.6)$ | $2.6(2.0)$ | - | - |
| 1987 | $5.4(5.1)$ | $4.3(4.1)$ | - | - |
| 1988 | $3.7(3.1)$ | $7.1(6.8)$ | - | - |
| 1989 | $6.3(5.7)$ | $7.0(6.1)$ | - | - |
| 1990 | $5.4(5.1)$ | $6.3(5.7)$ | - | - |
| 1991 | $4.6(4.2)$ | $5.1(4.8)$ | - | $4.7(4.4)$ |
| 1992 | $3.6(3.3)$ | $4.3(4.2)$ | - | $4.6(4.3)^{*}$ |
| 1993 | $3.8(3.7)$ | $5.2(5.0)$ | - | $5.1(4.9)$ |
| 1994 | - | $4.1(4.1)$ | - | - |
| 1995 | $6.8(6.0)$ | $6.7(6.1)$ | - | $6.9(6.1)$ |

* with calibration factor: 1.38

The variability between survey estimates in the early years of the period listed above has been discussed in previous Blue Whiting Working Groups. As also mentioned in previous reports the main factors will be the difference in acoustic equipment, weather conditions during the surveys, size of the area surveyed and timing of the survey with respect to spawning progression.

From 1988/89 up to 1992 there has been a downward trend in the spawning stock estimates. In 1993 the stock
increased slightly due to the notable arrival to the spawning stock of the rich 1989 year class, but in 1994 it was again estimated to be lower, i.e. at the same level as in 1992. Generally the spawning stock acoustic estimates are considered under-estimates, due to the continuous long lasting pre- and post-spawning migration throughout the season. The 1994 estimate of 4.1 mill. tonnes, however, has to be considered as a more serious underestimate than average because of the extremely bad weather conditions during that year's survey. The weather conditions in 1995 were however, very favourable and hence the best possible coverage of the spawning stock within the survey period was obtained. The result of 6.1 mill. tonnes for the spawning stock can therefore be regarded a more precise estimate than the results for many years. The significant increase in the stock size in 1995 of approximately 1 and 2 mill. tonnes from 1993 and 1994 respectively, are partly due to differences in recording conditions, but also to the increased recruitment to the spawning stock.

The 1994 year class made up almost $30 \%$ of the stock recorded during spring 1995, which is the highest contribution recorded for one year olds during similar surveys in the area. This year class dominated in the Faroes-Shetland area. Among the adults, however, the 1992 year class was the most numerous one, but the 1989 year class, which has predominated in the spawning stock since 1991, still contributed significantly.

During the post-spawning and feeding period of 1995 the surveys in the Norwegian Sea covered altogether rather large areas of the main blue whiting stock's assumed feeding area. One should therefore expect to observe a greater part of the stock, but this was not experienced in earlier years nor in 1995. Except for a few localities, only weak recordings of blue whiting were obtained. That led to the conclusion that either a greater part of the stock remains outside the surveyed area, or that the fish behave in ways that make them difficult to observe, e.g. scattered over vast areas at great depths (Anon. 1985).

In summer 1994 the blue whiting stock in the Norwegian Sea was not assessed. In summer 1993 the biomass was estimated to be 1.7 mill t , but within the area from Skagerrak to $74^{\circ} \mathrm{N}$ in the Norwegian Sea. Within the same area, covered both these years, the difference was approximately 0.3 mill tonnes more in 1995 than estimated in 1993. The spawning stock to the west of the British Isles was, however, estimated to be 6.1 mill tonnes in March/April 1995, which demonstrates that only a part of the total stock was measured during its feeding season in the Norwegian Sea.

As observed during the joint survey west of the British Isles in 1995, one year old blue whiting dominated also in the feeding area, i.e. in the central and eastern part of
the Norwegian Sea, where it contributed with $45 \%$ in numbers.

The German ichthyoplankton investigations carried out during spring 1994 in the area west of the British Isles, indicated that the 1994 year class was a rich one (Hillgruber et al., 1995).

### 6.4.2 Bottom trawl surveys in the Southern area

Bottom-trawl surveys have been conducted off both the Galician (NW Spain) and Portuguese coast since 1980 and 1979 respectively, following a stratified random sampling design and covering depths down to 500 m . Since 1983, the area covered in the Spanish survey was extended to completely cover the Spanish waters in Division VIIIc. Stratified mean catch and standard error in Spanish bottom trawl surveys (in weight and in number by haul) since 1985 are shown in Table 6.4.1.

### 6.4.3 Catch per unit effort

Data on CPUE from the fisheries in the Northern area were submitted only by Norway. Those data, which were from the directed fishery in 1994, were broken down by vessel tonnage class, area, and month. The data were combined and added to the time series of overall aggregated CPUE values across areas in the Norwegian blue whiting directed fisheries, and presented in Fig.6.4.9. There was a decline from $33 \mathrm{t} / \mathrm{h}$ in 1983 to 10 $\mathrm{t} / \mathrm{h}$ in 1991, then an increase to approximately the same level of 25,28 and $27 \mathrm{t} / \mathrm{h}$ for 1992, 1993 and 1994 respectively.

Data on CPUE of 1994 from two fleets were submitted by Spain (Galician single and pair trawl), and shown in Fig. 6.4.10. While the CPUE varied throughout the 1980s for both fleets, it has been more stable in the 1990s. From 1993 to 1994, however, the single trawlers' CPUE was reduced slightly and the pair trawlers' increased slightly.

### 6.4.4 Virtual Population Analysis (VPA)

The blue whiting in the North Atlantic is treated as one combined stock in the present analysis.

### 6.4.4.1 Tuning the VPA to survey results

Big discrepancies are observed between SSB estimates from acoustic and VPA based on XSA, not only in the level, but also in the trend (Fig.6.4.11a). In the last few years, when the surveys are supposed to be more accurate, and the Norwegian and the Russian surveys are more in agreement, there are still conflicting trends between the surveys and the SSB from the VPA. This problem was analysed and it was found that when plotting the spawning stock in numbers obtained in the surveys and in the VPA, the trends are less conflicting (Fig.6.4.11b). The only explanation to the conflicting
trends in the spawning stock estimates in weight and in number must be found in the mean weights at age used for the survey and in the VPA. As a consequence, the weight at age matrices for 1991 onwards will be revised. The remaining difference could be explained by the use of a different maturity ogive each year in the acoustics, and a constant in VPA up to 1992.

Altogether 5 tuning series were used by the Working Group in 1994 to tune the VPA. Two series from the spawning area west of the British isles (Norwegian acoustic and Russian acoustic surveys, previously used in the tuning of the Northern stock), two from Spain (CPUE from pairtrawlers and bottom trawl survey), one series from the acoustic surveys in the Norwegian Sea during the feeding season in the summer. Especially the inclusion of the acoustic surveys in the Norwegian Sea with estimates of recruits (age range $0-11$ ) from 1980 to 1993, seem to improve the tuning, especially for the younger ages. In addition, a new tuning series was provided by Portugal, obtained in the bottom trawl surveys, and was also used in the assessment (Table 6.4.2).

Earlier tests (Anon. 1994b) had indicated that variations on XSA options did not improve the reliability of the results. For this reason only a standard XSA run is presented in Tables 6.4.2-6.

It is seen in this tables that standard errors of the catchabilities are very high and t-tests of the slope of regressions are in many cases quite high. In light of this and the various problems described in earlier sections, it was concluded that available input data is not sufficient to support a full-fledged XSA-based stock assessment.

### 6.4.4.2 Alternative Tuning Method

An alternative method (YC method) to estimate a year class based on survey results and catches is described in section 3.5.1.

The 1989 year class is used in this analysis, because it is strong and it might give a better approximation to the survey results, and furthermore it is still in the fishery. Two other choices, the strong 1982 and 1983 year classes, might be used, but as they are practically no longer present in the fishery, they add very little to the estimate of the present stock in 1995 in this method. Therefore they were not used. The age ranges used for the 1989 year class were from age 3-6, i.e. the years 1992-95.

The Norwegian and the Russian acoustic surveys in the spawning area in the spring, and a Norwegian acoustic survey in the Norwegian Sea in the summer were used in this method. The large errors and variances associated with the Norwegian Sea survey from the method lead to the exclusion of this survey in the analysis.

Results from the estimation of the terminal number in the stock of the 1989 year class in 1995 are shown in Table 6.4 .7 in the column labelled "YC estimate". The acoustic estimates from the Norwegian and the Russian surveys are also shown, and for comparison the XSA estimates of the 1989 year class (unweighted and weighted) are also given. The unweighted XSA is just an ordinary XSA (Section 6.4.4.1) where the tuning series (fleets) are weighted due to the inverse variance in the data, while in the weighted XSA the fleets are manually weighted according to the catch proportions in the area where the surveys have been conducted. The weights given to the fleets were as follows:

| Norwegian spawning area acoustics: | 0.40 |
| :---: | :---: |
| Russian spawning area acoustics: | 0.40 |
| CPUE Spanish pair trawlers: | 0.04 |
| Spanish bottom trawl survey: | 0.03 |
| Norwegian Sea acoustic survey: | 0.10 |
| Portuguese bottom trawl survey: | 0.03 |
| Total: | 1.00 |

This downweighting of the Spanish, Portuguese and the Norwegian Sea acoustic surveys do not reflect the Working Group's confidence in any particular survey.

It should be noted that the estimated catchability (availability) factor $q_{s}$ for the Russian survey was nearly 2 and nearly 3.5 for the Norwegian survey as compared to the numbers back-calculated from the catches (Table 6.4.7), indicating that the surveys and especially the Norwegian survey give consistently higher stock estimates compared to VPA as noted earlier.

In Figure 6.4.12 the "YC estimate" is shown as a solid line for the years 1992-1995, and the other year class estimates are also indicated by points. There appears to be relatively good fit of the acoustic surveys to the YC estimate (line) for all but the first year, where the Norwegian estimate seems to be too low. It is worth noting the very good agreement between the YC estimate and the ordinary unweighted XSA, while the weighted XSA estimate is consistently higher by approximately 2 billion fish but with exactly the same trend. The good agreement in trend between the YC method and the XSA methods are not unexpected, since both methods are based on the same principles of minimising the SS between the survey estimates and the VPA stock estimates of the different year classes simultaneously.

### 6.4.4.3 Conclusion

The Working Group concluded that the available data are not of sufficient quality to support an analytical stock assessment at this time. It was noted, however, that several data problems have been explicitly identified and some of these would work to the effect of reconciling the data series.

### 6.5 Spatial, temporal and zonal distribution

The available knowledge from various sources on the distribution and the main fishing areas of blue whiting in the northern area were summarized and presented in the previous Working Group Reports (Anon., 1985, 1991b and 1995c).

During 1995 rather interesting new information were obtained about distribution of eggs and larvae west of the British Isles. Icthyoplankton observations were made by R.V. "Johan Hjort" (Monstad et al., 1995). Blue whiting eggs were numerous in the sampling area except to the north of Scotland where spawning had not yet commenced (Fig. 6.5.1). Larvae of blue whiting were taken mostly at the same stations as the eggs, but with relatively higher concentrations around Porcupine, indicating that spawning had taken place for a longer period of time in that area, than to the west of Scotland (Fig.6.5.2).

Under-sampling of larvae was probably of less significance than for the eggs. The blue whiting larvae ranged from 2.0-7.5 mm in length with a mean of 3.75 mm . Larvae larger than 4.5 mm predominated over and to the south of the Porcupine Bank, indicating that spawning had been in progress for at least a few weeks in those areas.

During spring, most of the blue whiting recordings were made within the EU-zone, i.e. in British and Irish waters. Most of the blue whiting concentrations in the feeding season in the Norwegian Sea were observed in the Norwegian and The Faroese zones (Fig. 6.4.7), however, this might not be the true picture of the total stock situation. The WG, concludes every year that the percentage distribution of concentrations obtained within various zones strongly depends upon the geographical size and location of the survey area.

Total catch of blue whiting in 1978-1994 divided into areas within and beyond national fisheries jurisdiction of NEAFC area are presented in Table 6.5.1, as provided by the Working Group members. The catches of nations not attending the WG meeting have been subjectively allocated to the probable appropriate zones. This is a complicated and hazardous undertaking, as the data available to the WG are insufficient for the task. Consequently, the WG has only limited confidence in the final table.

### 6.6 Biological uncertainties

In the Blue Whiting Assessment Working Group Report of 1994 (Anon., 1994b) three main sources were identified as problems for the assessment of the blue whiting stock; age determination, stock identity and acoustic estimates.

Age determination: Several otolith exchanges and workshops have been carried out since 1979 to solve discrepancies between countries. The workshop in November 1992, however showed that there is no difference in the structure of otoliths from the Southern and the Northern areas (Anon. 1993b). Further exchange programmes and workshops were recommended, to identify the causes of difference age readings between various countries on a regular basis, and especially between Norway and Russia.

In October/November 1994 another otolith reading workshop was held in Bergen, between otolith readers from Russia and Norway, with the main purpose to compare their different interpretation and traditions of age reading. The aim was also to start a process of gradually arriving at a common method for future age reading of blue whiting otoliths (Seliverstova et al.,1994).

There were disagreements both between the readers from the two different institutes (12-22 \%) and between individual readers from each country (12-13 \%). The greatest disagreement in the age evaluation occurred from otoliths of age 3-5 years old and older, i.e. when false rings were present. Great difficulty also occurred when reading otoliths taken around mid-summer, due to the determination of the last ring.

## Stock identity

The study of genetic population structure has so far not given indications on genetic substructure among blue whiting from west of the British Isles to Gibraltar (Mork and Giæver, 1993). Since 1994 the blue whiting in the North-East Atlantic therefore has been assessed as one stock. However, the blue whiting population question is far from solved, and further genetic studies to clarify the picture continue.

## Acoustic estimates

The discrepancies between different acoustic estimates are caused by several factors. Among these the influence of the biological conditions and fish behaviour on target strength values are major, as is the effect of timing and direction of stock migration during the survey area, as well as the hydrological situation, trawl sampling differences and, as mentioned above, the age reading errors. The extremely large area to be covered has also to be considered as an important source of error.

## 7. ECOLOGICAL CONSIDERATIONS

In the terms of reference item (e) the Working Group is asked to consider how biological interactions can be incorporated into the assessments of capelin, herring and cod stocks. In this chapter we provide relevant new information on this subject.

### 7.1 Barents Sea/Norwegian Sea

### 7.1.1 Oceanography

The recruitment of herring and cod is positively influenced by high temperatures (Sætersdal and Loeng, 1987). The temperature in the Barents Sea in 1995 is above the long-term average, according to several Norwegian and Russian surveys. However, the temperature itself is only a proxy for several important underlying parameters. Such parameters can be the degree of drift into optimal nursery areas, turbulence and feeding conditions (Sundby 1995). More research is needed to clarify the full impact of these parameters on recruitment variability.

### 7.1.2 Plankton

The plankton abundance in the Barents Sea in 1995 is described in a working document by Hassel and Johannesen. Figure 7.1 gives the plankton abundance by area and year for the period 1986-1995. From 1991 to 1994 the plankton abundance increased in all areas. In the north-eastern part of the Barents Sea, the abundance increased from 1994 to 1995, while a reduction was observed in the remaining areas.

### 7.1.3 Predation by cod

Data on the predation by cod on various prey species, including capelin and herring, are compiled and discussed in a working document by Bogstad and Mehl. The annual consumption of various prey stocks by cod in the period 1984-1994 is given in the text table below.

Consumption by cod of various prey species 1984-1994, in thousand tonnes.

| Year | Krill | Amphipo <br> ds | Shrimp | Capelin Herring | Cod | Haddoc <br> k | Polar <br> cod | Redfish | Others | Total |  |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 1984 | 120 | 28 | 442 | 735 | 77 | 23 | 53 | 15 | 369 | 520 | 2382 |
| 1985 | 49 | 156 | 155 | 1630 | 187 | 32 | 47 | 3 | 226 | 1138 | 3623 |
| 1986 | 111 | 1232 | 140 | 833 | 136 | 82 | 109 | 140 | 315 | 663 | 3761 |
| 1987 | 71 | 1107 | 191 | 221 | 32 | 24 | 4 | 202 | 313 | 703 | 2868 |
| 1988 | 334 | 1299 | 137 | 325 | 8 | 9 | 3 | 91 | 235 | 476 | 2917 |
| 1989 | 274 | 895 | 141 | 641 | 3 | 9 | 11 | 37 | 250 | 922 | 3183 |
| 1990 | 85 | 155 | 214 | 1788 | 8 | 21 | 18 | 7 | 277 | 2087 | 4660 |
| 1991 | 93 | 80 | 308 | 3250 | 9 | 31 | 23 | 13 | 360 | 1853 | 5920 |
| 1992 | 285 | 155 | 429 | 3107 | 389 | 127 | 165 | 138 | 242 | 1718 | 6755 |
| 1993 | 499 | 280 | 365 | 3690 | 198 | 361 | 90 | 341 | 122 | 1250 | 7196 |
| 1994 | 819 | 809 | 629 | 1094 | 175 | 311 | 51 | 803 | 118 | 1007 | 5816 |

The table shows that the cod's consumption of capelin decreased by 2.6 million tonnes from 1993 to 1994, showing the same trend as the acoustic abundance estimates in the autumn 1993 and 1994 (796 and 199 thousand tonnes, respectively). The same phenomenon was also observed in 1986, when the capelin stock also was low. We also see that the annual consumption of shrimp by cod increased by about $50 \%$ from the 19921993 level to 1994. The consumption of cod by cod (cannibalism) increased dramatically from 1992 to 1993-1994. The fraction of cod in the diet is, however, not higher than the few stomach content data from the 1950s (Bogstad et al. 1994) indicate. The amount of redfish consumed dropped from a previously stable level of about 250-350,000 tonnes in 1984-1992 to about 120,000 tonnes in 1994. The amount of amphipods consumed increased considerably in 1994, but has not yet reached the level observed during the previous capelin stock collapse in 1986-1989, when the cod switched from capelin to amphipods as prey. The amount of herring consumed is not very high, and was reduced by about $50 \%$ from 1992 to 1993-1994. The rapid increase in the consumption of polar cod in 19921994 should also be noted.

### 7.1.4 Marine mammals

Cod is the most important predator on fish stocks in the Barents Sea, but predation by marine mammals (especially harp seal and minke whale) may also have a significant impact on the fish stocks in the Barents Sea. The food consumption by harp seals and minke whales in the Barents Sea has been estimated by Nordøy et al. (1995a,b). They calculated that minke whales consumed 450,000 tonnes of herring and 355,000 tonnes of capelin in the Barents Sea and Norwegian Sea in 1992, while harp seals consumed about 200,000 tonnes of herring and 250,000 tonnes of capelin in the Barents Sea in 1993. These estimates are based on a small number of stomach samples, and are more uncertain than the estimates of the consumption by cod. Also, the knowledge about year-to-year variability in the consumption by marine mammals is scarce.

The impact of harp seal and minke whale on the cod, capelin and herring stocks was studied by Bogstad et al. (1995) using the Multspec model. Simulations were carried out over a 20-year period for various assumptions about the diet composition for minke whales.

### 7.1.5 Consumption of herring

It is very important to relate the herring mortality rates calculated by Barros (1995) to mortality rates calculated from stomach content data and gastric evacuation rate models. It should be investigated whether the amount of herring consumed by cod, minke whale and harp seal according to the consumption calculations is compatible with the biomass removed by natural mortality, and reasons for discrepancy should be investigated.

### 7.2 Icelandic waters

An earlier multispecies model described in Stefánsson et al. (1994) included cod, capelin and shrimp in an aggregated model. Two major extensions to this may be important, i.e. including marine mammals in light of the indications in Sigurjónsson and Víkingsson (1995) and differentiating areas and seasons as indicated in Anon. (1994a). The past few years have seen the development and adoption of a formal harvesting strategy for cod in addition to the de facto $\mathrm{F}_{0.1}$ harvesting strategy for herring, the 400 thousand tonnes target SSB strategy for capelin and a de facto biomassbased strategy for shrimp. This development makes modelling easier than earlier since there is no need to model a large variety of harvesting strategies for all species but rather to focus on the development of biological models.

The above models have been extended by including marine mammals in an aggregated model as described in Stefánsson et al. (1995). The analysis indicates that the marine mammals are potentially quite important factors in the development of the cod and capelin stocks and catches. Furthermore, the uncertainty in predictions
is increased due to the uncertainty in consumption by marine mammals and cod.

The models are currently being extended in the direction of including spatial and seasonal effects as described in Pálsson and Stefánsson (1995). The preliminary results seem to indicate that it is feasible to combine a wide variety of data sources to estimate parameters describing migration, consumption and inflicted natural mortality, growth and harvest.

### 7.3 Multispecies modelling at other meetings

This year, the Multispecies Assessment Working Group (Anon., 1996) reviewed three multispecies models for boreal ecosystems:

1) The Norwegian multispecies model Multspec, which include the species cod, capelin, herring, minke whale and harp seal.
2) The Icelandic multispecies model Bormicon, containing the species cod and capelin.
3) The Russian MSVPA model for the Barents Sea, containing the species cod, herring, capelin and shrimp.

The meeting focused on cod-capelin interactions. All models were able to reproduce the main features observed in the ecosystems (fluctuations in stock size and in individual growth of cod).

### 7.4 Conclusions

The Working Group noted that the multispecies models may potentially resolve some important questions regarding e.g. natural mortality of herring and capelin. It is recommended that the work described above be continued and advances reported to the next meeting of the group.

In particular it is of considerable interest to estimate the consumption of herring by e.g. killer whales in Icelandic waters in relation to natural mortality of herring. It is recommended that attempts be made to evaluate the possible effects of predation on the natural mortality of herring and advances reported to the next meeting of the group.

The Working Group also noted that it is important to continue the development of multispecies models for boreal systems in order to obtain a better understanding of both fish-fish and marine mammals-fish interactions that are of relevance to the stocks assessed by this Working Group.

## 8. RECOMMENDATIONS

1) The Working Group considers it very important that the blue whiting stock is monitored each year. It therefore recommends the continuation of the joint Norwegian-Russian acoustic survey aimed at assessing the stock biomass in the spawning area during spring, and also, the continuation of surveys in the Norwegian Sea in the feeding season on a national basis.
2) Based on observations made in 1994 and 1995, the WG believes that the 1994 and 1995 year classes of Blue Whiting are strong. As a result, the industrial mixed fishery will tend to be aimed at the high abundance of this resource, and hence a rather high number of small individuals will be caught. To avoid serious biases in the data set for the stock analysis, it is strongly recommended that the countries participating in this fishery frequently sample the catches and bring to the WG biological data as well as the catch data.
3) Annual workshops for blue whiting otolith reading should continue. This is for comparison of the various countries different methods and further discussion to gradually arrive at a common method for future age reading. The WG therefore recommends that a Workshop for reading of blue whiting otoliths should be held in Vigo, Spain in February 1996, with Manuel Meixide as coordinator.

## 9. SAMPLING SUMMARY

### 9.1 Icelandic summer spawning herring

| Investigation | No of <br> samples | Length <br> measurements | Aged <br> individuals |
| :--- | :---: | :---: | :---: |
| Fishery (1994-1995) | 26 | 2558 | 2558 |

### 9.2 Norwegian spring spawning herring

| Investigation | No of <br> samples | Length <br> measurements | Aged <br> individuals |
| :--- | :---: | :---: | :---: |
| Norwegian fishery <br> (1994) | 21 | 11700 | 2045 |
| Mean weight in stock <br> 1 Jan 1995 | 47 |  | 4195 |
| Acoustic wintering <br> area 1994 -95 | 22 | 2185 | 1980 |
| Acoustic spawning <br> area 1995 | 2 | 2400 | 200 |

Catches adequately sampled. Very difficult to obtain satisfactory knowledge of age distribution of wintering and spawning population due to present extreme dynamic recruitment situation.

### 9.3 Barents Sea capelin

| Investigation | No of <br> samples | Length <br> measurements | Aged <br> individuals |
| :--- | :---: | :---: | :---: |
| Acoustic survey 1995 | 95 | 4619 | 2710 |

No fishing have been taking place, and therefore no samples from catches. Adequate number of samples in acoustic survey.

### 9.4 Capelin in the Iceland-East Greenland-Jan Mayen area

Adequate sampling.

### 9.5 Blue Whiting

| Investigation | No of <br> samples | Length <br> measurements | Aged <br> individuals |
| :--- | :---: | :---: | :---: |
| Fishery | 96 | 4617 | 780 |
| Survey British Isles | 11 | 749 | 669 |
| Survey Norwegian <br> Sea | 39 | 1146 | 682 |
| Southern fishery | 368 | 32348 | 1209 |
| Southern surveys | 126 | not available | 1208 |

Table 2.4.1 Stock abundance and catches by age groups (millions) and fishing mortality rate for the Icelandic summer spawners. $\mathrm{F}^{1}$ is the F calculated from the acoustic surveys. Estimates for the 1-4 ringers in 1994. $\mathrm{F}_{\mathrm{p} 94}$ is the exploitation pattern in 1995 (used in the prognosis) and $\mathrm{F}_{\mathrm{p} \text { av }}$ is the average exploitation pattern for 1986-1990.

$\mathrm{A}=$ catches of adult herring in winter
$B=$ mixed herring fishery in autumn
$C=$ by-catches of 0 - and 1 -group herring in the sprat fishery
$\mathrm{D}=$ USSR-Norway by-catch in the capelin fishery (2-group)

Includes also by-catches of adult herring in other fisheries
${ }^{2}$ In 1972, there was also a directed herring 0-group fishery
3 Includes mortality caused by fishing operations in addition to unreported catches
4 Includes 26,000 t of immature herring (1983 year-class) fished by USSR in the Barents Sea

* Invalid due to ice conditions.
** Calculated from total abundance recorded in autumn/winter 1994/95, catches and natural mortality.

Table 5.3.2 Mean weight (g) in autumn of mature capelin of the 1978-1992 year classes

| Year class | Age 2 | Age 3 |
| :--- | :--- | ---: |
| 1978 |  | 24.0 |
| 1979 | 19.2 | 24.1 |
| 1980 | 16.5 | 22.5 |
| 1981 | 16.1 | 25.7 |
| 1982 | 15.8 | 23.8 |
| 1983 | 15.5 | 24.1 |
| 1984 | 18.1 | 25.8 |
| 1985 | 17.9 | 23.4 |
| 1986 | 15.5 | 25.5 |
| 1987 | 18.0 | 25.5 |
| 1988 | 18.1 | 25.4 |
| 1989 | 16.3 | 22.6 |
| 1990 | 16.5 | 23.3 |
| 1991 | 16.2 | 23.6 |
| 1992 | 16.0 |  |
|  |  |  |
| Average | 16.8 | 24.3 |

Table 5.3.3 Predictions of fishable stock abundance and TACs for the 1982/83-1995/96 seasons. The last column gives contemporary advice on TACs for comparison.

Age 2 and age $3=$ Numbers in age groups at the beginning of season.
Fish.st. = calculated weight of maturing capelin in thous. tonnes (ref. 1 August).
TAC calc $=$ predicted TAC and TAC adv $=$ advised TAC.
Mean weight of maturing 2 and 3 group capelin in October/November 1981-1991 is 17.0 and 24.3 g respectively. Numbers are billions; weights in thous. tonnes.

| Season | Year <br> classes | Age 2 | Age 3 | Fish.st. | TAC calc | TAC adv |
| :--- | ---: | :--- | ---: | ---: | ---: | ---: |
| $1982 / 83$ | $80-79$ | 26.6 | 4.1 | 549 | 17 | 0 |
| $1983 / 84$ | $81-80$ | 63.0 | 0.0 | 1065 | 465 | 573 |
| $1984 / 85$ | $82-81$ | 43.4 | 26.3 | 1373 | 733 | 897 |
| $1985 / 86$ | $83-82$ | 67.8 | 20.2 | 1637 | 963 | 1311 |
| $1986 / 87$ | $84-83$ | 34.9 | 55.0 | 1926 | 1215 | 1333 |
| $1987 / 88$ | $85-84$ | 55.3 | 13.7 | 1268 | 642 | 1115 |
| $1988 / 89$ | $86-85$ | 64.8 | 29.0 | 1800 | 1105 | 1036 |
| $1989 / 90$ | $87-86$ | 43.2 | 25.5 | 1350 | 713 | 550 |
| $1990 / 91$ | $88-87$ | 31.1 | 8.2 | 724 | 170 | 265 |
| $1991 / 92$ | $89-88$ | 39.4 | 3.7 | 755 | 197 | 740 |

Table 6.4.2 (cont.)

Table 6.4.3 Blue whiting combined. XSA diagnostics.

Time series weights :
Tapered time weighting applied
Power = 3 over 20 years

Catchabillty analysis :
Catchability dependent on stock size for ages < 2
Regression type $=C$
Minimum of 5 points used for regression
Survivor estimates shrunk to the population mean for ages < 2

Catchability independent of age for ages $>=7$

Terminal population estimation :
Survivor estimates shrunk towards the mean $E$
of the final 5 years or the 5 oldest ages.
S.E. of the mean to which the estimates are shrunk $=.500$

Minimum standard error for population
estimates derived from each fleet $=\quad .300$
Prior weighting not applied

Tuning had not converged after 30 iterations
