## REPORT OF THE

# WORKING GROUP ON NORTH ATLANTIC SALMON 

## ICES Headquarters

7-16 April 1997

This report is not to be quoted without prior consultation with the General Secretary. The document is a report of an expert group under the auspices of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council.

2.8 Discards ..... 9
3 FISHERIES AND STOCKS IN THE NORTH EAST ATLANTIC COMMISSION AREA ..... 11
3.1 Fishing at Faroes in 1995/1996 and 1996/1997 ..... 11
3.2 The Research Programme at Faroes ..... 11
3.2.1 Smolt age and sea age distribution in the Faroese fishery ..... 11
3.2.2 Origin of wild and farmed salmon tagged north of the Faroes ..... 12
3.2.3 Incidence of escaped farmed salmon in the Faroese fishery and estimates of catches of wild salmon ..... 14
3.2.4 The food of Atlantic salmon north of the Faroes. ..... 15
3.3 Homewater Fisheries in the NEAC Area in 1996 ..... 16
3.3.1 National reports. ..... 16
3.3.2 Gear ..... 20
3.3.3 Effort ..... 20
3.3.4 Catches ..... 20
3.3.5 Catch per unit effort (CPUE) ..... 20
3.3.6 Age composition of catches ..... 21
3.3.7 Farmed and ranched salmon in catches ..... 21
3.3.8 National origin of catches ..... 21
3.3.9 Exploitation rates in homewater fisheries ..... 21
3.3.10 Summary of homewater fisheries in the NEAC area. ..... 22
3.4 Status of Stocks in the NEAC Area ..... 22
3.4.1 Attainment of spawner reference levels ..... 22
3.4.2 Measures of juvenile abundance ..... 22
3.4.3 Measures of spawning escapement. ..... 23
3.4.4 Survival indices ..... 23
3.4.5 Summary of status of stocks in the NEAC area ..... 23
3.5 Evaluation of the Effects of the Suspension of Commercial Fishing Activity at Faroes ..... 23
3.6 Development of Age Specific Spawning Targets ..... 24
3.7 Catch Options with an Assessment of Risk ..... 26
3.7.1 Introduction ..... 26
3.7.2 Pre-fishery abundance estimates for the NEAC area ..... 26
3.7.3 Levels of exploitation by Faroes fishery ..... 28
3.7.4 Development of catch advice ..... 28
3.8 Catches of Post-Smolts in the Norwegian Sea ..... 28
3.8.1 Results of post-smolt surveys in 1991-96 ..... 28
3.8.2 Potential of by-catch of post-smolts in pelagic fisheries ..... 29
3.8.3 Potential of by-catch in herring and redfish fisheries ..... 30
3.9 Data Deficiencies and Research Needs in the NEAC Area ..... 30
4 FISHERIES AND STOCKS IN THE NORTH AMERICAN COMMISSION AREA ..... 30
4.1 Description of Fisheries ..... 30
4.1.1 Gear and effort ..... 30
4.1.2 Catch and catch per unit effort (CPUE) ..... 31
4.1.3 Origin and composition of catches ..... 33
4.1.4 Exploitation rates in Canadian and U.S.A. fisheries ..... 33
4.2 Status of Stocks in the North American Commission Area ..... 34
4.2.1 Measures of abundance in monitored rivers ..... 34
4.2.2 Estimates of total abundance by geographic area ..... 35
4.2.3 Pre-fishery abundance estimates of non-maturing and maturing 1SW North American salmon ..... 37
4.2.4 Spawning escapement and egg deposition ..... 39
4.2.5 Survival indices ..... 42
4.2.6 Summary of status of stocks in the North American Commission Area ..... 43
4.3 Effects on US and Canadian Stocks and Fisheries of Quota Management and Closure after 1991 in Canadian Commercial Salmon Fisheries ..... 44
4.4 Spawning Requirements ..... 46
4.5 Catch Options for the North American Commission Area ..... 46
4.6 Multi-Year Projections of Salmon Abundance. ..... 47
4.7 Data Deficiencies and Research Needs in the North American Commission Area ..... 49
5 FISHERIES AND STOCKS IN THE WEST GREENLAND COMMISSION AREA ..... 50
5.1 Description of Fishery at West Greenland ..... 50
5.1.1 Catch and effort in 1996 ..... 50
5.1.2 Origin of catches at West Greenland ..... 50
5.1.3 Biological characteristics of the catches ..... 51
5.1.4 Status of the stocks in the West Greenland Commission area ..... 51
5.2 Catch Options with an Assessment of Risks Relative to the Achieving Spawning Requirements ..... 52
5.2.1 Overview ..... 52
5.2.2 Forecast model for pre-fishery abundance of North American 2SW salmon ..... 54
5.2.3 Development of catch options for 1997 ..... 56
5.2.4 Risk assessment of catch options ..... 58
5.3 Data Deficiencies and Research Needed for the West Greenland Commission Area ..... 60
6 ESCAPES FROM FISH CULTURE OPERATIONS ..... 60
6.1 Background ..... 60
6.2 National Reports ..... 61
6.3 Population Level Effects ..... 64
7 PROGRESS ON THE IMPLEMENTATION OF SPAWNING TARGETS ..... 65
8 RECOMMENDATIONS ..... 66
8.1 Fisheries ..... 66
8.2 Meetings ..... 66
8.3 Data Deficiencies and Research Needs ..... 66

Appendix 8: Preliminary list of rivers and contact individuals collecting data and/or developing models and methods of relevance to the development of reference points for Atlantic salmon ..... 237

### 1.1 Main Tasks

At its 1996 Statutory Meeting, ICES resolved (C. Res. 1996/2:14:13) that the Working Group on North Atlantic Salmon (Chairman: Dr T.L. Marshall, Canada) will meet at ICES Headquarters from 7-16 April, 1997 to consider questions which include those posed to ICES by the North Atlantic Salmon Conservation Organisation (NASCO) and by the Oslo and Paris Commissions (OSPAR). ICES also resolved that a half day joint session will be held with the Baltic Salmon and Trout Assessment Working Group (Co-Chairmen: T.L. Marshall and L. Karlsson) on 12 April 1997 to consider questions posed by ICES. The terms of reference and sections of the report in which the answers are provided, follow.

| a) With respect to Atlantic salmon in the North Atlantic area: | Section |
| :---: | :---: |
| i. provide an overview of salmon catches, including unreported catches, and production of farmed and ranched salmon in 1996; | $\begin{gathered} 2.1 \\ \& 2.2 \end{gathered}$ |
| ii. report on significant developments which might assist NASCO with the management of salmon stocks; | 2.3 |
| iii. describe the causes of long-term changes in sea-age composition of salmon stocks; | 2.4 |
| iv. describe the causes of changes in abundance of salmon with special reference to changes in natural mortality and ocean climate; | 2.5 |
| v. provide a compilation of microtag, finclip and external tag releases by ICES member countries in 1996; | 2.6 |
| vi. propose a definition of safe biological limits using target reference points based, where appropriate, on biomass, fishing mortality, maturity, growth, age structure, exploitation pattern, geographic distribution and other relevant parameters; based on the above parameters, propose limit reference points to be avoided with a high probability; | 2.7 |
| vii. provide information on quantities of discards by gear type and area for the stocks of fish and fisheries considered by this group [OSPAR 1997/5.3] and report to WGECO. | 2.8 |
| b) With respect to Atlantic salmon in the North-East Atlantic Commission area: |  |
| i. describe the events of the 1996 fisheries and the status of the stocks; | 3.1-3.4 |
| ii. update the evaluation of the effects on stocks and homewater fisheries of the suspension of commercial fishing activity at Faroes since 1991; | 3.5 |
| iii. develop age specific spawning targets; | 3.6 |
| vi. provide catch options with an assessment of risks relative to the objective of achieving spawning targets; | 3.7 |
| v. evaluate the potential by-catch of post-smolts in pelagic fisheries; | 3.8 |
| vi. identify relevant data deficiencies and research requirements. | 3.9 |
|  |  |
| c) With respect to Atlantic salmon in the North American Commission area: |  |
| i. describe the events of the 1996 fisheries and the status of the stocks; | 4.1, 4.2 |
| ii. update the evaluation of the effects on US and Canadian stocks and fisheries of quota management and closures implemented after 1991 in the Canadian commercial salmon fisheries; | 4.3 |
| iii. update age-specific spawning targets based on new information as available; | 4.4 |
| iv. provide catch options with an assessment of risks relative to the objective of achieving spawning targets; | 4.5 |
| v. provide multi-year projections of salmon abundance; | 4.6 |
| vi. identify relevant data deficiencies and research requirements. | 4.7 |
|  |  |
| d) With respect to Atlantic salmon in the West Greenland Commission area: |  |
| i. describe the events of the 1996 fisheries and the status of the stocks; | 5.1 |
| ii. provide catch options with an assessment of risks relative to the objective of achieving spawning targets; | 5.2 |
| iii. identify relevant data deficiencies and research requirements. | 5.3 |

| e) provide information on the scale of escapes from fish culture operations and quantify the expected <br> effects at the population level [OSPAR 1997/4.1]. | 6 |
| :--- | :---: |
|  |  |
| A half-day joint session will be held with the Baltic Salmon and Trout Assessment Working Group <br> in Charlottenlund (revised ICES) on 14 April 1997: |  |
| a) to discuss current progress with the implementation of spawning targets with reference to the <br> conclusions of the Workshop on Spawning Targets held in France in June 1996; | 7 <br> b) define the term "wild salmon". |

The minutes of the Joint WGNAS and WGBAST Session appear in Appendix 1.
The Working Group considered 36 Working Documents submitted by participants (Appendix 2); other references cited in the report are given in Appendix 3.

### 1.2 Participants

| Baum, E.T. | U.S.A. |
| :--- | :--- |
| Caron, F. | Canada |
| Chaput, G. | Canada |
| Friedland, K. | U.S.A. |
| Gudbergsson, G. | Iceland |
| Hansen, L.P. | Norway |
| Holm, M. | Norway |
| Holst, J.C. | Norway |
| Insulander, C. | Sweden |
| Jacobsen, J.A. | Faroes |
| Kanneworff, P. | Greenland |
| Länsman, M. | Finland |
| MacLean, J. | U.K. (Scotland) |
| Marshall, L. (Chairman) | Canada |
| Meerburg, D.J. | Canada |
| Ó Maoiléidigh, N. | Ireland |
| Potter, E.C.E. | U.K. (England \& Wales) |
| Reddin, D.G. | Canada |
| Roche, P. | France |
| Samoilova, E. | Russia |
| Stolte, L.W. | U.S.A. |
| Whoriskey, F. | Canada |
| Youngson, A. | U.K. (Scotland) |
| Zubchenko, A. | Russia |

A full address list for the participants is provided in Appendix 4.

## 2 ATLANTIC SALMON IN THE NORTH ATLANTIC AREA

### 2.1 Catches of North Atlantic Salmon

### 2.1.1 Nominal catches of salmon

Total nominal catches of salmon reported by country in all fisheries for 1960-1996 are given in Table 2.1.1.1, and nominal catches in homewater fisheries, divided into size or age categories where such data are available, are given in Table 2.1.1.2. Catch statistics in the North Atlantic also include fish farm escapees and, in some northeast Atlantic countries, ranched fish (see Section 3).

In contrast to previous years' reports, the nominal catch of salmon reported for Iceland has been altered (from 1960) to exclude ranched salmon. The rationale for this unilateral decision was that as the ranched component of the previously reported nominal catch was large ( $66 \%$ in 1995) trends in the catch of wild salmon were masked. Although there are several definitions of "ranching," Iceland takes the view that it is defined as "... [large] scale
releases of salmon smolts by private companies with the intent of harvesting all the salmon, upon their return, [at the release site.] ..." (Isaksson, 1994). On this basis, the Working Group considered that while it was appropriate to remove the ranched component from the Icelandic catch it was also appropriate to leave in the ranched component in other countries catches where ranching was on a smaller scale, experimental or where harvesting was not conducted solely at the release site.

Figure 2.1.1.1 shows the nominal catch data grouped by the following areas: 'Scandinavia and Russia' (including Denmark, Finland, Iceland, Norway, Russia and Sweden); 'Southern Europe' (including France, Ireland, U.K. (England and Wales), U.K. (Northern Ireland) and U.K. (Scotland)); and 'North America' (including Canada, U.S.A. and St Pierre et Miquelon); and 'Greenland and Faroes'.

The updated total nominal catch for 1995 of $3,339 \mathrm{t}$ is 289 t less than the total for 1994 of $3,628 \mathrm{t}$. Catches in most countries remain below the averages of the previous 5 and 10 year averages. Figures for 1996 ( $2,860 \mathrm{t}$ ) are provisional and incomplete, but the final total is unlikely to exceed the 1995 value.

The lack of information on fishing effort presents major difficulties in interpreting catch data for any one year and also in comparing catches in different years. However, it is clear that management plans in most countries have decreased fishing effort and this accounts for some of the decline in catches in recent years.

### 2.1.2 Catches in numbers by sea-age and weight

Reported nominal catches for several countries by season and weight are summarised in Table 2.1.2.1. As in Tables 2.1.1.1 and 2.1.1.2, catches in some countries include both wild and reared salmon and fish farm escapees. Figures for 1996 are provisional and incomplete. Different countries use different methods to partition their catches by sea-age class. These methods are described in the footnotes to Table 2.1.2.1. The composition of catches in different areas is discussed in more detail in Sections 3, 4 and 5.

### 2.1.3 Unreported catches

Unreported catches by year and Commission Area are presented in Table 2.1.3.1. A discussion of the methods used to evaluate the unreported catches is provided in Section 13 of last years report (ICES 1996/Assess:11). The total unreported catch in NASCO areas in 1996 was estimated to be $1,123 \mathrm{t}$, an increase of about $6 \%$ compared with 1995 but a decrease of about $26 \%$ on the 1991-95 mean of 1525 t .

The unreported catch estimated for the North East Atlantic Commission Area in 1996 was 947 t , a $32 \%$ reduction on the mean for 1991-95 of 1,390 t, and that for the North American Commission Area was $156 \mathrm{t}, 24 \%$ above the 1991-95 mean of 126 t . There was no change in the small estimated unreported catch for the West Greenland Commission Area of around 20 t .

No data were available on fishing for salmon in international waters in the Norwegian Sea or on vessels landing catches from this area in the 1995/1996 season. A total of 24 surveillance flights was reported to have been undertaken by the Icelandic and Norwegian Coastguards between late autumn and early summer, and no salmon fishing was observed in the area.

### 2.2 Farming and Sea Ranching of Atlantic Salmon

### 2.2.1 Production of farmed salmon

The production of farmed salmon in the North Atlantic area in 1996 was $450,394 \mathrm{t}$ (Table 2.2.1.1 and Figure 2.2.1.1). This was the highest production in the history of the farming industry and represented a further $9 \%$ increase compared to 1995 ( $411,580 \mathrm{t}$ ) and a $54 \%$ increase on the 1991-95 average ( $292,632 \mathrm{t}$ ). The countries with the largest production were Norway and Scotland, which accounted for $68 \%$ and $18 \%$ of the total respectively. Proportional increases in production in the other seven countries were limited to between $0 \%$ and $4 \%$. The production of farmed salmon in 1996 was over 150 times the nominal catch of salmon in the North Atlantic.

### 2.2.2 Production of ranched salmon

Ranching has been defined as the production of salmon through smolt releases with the intent of harvesting the total population that returns to freshwater (harvesting may include collecting fish for broodstock) (ICES 1994/M:16). The total production of ranched salmon in countries bordering the North Atlantic in 1996 was 266t which is the lowest value since 1989 (Table 2.2.2.1 and Figure 2.2.2.1). The majority ( $89 \%$ ) of the ranching is conducted in Iceland, where the production is almost double the nominal catch. Production at experimental facilities in Ireland, U.K. (N. Ireland) and Norway has remained low. Production in Ireland includes catches in net, trap and rod fisheries. Icelandic catches, on the other hand, are entirely from estuarine and freshwater traps at the ranching stations.

### 2.3 Significant Development towards Management of Salmon

### 2.3.1 Stock discrimination at West Greenland

The Atlantic salmon (Salmo salar L.) fishery along the west coast of Greenland presents a complex problem, in that this fishery is based mainly on salmon originating from rivers in North America and Europe. These salmon belong to the multi-sea-winter components of the stocks involved and, in recent years, the catch has predominantly consisted of 1 -sea-winter (1SW) salmon that, if not caught, would have returned to home waters as 2-sea-winter (2SW) salmon. Since 1969, discriminant analysis based on scale characters has been used to determine the proportions of the two continental stock groups in this fishery. Both scale characters and protein polymorphisms have been used extensively to discriminate between stocks or groupings of stocks of Atlantic salmon (Payne and Cross 1977; Cook and Lord 1978; Lear and Sandeman 1980; Cross and Healy 1985). The genotypic approach using protein polymorphisms has the advantage over the phenotypic approach using scale characters, in that it is not subject to annual variation. However, its routine use for discriminating North American from European salmon at Greenland is precluded because it is impossible to obtain the necessary tissue samples from a large enough sample of fish caught in the Greenland fishery. Beginning in 1986, a combined genotypic/phenotypic approach was used whereby a subset of the samples obtained from the Greenland fishery was also sampled for liver and muscle tissue, from which continent of origin was determined using genetic protein polymorphisms (Reddin et al. 1987a). The scale characters from this subset were used as a database for discriminant analysis to determine the proportions of North American and European salmon in all of the samples from this fishery.

Samples of muscle tissue were taken from salmon landed at the fish plant in Nuuk, Greenland during the 1995 sampling programme at Greenland. A total of 132 salmon were systematically sampled from the West Greenland fishery on two days, viz. August 21 and 22.

## Genetic analyses

Microsatellite markers: In North America only 5 animals out of more than 480 sampled exhibited alleles of less than 266 base pairs. All five animals were from the Gander River. Therefore, anything with allele size less than 266 will be called European/North American.

Mitochondrial DNA markers: There were no contradictions among the NADH and D-loop markers. The pattern is either one $(1=$ North America) or the other $(2=$ Europe $)$. The only D-loop haplotype observed in Europe (about 160 animals) is a 122 pattern. Any animal with a 2 for ALU (the first number in the haplotype) is called North America. Similarly, any animal with a 1 for Mse or Tsp 509 was called North American.

The samples were run through the same discriminant analysis as was used to determine the continent of origin in 1995. In 1995, the discriminant analysis was based on river age and CS1S, and CS1W scale character variables. The assumption is that the DNA analysis provides an absolute marker for continent of origin while the scale analysis has an associated level of misclassifications. Comparison of the results from the discriminant analysis of scale characters and the DNA analysis provides information on the reliability of classifications. Out of the 132 samples collected there were 12 samples with DNA of poor quality for which a continent of origin could not be determined. In total, from samples collected in 1995 for which origin could be determined by DNA analysis, there were $107(89 \%)$ North American and $13(11 \%)$ European. Of these, there were 10 samples with scales of insufficient quality for scale reading. In total, for the samples with results from both scales and DNA classifications, there were 99 (90\%) North American and 11 (10\%) European salmon. The results of classifying test samples indicated misclassification rates of $14.5 \%$ and error rates of $\pm 9.1 \%$. This is an acceptable level of
misclassifications given the low number of European salmon in the test sample. The two samples from which the tissue samples for DNA analysis were taken were classified as $74-77 \%$ North American origin.

The Working Group continues to recognise the importance of in-season identification to continent of origin using genetic techniques to calibrate scale-based identification of the fishery catch at Greenland. The need for these data arose when it was found that scale-based growth features deposited during the post-smolt year that differentiate the continental groups can converge, thus making continent of origin identification less reliable. This problem can be rectified by in-season genetic sampling, however, the Working Group recommended that other methods be explored which may be used to evaluate the scale-based method without the added expense and difficulty of the present genetic sampling. Specifically, the Working Group recommends that an investigation of environmental predictors of the scale-based features used in the classification be undertaken. Further to the larger problem of accurately identifying larger segments of the catch to continent of origin, the Working Group encourages the development of new genetic techniques that can be applied to larger quantities of catch than present methods. The Working Group continues to support and encourage existing genetic monitoring programs identifying continent of origin of in-season samples from W. Greenland.

### 2.4 Causes of Long-Term Changes in Sea-Age Composition of Salmon

Material discussed in the 1996 WGNAS (Sections 7.1, 7.4 and 14; Section 7.1, Possible explanations for changes in sea-age at maturity) summarised the likely roles of genetic and environmental (including fishery) effects in determining sea-age at maturity in stocks, populations or individuals. Section 7.4 (Use of $\mathrm{Sr}: \mathrm{Ca}$ ratios in otoliths to determine maturation status) described a new method that may permit indirect examination of the events leading up to sexual maturity. Section 14 (Changes in growth rate, mean weight at age and proportion of different size groups) collated national data sets for weight, age and maturity rate in salmon stocks.

The Report stressed differences between the sexes and the multiplicity of possible interactive effects acting at every level and throughout life to determine age at maturity. The available field data sets lacked sufficient robustness to test general hypotheses. In particular, data sets that combine measures of absolute abundance with measures of maturity rate are not generally available.

This poses particular difficulties for determining the mechanisms which interact to determine when fish mature, and the causes of long-term trends. Long-term trends in the frequency of maturing fish at any sea-age in any stock or population might arise from:

1. changes in the absolute abundance of the maturing class being considered,
2. changes in the absolute abundance of other classes,
3. changes in the absolute abundance of both groups,

In turn, these component changes might be caused by:
4. changes in the development of genetically unchanged individuals in response to environmental change,
5. differential mortality among population or stock groupings that are unequally exposed or unequally susceptible to environmental change (in particular differing effects in the fresh water and marine environment),
6. changes of balance among population groups, as stronger groups expand to exploit resources vacated by weaker ones.

Unlike 1-4 above, points 5 and 6 are population-based concepts that have not been explored in relation to salmon. Phenomena such as those described in points 5 or 6 are capable of generating long-term trends in characteristics like sea-age at maturity that are partly determined by genetics and that vary among populations. The same concepts are potentially informative in relation to long-term trends in abundance considered in Section 2.5 .

### 2.5 Causes of Changes in Abundance of Salmon

Temporal changes in marine abundance at any sea-age may relate to variation in marine survival or to variation in smolt recruitment. Causes of marine mortality were discussed in the 1996 Report of the WGNAS (Sections 4.5 and 5.3). No new information on the effects on abundance of diseases, pathogens or predators has been made available to the WGNAS.

### 2.5.1 Mortality and ocean climate

This rapidly developing area has been the subject of intense study. Recent attention has been directed at modelling the responses of Northeast Atlantic salmon populations to marine environmental change. Trophic studies off the Faroes (Jacobsen and Hansen 1996) indicate that feeding cycles and possible prey abundance are changing, which will affect salmon growth and survival (see also Section 3.2.4 of this report).

## Sea Surface Temperatures and Post-smolt Survival in the Northeast Atlantic

The first year of ocean life of Atlantic salmon is shaped by natural mortality and sexual maturation (Thorpe 1994; Friedland and Hass 1996; Friedland et al. 1996). However, it is clear that populations have differing maturity schedules and that stocks can show dramatic variation in maturity rate (Power 1981, Saunders 1981, Shearer 1990, Summers 1995). Marine natural mortality in salmonids is believed to be most severe on populations during the first weeks to months at sea (Fisher and Pearcy 1988; Holtby et al. 1990, Eriksson 1994, Salminen et al. 1995). It is also believed that mortality effects are growth mediated during this period due to either variation in ocean productivity, interspecific competition, or intraspecific interactions (Ricker 1962; Neilson and Geen 1986; L'Abée-Lund et al. 1993; Friedland et al. 1996). Therefore, broad scale processes that may affect salmon growth are of particular interest.

Ocean climate appears to be intimately linked to mortality and maturation mechanisms in salmon. Wild salmon smolts have been tagged in the rivers Figgjo (southern Norway) and North Esk (eastern Scotland) (Figure 2.5.1) since 1965. A study was presented to the working group where return rates of tagged one and two seawinter salmon from these rivers were used to evaluate survival conditions for this region. Survival rates were correlated between rivers and among sea ages (Figure 2.5.2). Survival rates were compared to the areal extent of thermal habitat in the Northeast Atlantic Ocean. The strongest correlations between survival rate and areal extent of thermal habitat occurred during the month of May ( $8-10^{\circ} \mathrm{C}$ water), and were positive. A reciprocal negative correlation was also found between survival and $5-7^{\circ} \mathrm{C}$ water in the same month (Figure 2.5.3), and significant correlations to cold water habitat were also observed for June data. An analysis of sea surface temperature distributions for periods of good versus poor salmon survival showed that when cool surface waters dominate the Norwegian coast and North Sea during May, salmon survival has been poor (Figure 2.5.4). Conversely, when the $8^{\circ} \mathrm{C}$ isotherm extended northward along the Norwegian coast during May, survival was good. Thus, it is the variation in temperature conditions for this segment of the Norwegian coast which is most critical to the postsmolts. This section of the Norwegian coast is dominated by a coastal current that travels to the northeast at a mean seasonal rate of $15-20 \mathrm{~cm} \mathrm{sec}^{-1}$ (Hopkins 1991). Jonsson et al. (1993) reported on the migration of postsmolts in this current. Migratory speeds averaged $7.45 \mathrm{~km} \mathrm{day}^{-1}$ and post-smolts rarely moved southward against the prevailing currents. Thus, salmon post-smolts from the Figgjo and North Esk would be expected to occupy this thermally dynamic segment of the coast.

In this study, it was not possible to ascertain when during the post-smolt year the highest mortalities occurred. Eriksson (1994) reported that the highest post-smolt mortalities in the Baltic Sea occurred during the first weeks at sea. This suggests that the important period is when Figgjo and North Esk salmon would first be entering the marine environment, which is consistent with the results of the sea surface temperature correlation analysis. Interestingly, survival fluctuated similarly for both 1 SW and 2 SW salmon for both populations, thus the contribution of maturation mechanisms to the observed return rates can be discounted.

Indirect linkages between environmental conditions and smolt survival could be tested with retrospective growth analyses. Friedland et al. (1996) demonstrated a relationship between post-smolt growth and survivorship in hatchery stocks from North America.

Climate mediated recruitment patterns may be occurring in this region. To study the impact of climate on quantitative characteristics of salmon populations, mean yearly water temperatures in the $0-200 \mathrm{~m}$ depth interval along the Kola Meridian transect in the Barents Sea and data on the abundance of recruitment and spawning stock of the Tuloma River (Figure 2.5.5) have been analysed. A Ricker curve was fitted to the stock-recruit data. A linear relationship has been established between the abundance of this spawning stock and water temperature at sea (Figure 2.5.6).

In the light of this relationship all salmon year-classes that had fully gone through the fisheries were analysed. A comparison of the strength of recruitment from those year classes and water temperatures at sea and in the river showed cyclical variations of recruits and temperature regime (e.g. Figures 2.5.7 and 2.5.8). This relationship is rather weak $\left(r^{2}=0.24\right)$, however, these two time series have a common cycle, revealed by a harmonic analysis, with a period close to 7 years. Rich year classes appeared in the years when mean yearly water temperature at sea was about $4^{\circ} \mathrm{C}$ or warmer.

### 2.5.2 Smolt recruitment

The number of salmon at sea depends on several variables, including the number of smolts which leave the river systems. Smolt production is susceptible to the effects of adult numbers through levels of egg deposition. Declines in spawner numbers caused by declining trends in marine survival have the potential to feed-back negatively on marine abundance.

For example, in recent years marine mortality has become the driving variable in determining smolt recruitment for the Girnock Burn, a tributary of the River Dee (U.K., Scotland). Trap counts indicate that smolt numbers are declining in response to a sequence of years in which egg deposition has been marginal or inadequate in relation to a threshold value (ca. 40 females). This threshold has been derived empirically from a long time series of data (1966-present) relating smolt output to estimates of egg deposition based on trap counts of female spawners. Fishing effort has been reduced in the oceans and in coastal homewaters and in-river mortality for the River Dee, specifically, has been reduced by the introduction of an advised catch-and-release policy for Dee anglers. Recent high levels of mortality among pre-spawners are therefore attributed to non-fishing causes. At spawning, the Girnock Burn population is composed of early-running 2SW, and a small proportion of early-running 1SW fish. In recent years, early-running 2 SW fish generally have suffered high rates of marine mortality, as evidenced by strong declining rod catch trends for early-running 2 SW (i.e. spring) salmon in all the major U.K. rivers (Youngson 1995).

In the case of the Girnock Burn, the extra marine mortality of recent years has reduced smolt production. This effect will feed back on future recruitment of spawners.

The Girnock Burn produces mainly 2- or 3-year-old smolts. Interactions among juvenile cohorts and changes in mean age composition at smolting provide some robustness to single episodes of inadequate spawning. Smolt production is not expected to be robust in a series of marginal or inadequate spawning years.

The full effects of increased mortality among pre-spawners have been lessened by the introduction of a voluntary but effective catch-and-release policy for the River Dee. In 1996, for example, eight of the 41 female spawners captured at the Girnock trap ( $20 \%$ ) showed evidence of being released after capture by angling. Seven showed evidence of hook damage to the mouthparts. Another fish with no obvious hook wound had been radiotagged after capture by angling.

### 2.6 Compilation of Tag Release and Finclip Data for 1996

Data on releases of tagged and finclipped salmon in 1996 were provided by the Working Group and will be compiled as a separate report. A summary of national markings is given in Table 2.6.1. In 1996, a total of nearly 3.4 million salmon were marked, nearly equal to the number marked in 1995 ( 3.5 million). Finclips ( 1.63 million) and microtags ( 0.82 million) were the most frequently used marks. Most marks were applied to reared parr and smolts ( 3.33 million) with only small numbers of wild parr and smolt ( 0.049 million) and adult fish ( 0.020 million) being marked.

### 2.7 Safe Biological Limits

Proper management of Atlantic salmon requires that the spawning populations of each river (and possibly subcatchments within the river) be conserved. This necessitates setting a minimum threshold below which populations should not fall, and a higher target reference level for managing fisheries. However, the life cycle of the salmon and the nature of the fisheries limit the possible management approaches and tools. Anadromous Atlantic salmon leave their rivers to undertake feeding migrations to the ocean. Most are at sea for 1 (1SW or Grilse) or 2 (2SW) years before returning to spawn, with the fish returning after 2 or more years (MSW) undertaking more distant migrations than those that return after 1 year. In the ocean, fish from many different populations mix together and catches are probably not evenly distributed among individuals from all the contributing populations. Grilse and MSW cohorts are for the most part exploited by sea and home water fisheries in a single year (similar to a short lived species, see ICES 1993/Assess:12). Independent verifications of projections of prefishery abundances are not available until after the fisheries, and age-structured methodologies like VPA are not applicable. In addition, the salmon will not react like many other species in that if disproportionate catches on one river's population are taken, compensatory shifts in growth and recruitment among the juveniles in other rivers will not occur. Taking these considerations into account, the Working Group has established the following biological reference points:

### 2.7.1 Conservation limit

Within the North Atlantic Salmon Working Group, there is general acceptance of the MBAL (minimal biologically accepted level) as a threshold below which spawning biomasses should not fall (ICES 1995/Assess:14). MBAL has been defined by the Working Group as the stock level that produces maximum gain (MSY) (ICES 1995/Assess:14). The Working Group selected this point because it could be defined unambiguously from fitted stock/recruit relationship. Methodologically consistent MBAL values can therefore be derived wherever appropriate data are available. This choice is also consistent with ACFM's advice approach, where "... MBAL can be defined by the level of spawning stock below which the data indicated that the probability of poor recruitment increases as the spawning stock size decreases. Any action that was expected to reduce spawning stock size below this level would, therefore, be outside biological limits."

In Canada, wherever possible this threshold is derived from stock-recruit relations on a river-by-river basis. Originally, CAFSAC (1991) suggested as conservation levels an egg deposition rate of $2.4 \mathrm{eggs} / \mathrm{m}^{2}$ of fluvial habitat and for areas of Newfoundland where many juveniles rear in lakes, an additional 368 eggs/ha of lacustrine habitat ( 105 eggs/ha in SFAs 1, 2, and 14a,b which include Labrador and the Great Northern Peninsula). A recent revaluation of these figures concluded that they were a fair approximation of MBAL. To calculate egg needs, river habitat area is multiplied by the appropriate deposition value, then fecundity values are used to determine the number of females (usually MSW) necessary to deposit the requisite number of eggs. Where possible, one male is provided for each female. Spawner requirements can then be summed by region, or country. A similar approach is used in the U.S.A.

Countries in the North East Atlantic are in various stages of developing MBALs (Table 3.6.1), and are focusing on ensuring appropriate egg deposition rates. Long term data bases for calculating stock-recruit relations are rare and from geographically limited areas, and it is difficult to extrapolate from them to the very different river structures and climates found throughout the North East region. However, in the U.K. (England and Wales), detailed methodologies have been developed to use data from rivers with established stock/recruit relationships and reference points to establish reference points for other systems (Environment Agency 1996). The Workshop on Salmon Spawning Targets in the North-East Atlantic recommended that "Spawning targets should be applied on a whole river basis unless evidence of suitability of more local (i.e. tributary based) targets were available." (ICES 1994/Assess:16). However, runs with unique characteristics (e.g. "springers" and "normal salmon") may be present within one system, and genetics studies are revealing substructures within catchment populations which may require approaches at sub-catchment levels. This complicates the task of setting any reference points.

### 2.7.2 Target reference point

The Working Group has used a fixed escapement policy to provide advice. Where MBALs are valid and met, then in theory all fish exceeding this number are available for harvest. However, this may not always be an appropriate management practice. In practice, natural perturbations and imperfect management and enforcement tools do not permit us to manage so precisely. MBAL is a threshold which should not be crossed because spawning escapements below this point will on average produce poorer recruitments and harvest potentials.

Setting the target point at higher levels will reduce the risk of falling below MBAL. The target is best set locally by scientists and managers who are most familiar with the biological characteristics of the population, the stockrecruit relation, and the realities of implementing and enforcing the management plan. Managers of in-river fisheries have the final responsibility of ensuring compliance with the targets, but they must also allocate surpluses among the needs of competing user groups. They are also in the difficult position of being the final guardians of MBAL, having to curtail in-river fisheries to compensate for management failures in sea fisheries and/or environmental conditions which have reduced anticipated fish returns.

### 2.7.3 Problems and constraints

To cope with unexpected events, the number of fish required to insure that spawning escapement exceeds a set MBAL may have to be considerably higher than the theoretical minimum. For example, straying may reduce the numbers of fish which enter spawning tributaries within a river, fish will be lost to predation, and physiological problems may block maturation for some fish. Another problem is that conservation limits based on genetics considerations may require higher MBALs. Where distinct populations exist within a catchment, more spawning fish may be required to maintain genetic diversity than would be called for by a simple reference point based on whole catchment egg depositions.

Furthermore, fisheries for Atlantic salmon that operate on a mixture of populations are by definition high risk (i.e. non-precautionary), particularly when reference points for individual stocks are combined. Accepting the individual river as our management unit, then the management goal becomes insuring that sufficient escapement occurs such that all rivers meet their conservation limits. Where mixed population fisheries are occurring, reference points need to be conservative.

As reference points are defined on increasingly fine scales (e.g. smaller and smaller tributaries), the number of fish required to escape all fisheries rapidly increases.

### 2.7.4 Salmon assessments from the perspective of the precautionary principle

The ICES Study Group on the Precautionary Approach to Fisheries Management has indicated that the precautionary approach requires that the risk of exceeding limit reference points must be kept very low (ICES 1997/Assess:7). To them, this meant that "the probability of exceeding the limit should be no more than $5 \%$ in any given year". Where a stock or population is at risk of or actually falls below the limit, then conservation or management action should be initiated to facilitate stock recovery (ICES 1997/Assess:7). Given the fixed escapement strategy used in salmon management, it is critical to keep salmon populations from falling below MBAL. Present assessments have a high risk of failing to do this, for several reasons. The Working Group notes that present salmon management practice pays too little heed to the confidence limits about the calculated prefishery abundance (pfa) estimates. This is evident from the use of the calculated mid point pfa value to set quotas, which gives a risky $50 \%$ probability of failing to reach the conservation escapement point. Variations in the proportions of females and the origin of the fish in the fishery will also increase the probability of falling below MBALs. For this reason, new methodologies are being developed within the group to give catch advice based on the risk of not meeting spawner requirements.

### 2.8 Discards

No new information was presented to the Working Group on quantities of discards (by gear type and area). The only area for which discards were routinely reported by the Working Group was for the Faroes fishery. These reports ceased with the discontinuation, in 1991/92, of the Faroes commercial long line fishery for Atlantic salmon. In the seasons 1982/83-1990/91 discards (salmon <60 cm total length) were estimated to be comprised of comprised 0-9.9\% of the seasonal catch (ICES 1993/Assess:13).

In 1993, the Working Group on North Atlantic salmon was asked to evaluate the by-catch and mortality of salmon in non-salmonid fisheries. At that time (ICES 1993/Assess:13) the Working Group noted with respect to the North East Atlantic that:

[^0]Small numbers of salmon may be caught in shore-based gill net fisheries for species such as mullet and bass (England and Wales), lumpsuckers (Iceland) and mackerel (Norway). In Iceland, the authorities are currently negotiating the closure in June and July of the of the fishery for male (small) lumpsuckers in order to protect salmon. In Norway, fishing experiments with mackerel gill nets showed a relatively high catch efficiency also for small salmon. Norwegian authorities are currently discussing regulations on mesh sizes and a closed season in June and July for the mackerel season in order to protect salmon.

There are only occasional instances of salmon being reported as taken in near- or off-shore fisheries with purse seines or pelagic trawls. This information is confirmed by the low frequency of such catches on research vessel cruises. The by-catch of salmon from these fisheries is considered to be negligible.

The Working Group noted a report from NASCO in which information was given on the incidental catch of salmon in a pelagic trawl fishery for mackerel and horse mackerel during June to August 1991 in international waters close to the Norwegian EEZ. It was not possible with information available to determine whether such catches are regular occurrences."

As an update, the Working Group noted that the lumpsucker fishery in Iceland is now closed in June and July. In the U.K. (England and Wales) local regulations have been introduced concerning the operations of fixed nets to limit catches of migratory salmonids.

In the northwest Atlantic area, landing of by-catch in non-salmon fisheries is illegal in Canada and the U.S.A. Bycatch was examined by searching tagging, sea sampling, commercial catch, and research vessel databases (ICES 1993/Assess:10). Results for U.S.A. and Canada were as follows:
"By-catch of Maine-origin Atlantic salmon in non-salmon directed fisheries has been estimated by Carlin tag return data. The by-catch is almost exclusively 2 SW salmon that are captured along the Maine coast. By-catch in Maine waters has occurred in gill nets, mackerel traps, pound nets, and saltwater weirs; however, it should be noted that only $40 \%$ of the tag recoveries from coastal fisheries can be attributed to a specific gear. The by-catch prior to 1988 averaged 10 fish; there were no reports of by catch since 1988."
"In Canada, the Working Group examined over 20 years of records of catches by domestic and foreign off-shore commercial fishing vessels, as reported by government observers, and records from research vessel cruises for up to 30 years. There were only 12 salmon reported from commercial offshore vessels and 5 salmon from the research vessel cruises which indicated that the catch of salmon in the offshore fisheries is negligible. Two percent of the tag returns in the Scotia-Fundy Region from 1996-1991 were returned from non-salmon gear; primarily mackerel, herring, shade, cod, gaspereau, and bass.

By-catch of juvenile and adult Atlantic salmon also occurs in the gaspereau and eel fishing gear in the Gulf region and eel fisheries of insular Newfoundland. The trap nets and fyke nets used in these fisheries are of such a small size that mortalities from meshing are considered minimal; bur mortality of juvenile salmon are reported to be high in some rivers in insular Newfoundland.

The Working Group concluded that adult salmon appear to be caught in low frequencies in non-directed fisheries. The tonnage appears to be negligible relative to the unreported catch in salmon gear. Estimates of by-catch loss are partially addressed in the estimates of unreported catches, when these arise from illegal landings in non salmon gear."

The Working Group noted that the previous search for by-catch of salmon in Canada had principally been among landings of trawl fisheries and that there where opportunities for by-catch in the extensive in-shore fixed gear fisheries for pelagic species and ground fish. Recent closures of many of these in shore fisheries, beginning in 1992, and reduced abundances of Atlantic salmon suggest that the opportunity to discard/by-catch salmon has likely further diminished. In the U.S.A., juvenile and adult salmon are occasionally taken in various sport and commercial fisheries for other species that occur in freshwater and saltwater. Examples of such fisheries include those for the trout, striped bass, gaspereau and eel. The numbers retained (which is not legal) are thought to be negligible.

By-catch in West Greenland can occur in gill nets set in fjords for charr but is thought to be negligible because of the different timing of these fisheries.

### 3.1 Fishing at Faroes in 1995/1996 and 1996/1997

The Faroese salmon quota has been bought out since 1991, however, the Faroes Government continued sampling inside the 200 mile EEZ. The aims were to monitor the salmon present in the Faroese area and to update time series of catch, catch per unit effort (CPUE), size and weight distributions of the fish, and of the proportion of discards (i.e. salmon below 60 cm total length). The small annual catches in recent years of less than 30 t have been the result of this activity.

No commercial fishery took place in 1995/1996. The research vessel M/S "Hvítiklettur", which was used previously in the research program, went to other fishing after the sampling was finished in spring 1995. As prospects for the future of the salmon fishery appeared poor, the skipper was not able to invest in new gear which would have been required to continue the research fishery. As a result a new vessel had to be contracted to conduct the research fishing. After negotiations, the M/S "Polarlaks" was hired. However, the crew had little previous experience of salmon fishing and the only available gear was several years old. Trials were carried out with this vessel in December 1995, but they only caught 282 salmon during one trip lasting two weeks ( 8 sets or fishing days). Such a catch might have been expected in a single set under normal circumstances. Financial limitations and the inexperience of the crew are considered to be the main reasons for the low catches in December and no further fishing was performed for the rest of the season.

The catch of 282 salmon ( 1 t ) taken in December 1995 (Tables 3.1.1 and 3.1.2) is too small to be considered representative of the size and age distribution of fish in the area, of catch rates (CPUE) that might have been expected in all or part of the 1995/1996 season. Consequently no further use will be made of the samples from December 1995 to represent catch or catch rates at Faroes in the 1995/1996 season. No fishing has taken place in the 1996/97 season.

The analysis of data collected in the research programme conducted in the 1991/92 to 1994/95 seasons is discussed in Section 3.2. Information on the level of exploitation in the Faroes fishery on various river stocks is presented in Section 3.7.

### 3.2 The Research Programme at Faroes

Since 1992 a joint Nordic research programme has been carried out on the salmon stocks north of the Faroes. The intention was to gain more knowledge about salmon in the Norwegian Sea and the aims were to investigate the migration to and from the feeding areas in the sea north of the Faroes, feeding habits of salmon during the winter months, growth in the sea, presence of escaped farmed salmon in the sea, parasites on wild and farmed salmon, and population structures (e.g. smolt and sea ages).

In the following four sections the analysis of parts of the data collected in the research fishery is discussed. Throughout Sections 3.2.1-4 the term autumn refers to the fishing period from November to December in any given fishing season and the term winter refers to the period January to April. In some fishing seasons, particularly in recent years the winter period is shorter and lasts from February to March.

### 3.2.1 Smolt age and sea age distribution in the Faroese fishery

Smolt age and sea age of Atlantic salmon sampled in the research fishery at Faroes in the 1991/1992 to 1994/1995 fishing seasons were examined in order to estimate the age composition of wild salmon. The scale samples were collected from the dorso-lateral area of the fish as recommended by Shearer (1992).

Escaped farmed fish and fish which could not be positively identified as wild fish on the basis of scale analysis (Lund and Hansen 1991) were excluded from the analysis. Scales which showed incomplete annual zones or which could not be accurately assigned to a specific age group were also excluded from the analysis. The proportion of the indeterminate fish in the samples varied between 2 and $39 \%$ for smolt age material and between 0 and $2 \%$ for sea age material.

Total sample size for different fishing seasons varied from 143 to 278 for smolt age and from 190-290 for sea age analysis (Table 3.2.1.1 and 3.2.1.2).

Chi-square tests were used to test for differences in smolt and sea age distributions between seasons and periods.
Age composition in samples from the four fishing seasons showed similar trends. Both smolt age and sea age tended to be lower in the earlier part of the fishing season than in the later part of the season.

Smolt age varied between 1-4 years in most samples and included some smolts which were five years old. These were added to smolt age group 4+ (Table 3.2.1.1). Mean smolt age during the four fishing seasons varied between 2.3-2.6 years in the autumnal samples and between 2.6-2.8 years in the spring samples (Table 3.2.1.3). Smolt age distribution was significantly different between the autumn and spring samples in only two of the fishing seasons (1992/93: $\mathrm{df}=3 ; \mathrm{p}<0.001$ ) and (1994/95: $\mathrm{df}=3 ; \mathrm{p}<0.001$ ).

Sea age varied mainly between 1-3 years. Some samples included a few specimens of sea age 4-6 and they were added to the sea age group $3+$ (Table 3.2.1.2). Mean sea age during the four fishing seasons varied between $1.8-$ 2.0 years in the autumn samples and between $2.1-2.4$ years in the spring samples (Table 3.2.1.4). Sea age distribution was significantly different between the autumn and spring samples in all fishing seasons (1991/92: $\mathrm{df}=2, \mathrm{p}<0.001 ; 1992 / 93: \mathrm{df}=2, \mathrm{p}<0.001 ; 1993 / 94: \mathrm{df}=2, \mathrm{p}<0.01 ; 1994 / 95: \mathrm{df}=2 ; \mathrm{p}<0.001)$.

The lower smolt age and sea age distributions during the autumn suggests that a large proportion of the salmon stocks in Faroes area during this period originate from southern European countries, where stocks are predominantly grilse and smolts are of age 1' to 3. Recoveries of microtagged fish from Ireland and Scotland, especially during the autumn, are consistent with the southern origin hypothesis. In the Feb-Mar part of the fishing season the results indicate a higher proportion of salmon from northern European countries. External tag recoveries from Norway and Russia also support this (ICES 1996/Assess:11).

### 3.2.2 Origin of wild and farmed salmon tagged north of the Faroes

Atlantic salmon are distributed over large areas in the Northeast Atlantic. Two sea winter salmon have been exploited for a relatively long period of time in the area north of the Faroes, although some 1SW and 3SW fish are also caught. Recaptures at Faroes of salmon tagged as smolts have revealed that salmon from many countries are present in the area. However, it has been suggested that the majority of these recaptures are of Norwegian origin (ICES 1996/Assess:11). A tagging experiment was carried out during the period 1969 to 1976 where in total 1,946 salmon was tagged and released back into the sea around the Faroes. In total 90 fish were recovered: 33 in Scotland, 31 in Norway, 15 in Ireland, 8 in other European countries, and 3 at West Greenland. The total recapture rate was $4.6 \%$; in the early years the tagging was conducted further south than the tagging from the recent Faroese research programme. The great majority of the tags were reported the same year as they were tagged, suggesting that many fish were sexually maturing. However, it is interesting to note that some fish were reported from West Greenland later the same year.

In recent years large numbers of farmed salmon have been observed at Faroes (Hansen et al. 1993a), accounting for a significant proportion of the Faroese salmon catch (Section 3.2.3). There is direct evidence that farmed salmon escaping from net pens in Norway enter this area (Hansen et al. 1987).

To examine the origin of the fish utilising the Faroese area between the years 1992 and 1995 wild and farmed Atlantic salmon caught on long-lines were tagged and released back into the sea. The fishing took place between November and March during the three fishing seasons 1992/93, 1993/94 and 1994/95. The areas fished during the autumn and the winter of the different fishing seasons are shown in Figure 3.2.2.1. Over 5,000 fish were tagged and released during the period 1992 to 1995 (Table 3.2.2.1).

Salmon were tagged either after being unhooked, or in the case of about one-third of the fish, with the hook remaining in the fish (unhooking of these fish would have created more damage). Fish tagged with hook-in-place had cut to the shortest possible length. After tagging the snood and before release, fish were allowed to recover in a tank supplied with a continuous inflow of sea water. All fish were classified as being of wild or farmed origin on the basis of fin erosion (Lund et al. 1989) and scale characteristics (Lund and Hansen 1991).

The sea age distributions of the tagged fish is shown in Figure 3.2.2.2.
To estimate the proportion of fish originating from the different countries, farmed or reared salmon was excluded from both the released and recaptured material. Furthermore, the observed distribution by country was corrected using the respective maximum and minimum exploitation rates for 2 SW salmon in homewaters provided by
national representatives for the assessment of pre-fishery abundance (ICES 1996/Assess:11). Furthermore, the recaptures from each country were adjusted for the best estimates of the respective homewater tag reporting rates, plus and minus $10 \%$ error (as provided by the North Atlantic Salmon Working Group members, 1997). The variance on the numbers of tags recovered in each country were estimated using a binomial function. "At Risk" simulations ( 1000 runs) were used to introduce error estimates ( $95 \%$ 'ile limits) on the estimated proportion of fish returning to different countries.

After four fishing seasons (i.e. 1993-1996) a total of 104 tagged fish have been reported recaptured in 10 different countries in the North Atlantic. No tags were recovered from the research fishery at Faroes nor from West Greenland. The overall recapture-rate of the salmon tagged was small ( $1.9 \%$ ). Of wild fish $2.2 \%$ were recaptured whereas $1.2 \%$ of the fish identified as fish farm escapees were recovered. The analysis suggests that the recapture rate of fish of farmed origin is lower than for wild fish ( $\mathrm{c}^{2}=6.8, \mathrm{df}=1, \mathrm{p}=0.009$ ).

There is a significantly higher recapture rate of large salmon (2 and 3+SW) among the recaptures than of 1SW fish (Figure 3.2.2.3) ( $\mathrm{G}=15.4, \mathrm{df}=2, \mathrm{p}<0.001$ ). However, the power of the test might be questioned, as only one 1SW fish was recovered. 1SW fish were observed to loose more scales and tolerate less stress than larger salmon during unhooking and tagging. Presumably, small salmon are also more vulnerable to predation than larger fish. An alternative explanation can be that 1SW fish are less vulnerable to homewater exploitation than larger salmon. However, this seems not to be the case since the exploitation rates in Norwegian index rivers do not differ markedly with respect to sea ages (ICES 1996/Assess:11).

Of the wild fish, 8 individuals of a total of 85 fish recaptured ( $9.4 \%$ ) probably stayed an additional year in the sea before returning to home waters. All 8 salmon stayed in the ocean for the whole period of time as inferred by their growth.

The recapture rates of both wild and farmed salmon were lower for fish tagged in the autumn (1.4\%) than in winter $(2.7 \%)\left(c^{2}=7.3, d f=1, p=0.007\right)$.

Among the salmon tagged, $30 \%$ were estimated to be of farmed origin. This figure is slightly higher than reported in recent years in the Faroese fishery (Section 3.2.3). The reason for this may be that fish farm escapees are used to being handled, and are thus less vulnerable than wild fish to capture and tagging procedure.

In total, 19 of the 1,637 fish farm escapees tagged were recaptured ( $1.2 \%$ ). Eighteen salmon were recovered from Norway, and one was recovered from the west coast of Sweden, at Ugglarp. This suggests that most of the tagged farmed salmon in the present experiment were recaptured in Norway and may suggest that these fish escaped from Norwegian fish farms.

For 2SW fish the recovery rate was significantly higher for fish with the hook left in the fish compared to fish without hooks when they were released $\left(c^{2}=7.6, \mathrm{df}=1, \mathrm{p}=0.006\right)$. This might suggest that the damage caused by removing the hook has a greater effect than leaving the hook in. It is likely that the hook eroded or was expelled by the fish shortly after tagging. In future tagging experiments, the size and design of the hook should be considered carefully. The hook should not be too large to cause excess mortality and the barb should be small or absent. Furthermore the hook should not be galvanised or durable, in case the hook is left in the fish oesophagus or stomach at release.

The results of the estimated proportions of wild salmon from different countries based on the recoveries (Figure 3.2 .2 .4 ) show that Norway accounts for the major part ( $42 \%$ ), although there are significant numbers also from Scotland, Russia and Ireland (Table 3.2.2.2). This mainly reflects the distribution of MSW salmon, because the reported recapture rate of tagged 1 SW salmon was significantly lower than for tagged 2 W and 3 SW fish (only a single 1SW salmon was recaptured). Because 1 SW salmon account for most of salmon runs in Ireland, it is reasonable to suggest that the total Irish contribution to the Faroes catches may be underestimated. This might also apply to other southern European countries. This is further supported by previous occurrence of microtagged 1SW salmon reported from the Faroes fishery, particularly during Nov-Dec part of the fishing seasons (ICES 1996/Assess:11).

The Working Group noted that 4 recaptures were reported from Canada, one tagged in March 1993 and recaptured in Miramichi River September 1993, three tagged in February/March 1995 and two subsequently recaptured in the Miramichi in September 1995 and one in Kouchibouguac River (close to Miramichi) in October 1995.

### 3.2.3 Incidence of escaped farmed salmon in the Faroese fishery and estimates of catches of wild salmon

In recent years salmon farming industry has expanded considerably. In 1996, 450,394 t were produced in the Atlantic, with Norway and Scotland accounting for the majority of the production (Section 2.2.1). The total nominal landings of salmon in commercial fisheries in the north Atlantic in 1996 was only $2,860 \mathrm{t}$ (Section 2.2.1).

Evidence from the Norwegian fish farming industry indicates that losses from the cages can occur at any time after the fish are placed in the sea and at all life stages. The escaped fish are caught in fisheries, and when sexually mature, they enter freshwater to spawn (e.g. Hansen et al. 1987; Gausen and Moen 1991; Lura and Sægrov 1991a; Webb et al. 1991).

The spread of fish farm escapees into all areas of the north Atlantic where wild salmon are also found, poses several possible problems. First, the interbreeding of farmed and wild salmon has been suggested to have negative effects on wild stocks (e.g. Hindar et al. 1991). Second, the transmission of parasites and diseases from farmed to wild stocks may cause problems (Johnson and Jensen 1994), thirdly, catch records from fisheries comprising both wild and farm escapees will complicate the assessment of the status of wild stocks. It is therefore of great importance to identify farmed fish and adjust catch records accordingly.

Norwegian tagged farmed salmon, released directly into coastal waters, were recaptured in the high seas fishery at Faroes (Hansen et al. 1987), and in a recent paper, Hansen et al. (1993a), demonstrated that large numbers of escaped farmed Atlantic salmon were present in oceanic waters in the north east Atlantic ocean and accounted for a significant part of the commercial salmon catch at Faroes.

Since the 1980/1981 fishing season, scale samples have been systematically collected from salmon caught in the long-line fishery for salmon north of the Faroes and in the Norwegian Sea (Figure 3.2.3.1). Identification of farmed salmon from scale patterns has been used to estimate the number of farmed and wild salmon caught in the Faroese fishery (Lund et al. 1989; Lund and Hansen 1991). From the 1980/81 fishing season to the end of 1990 sampling was carried out from commercial salmon catches, whereas from 1991 to 1995 sampling was carried out from research catches when only one vessel was operating.

This method has been developed by analysis of a series of "test" scales from Norwegian salmon of known reared and wild origin, using the following characters: smolt size, smolt age, transition zone from freshwater to saltwater, the position of sea winter bands, the number of summer checks and the proportion of replacement scales at the marine stage. Salmon of unknown origin were defined as reared if at least two out of the six scale characters examined were classified as reared characteristics. While this method has been shown to give good separation between adult farmed and wild salmon, fish at earlier life stages are difficult to detect accurately (Lund and Hansen 1991). The method will also detect some salmon released for ranching or as smolts in stock enhancement programmes. However, a large part of these fish carry external or internal tags, often combined with fin clips. The salmon analysed in the present material were screened for tags, and tagged fish were not included in the analysis. Furthermore, the number of hatchery reared smolts released into rivers in the east Atlantic is relatively small compared with the number of wild salmon present, except in Iceland where ranching has been established as an industry. However, very few fish tagged in Icelandic ranching operations have been reported from the Faroese fishery, suggesting that they exploit other feeding areas. This suggests that deliberately released salmon smolts are a small component of the salmon sampled, and that escaped farmed salmon account for the major proportion.

Table 3.2.3.1 shows the number of scale samples collected on a monthly basis since 1980. Sampling was not carried out all months throughout the fishing seasons. In 11 out of 16 seasons only one part of the season was sampled, i.e. either the autumn (Nov-Dec) or the winter part (Jan-Mar), and in two of those only one months was sampled. The detailed estimates of the proportion of farmed salmon in the Faroes fishery between the 1980/81 and the 1995/96 fishing seasons are shown in Table 3.2.3.1. Monthly variations within each fishing season in the proportion of farmed fish were examined using chi-squared tests. The only significant difference occurred in the 1991/1992 fishing season, whereas in the 13 other fishing seasons where data from two or more months were available, no significant differences were detected. To split the total catch of salmon at Faroes by season into wild and farmed salmon, it was therefore found appropriate to use the mean estimated proportions by season of fish from these two groups in the calculations.

Figure 3.2.3.2 shows the time series of the proportion of farmed fish in the Faroes fishery and the total production of farmed salmon in the Northeast Atlantic superimposed. The proportion was relatively low from the 1980/1981 to 1986/87 fishing seasons, and increased considerably thereafter and reached a peak in the 1989/1990 fishing season. Then the proportion declined, and in the past three fishing seasons the proportion of farmed fish was estimated to be around $20 \%$.

Adjusted catches at Faroes from the 1982/1983 fishing season and onwards were divided into wild and farmed salmon components are (Figure 3.2.3.3). The catches dropped rapidly after the Faroese salmon fishermen's organisation agreed to be compensated for their quota in the beginning of 1991. At the same time the proportion of escaped farmed salmon dropped from a record high level of about $40 \%$ to about 20\% (Figure 3.2.3.2).

The variation in the proportion of farmed salmon between seasons in the salmon fisheries at Faroes is relatively consistent with the increase in overall production of farmed salmon in the Northeast Atlantic. The total production of farmed salmon in the Atlantic in 1995 was $413,200 \mathrm{t}$ (ICES 1996/Assess:11). Of this, $95 \%$ were produced in Europe, and of the total production Norway and Scotland accounted for $71 \%$ and $17 \%$, respectively. The production at Faroes was $9,000 \mathrm{t}$ which represents about $2 \%$ of total production in the Atlantic (ICES 1996/Assess:11). Salmon escape from cages in all areas was farms are present, and the largest number of fish that escape are from Norwegian farms.

Systematic releases of tagged farmed salmon during their first year in sea cages have shown that the survival to sexual maturity is highest when the fish are released in the spring. When released in late summer and autumn, the survival is lower (Hansen and Jonsson 1989). Furthermore, in most cases these fish return, generally, to the marine area from where they escaped. However, when fish escaped in March they were observed to stray to rivers far away from the site of escape, although they were not reported in countries other than Norway and the west coast of Sweden (Hansen and Jonsson 1991). The high proportion of farmed salmon observed in Norwegian home water fisheries (Section 3.3.7), combined with the fact that Norway accounts for the major production of farmed salmon in the Atlantic, strongly suggest that most farmed salmon occurring in the Norwegian Sea are of Norwegian origin. This is supported by the fact that tagged farmed salmon released on the Norwegian coast were recaptured in the Faroese fishery (Hansen et al. 1987). However, it is possible that farmed fish escaping from cages in Scotland, Faroes and Ireland also contribute to the Faroese fishery.

When assessing salmon fisheries and wild salmon stocks, it is important to estimate the farmed and ranched component. If high proportions of unidentified farmed salmon are present in catches the wild stocks will be overestimated. The increase in the Faroese catches in the 1988/1989 and 1989/1990 fishing seasons might partly be explained by an increase in the proportion escaped farmed salmon in the catches. However, the results should be interpreted with caution as seasonal variations in the percentage of reared salmon in the catches may exist.

### 3.2.4 The food of Atlantic salmon north of the Faroes

Results from the analysis of 3,848 stomachs sampled in November-March during the three consecutive fishing seasons 1992/93, 1993/94 and 1994/95 in the research fishery north of the Faroes were reported by Jacobsen and Hansen (1996). They found that crustaceans of the genus Themisto, euphausiids and shrimps were most frequently found in the stomachs, followed by pelagic and mesopelagic fish consisting of lantern fishes, pearlsides and barracudinas (Figure 3.2.4.1). In total number the crustaceans accounted for more than $80 \%$ of the food. In weight more than $60 \%$ of the food was fish consisting of the same mesopelagic fish as previous but few herring, blue whiting and mackerel which were not well represented in numbers contributed significantly to the weight. Generally the average prey size in the stomachs did not depend on fish size, except for Themisto libellula, where a significant positive relationship was observed.

The proportion of stomachs containing food increased significantly from November-December (53\%) to February-March (78\%) (Figure 3.2.4.2), and the average stomach content in weight also increased during the season mainly due to an increase of fish species in the diet (Figure 3.2.4.3).

On the assumption that the proportion of empty stomachs is indicative of the intensity of feeding (Rae 1967), salmon feed more intensively in February-March than in November-December. The significantly higher average food content in weight per salmon (of the stomachs containing food) in the February-March period compared to the November-December period each season, emphasises the lower feeding rate of salmon observed during late autumn. This observation is consistent with work in the Baltic, where a tendency of decreasing food quantities in the salmon stomachs was observed during autumn until January-February when it again increased (Christensen

1961, Thurow 1966). Salmon sampled in the Labrador Sea had less food in their stomachs in the autumn than in the spring ( 3.1 g and 5.7 g food per kg of salmon respectively) and were feeding less actively ( $28 \%$ and $8 \%$ empty stomachs respectively) (Lear and Christensen 1980). The low feeding rate in late autumn could be an indication of low food availability, implying that salmon growth and survival may be decreased in the sea in this period. Survival of salmon in the sea has been shown to depend in some way on the environment (i.e. sea-surface temperatures (see Section 2.5). This may in part be the result of temperature dependence or preference of the available prey for salmon, as indicated by the low feeding rate in November-January.

There seems also to be a trend with time in the proportion of empty stomachs which increased from $25 \%$ in $1992 / 1993$ to $34 \%$ and $37 \%$ respectively during the next two seasons. The frequency with which fish species were found in the stomach samples fell from $76 \%$ to $44 \%$ and $45 \%$ during the same period (ICES 1996/Assess:11).

Early in the fishing season (Nov-Dec) the crustaceans dominated the stomachs whereas fish were most abundant during Feb-Mar (Figure 3.2.4.4).

The available prey sampled from 15 plankton tows at $0-50 \mathrm{~m}$ depth, generally included the same species as were found in the stomachs, although salmon did not feed on Sagitta spp. and Calanus finmarchicus which were observed in the plankton samples (Jacobsen and Hansen 1996).

### 3.3 Homewater Fisheries in the NEAC Area in 1996

### 3.3.1 National reports

This section provides a general overview of the homewater fisheries in each country in the NEAC area in 1996. Further analysis of these data is included in Sections 3.3.2 to 3.3.9.

## Finland

No significant change in gear was reported in 1996. There were minor fishing regulation changes for the river Teno concerning a reduction in recreational fishing time. Effort in the recreational fishery on the Teno continued to decline more prominently. Anglers and angling days decreased about $30 \%$ and recreational salmon catch decreased about $20 \%$ from year 1995. The effort in the native net fishery was about the same as in 1995.

The reported salmon catch of the river Teno was 43 t and of the river Näätämö 1 t . The river Teno salmon catch was $9 \%$ less than in 1995. Salmon catches have been decreasing since 1993. In the river Teno and the river Näätämö, the salmon run was about two weeks late in 1996. For the river Teno salmon catch, the proportion of grilse was greater and proportion of females decreased. A pronounced decrease was also observed in numbers of 3SW salmon. The age distribution was based on the river Teno mainstream mixed salmon population.

The river Teno salmon catch included $0.1 \%$ escapees from cage rearing. Escapees were caught in late August, near the end of the fishing season. The status of stocks in the river Teno and river Näätämö region was still quite "healthy" considering the presence of salmon cage rearing and the intensive river fishery. Some decline is shown in the parr densities, especially in the river Inarijoki tributary, which is about 250 km from the sea.

## France

There was no significant change in the fishing gear used in 1996. The number of angling licences decreased slightly (4\%) compared to 1995 but it was still higher than in 1994, the lowest number observed in a 9 -year continuous decline. The number of commercial licences (Adour) increased by $20 \%$ compared to 1995, but it is not clear whether the real effort increased in the same proportion. The sport and commercial fisheries in the Loire basin, closed in 1994 in order to protect the very low remaining stock, have not been re-opened. Angling effort on grilse is still increasing in Brittany and Normandy with a later closure of the fishing season in some rivers (a measure that started in 1993 and is being extended to a number of rivers in the area). In these regions, where the most important rod and line fishery takes place, a Total Allowable Catch (TAC), based on the attainment of a spawning reference point, was set for most rivers in 1996 in order to manage stocks on a river basis.

The total catch was 14 t in 1996, $56 \%$ more than in 1995 but representing only $67 \%$ of the mean catch of the 10 previous years. The anglers' share was 9 t and the commercial fishery's 5 t . In Brittany, anglers took only $38 \%$ of
their Total Allowable Catch. The average catch per angler was 1.57 salmon, about $40 \%$ more than in 1995 and 1994. The grilse component of the global catch was $51 \% ; 57 \%$ in the rod fishery, and $38 \%$ in the net fishery. The proportion of grilse in the last 3 years has been higher that the 5 -year average. Part of the reason is a later closure of the angling season in Brittany since 1993 and the closure of the fishery in the Loire since 1994 (stock mainly composed of MSW). The decreasing trend in the abundance of spring salmon is continuing. Data on exploitation rates are only available for the Brittany area and two other monitored rivers. Exploitation rates in freshwater for 1SW salmon in the river Scorff were $14 \%$ in 1996 and $8 \%$ in 1995. Exploitation rates of MSW were $11 \%$ in 1996 and $15 \%$ in 1995, lower than the 1992-1993 average for Brittany, estimated between 19 and $37 \%$. Exploitation rates in freshwater for the monitored rivers were $12 \%$ in the river Bresle and $2.7 \%$ in the river Nivelle.

A matter of concern is the finding of Gyrodactylus salaris for the first time in 1996 on trout raised in France. The parasite may already have disseminated in some rivers through brown or rainbow trout stocking. It poses a serious threat to French salmon stocks since salmon are killed by the parasite if the strain is not resistant. Resistance tests will be conducted with French strains as soon as possible. In the light of the Norwegian experience, where more than 20 stocks were definitely lost, strict prevention measures should be taken in order to protect French and European salmon stocks from infection and spreading of the parasite.

## Iceland

In 1996, one the of five coastal locations with gillnet fisheries was bought out permanently, one was leased by angling clubs and thus not operated, and one was only operational in August. Two locations are still operated where nets are set from land.

The total catch of wild origin salmon was 122 t . The reported catch in the rod fishery was 95 t which is about $14 \%$ lower than in 1995 ( 108.9 t ), $19 \%$ below the previous 5 -year average and $25 \%$ below the previous 10 -year average. The reported catch in the gill-net fishery was $27.7 \mathrm{t}, 33 \%$ lower than in $1995(41.3 \mathrm{t}), 21 \%$ lower than the previous 5 -year average and $35 \%$ lower than the previous 10 -year average). The lower net catch is related to the buy-out of coastal gill-nets. Catch-and-release by anglers has been increasing. In the 1996 season, 2.3\% of the rod catch was released. Tagging experiments indicate that around $30 \%$ of the released fish are caught more than once.

The contribution of 1 SW fish to rod and net catches was $73 \%$ and $27 \%$ respectively for 2 SW fish. This is about the average for the previous 5 years. The total number of 1 SW fish was 28,067 ( 69 t ) and for $2 \mathrm{SW} 9,983$ fish ( 53 t ).

Some ranched fish stray into salmon rivers and this is more common in rivers close to ranching operations. In the River Ellidaar ranched fish comprised $12.9 \%$ of the catch but no fish farm escapees were detected. There are also some wild salmon taken in ranching stations. Only a few fish farms are now rearing salmon in sea cages, most using land based facilities. As a result there are few escapees. The harvest of ranched salmon was 236 t and the fish farm production was 2772 t . This is a decrease from previous years.

The exploitation rate in the river Ellidaar was $56 \%$, which is higher than in the previous 5 years. The 5 -year exploitation rate for the rod fishery on the River Nupsa and River Blanda is $84 \%$ and $61 \%$, respectively. The exploitation rate on 2SW fish is higher than on grilse.

## Ireland

While fishing conditions were generally favourable, there was a slow start to the commercial drift net season with poor landings recorded by the boats which did fish. The situation improved later in the season, although most regions experienced a lower catch than in the previous year. Some rivers were reported to have had a poor early grilse run following a relatively good spring run, but again this situation did not appear to persist throughout the season. The declared catch in 1996 ( 685 t) was lower than in 1994 (817 t) and 1995 (790 t). This reflected decreases in most fishing sectors. Catches remain higher than the five year average but lower than the ten year average. The majority of the commercial catch ( $>90 \%$ ) is assumed to be comprised of grilse. Fish farm production of salmon in 1995 was $11,811 \mathrm{t}$ and increased to $13,500 \mathrm{t}$ in 1996. Three major escapes from fish farms were recorded of $5,000-8,000$ in the South West, 11,200 fish $>1 \mathrm{~kg}$ in the West and approximately 9,500 smolts in the North West in 1996. Overall the rate of escapees in Irish catches is very small $(<3 \%$,$) .$

Exploitation by commercial nets on wild and hatchery fish has increased in recent years and is approximately $50 \%$ and $80 \%$ respectively. This exploitation rate has returned to values experienced in the early and middle 1980s. Survival of Corrib wild and Burrishoole hatchery smolts returning to the Irish coast has followed a similar pattern since 1980. A period of high survival is noted from 1983 to 1988 followed by lower survival since this time. In general, survival of wild salmon to the river is higher than hatchery reared fish; the range for both groups is between 2 and $9 \%$. The main production and release of reared fish is of fry (fed and unfed). Approximately 3 million fry were released in 1995 and again in 1996. Stocking with parr also takes place with up to half a million stocked into Irish rivers. Smolt production for stock enhancement and fishery improvement is about half a million and this includes microtagged, finclipped and unmarked fish.

Major changes in the management of the Irish net fisheries for the 1997 season and subsequent years have been indicated following the recommendations of the Salmon Management Task Force Report (Government of Ireland, 1996)

## Norway

In 1996, there was no significant change in salmon fishery regulations in Norway, and there was no significant change in effort. It should be noted, however, that since 1990 small reductions in the salmon fishing season in different areas of the country have contributed to gradually reducing the overall fishing effort. It was recently decided to establish new regulations in the 1997 fishing season. The purpose is to reduce the overall fishing effort on salmon, and especially on MSW fish. These measures include a total ban on the use of bend nets in most of the country, and a reduction of the fishing season with bag nets. In freshwater, significant measures are going to be introduced to reduce angling effort in 1997.

Nominal catches of salmon in Norway in 1995 and 1996 are shown in Table 2.1.1.1. The figures are final. Total catches both in weight and numbers declined from $1995(839 \mathrm{t})$ to 1996 ( 787 t ). The catch in 1996 is the lowest recorded since 1960. The total number of salmon caught by anglers in the River Alta has increased in recent years, however the proportion of grilse in the catches has significantly increased. Work has been initiated to estimate unreported catches in Norway, and it is suggested that the unreported catches of salmon in Norway may be significant. No CPUE data are currently available. There was a slight increase in marine catches compared with 1995, whereas freshwater catches were reduced. The reduction was mainly due to lower catches of 1SW fish (Table 2.2.2.1).

Farmed salmon were estimated to comprise $54 \%$ of the catch in coastal bag nets and fjord bag net fisheries. In rod catches the estimated proportion of farmed salmon was $7 \%$, and in spawning populations $31 \%$. These figures are slightly higher than in 1995.

Table 3.3.9.1 shows marine exploitation rates of wild- and hatchery-reared Atlantic salmon from the River Imsa and hatchery fish from the River Drammen since 1985. For wild and hatchery fish from the Imsa, the exploitation rates on the 2 SW components are significantly higher than for 1 SW fish. This does not appear to be the case for the River Drammen fish. The rod exploitation rate in the River Drammen was $47 \%$.

## Russia

There were no changes in fishing gears and fishing effort compared to the last three years.
The total catch in 1996 was 131 t , and remained at the previous year's level ( 130 t ). In the recreational fishery the catch was 12,696 salmon, including 10,745 which were released. In general, in the last 4 years, catches of salmon stabilised, while a reduction of the commercial catch compared to the 1980s was associated with a cessation of fishery on the Pechora river and development of recreational fisheries.

Grilse accounted for about $80 \%$ of the catch which was $10 \%$ higher than the average for the last 5 years. This was probably related to a delayed commencement of the fishery as a result of which a considerable proportion of the MSW salmon escaped the fishery.

Catches were composed mainly of wild salmon. Only catches from the Kola and Keret rivers contained $24 \%$ and $56 \%$ of hatchery origin salmon, respectively.

## Sweden

In 1996, the salmon catches on the Swedish west coast were lower than both the 5 -year and 10-year means and declined in numbers by almost $25 \%$ from 1995. The decrease was mainly caused by a decline in the grilse catch of nearly $40 \%$, while the catch of MSW salmon increased by a little more than $25 \%$. As a result the catch in weight decreased by about $10 \%$. The decline could not be correlated to changes in exploitation as no new regulations or other major changes in the fishery were implemented.

Besides the decline in grilse catch, concern was also expressed about increasing catches of large salmon which had paler flesh than expected for normal salmon from the west coast. Both the size and the pale flesh suggest that they were strayers from the Baltic. The assumption was underlined by some recaptures on Sweden's west coast of tagged salmon originally delayed-released from the Danish Islands and the island of Bornholm.

## U.K. (England \& Wales)

There were no significant changes in the fishing gear used in 1996. The number of licences issued for nets and fixed engines has continued to decline due mainly to the continued phase-out of the drift net fishery on the northeast coast. A number of rod and net fisheries in south-west Wales were closed for part of the season as a result of an oil spill. The fishing effort has decreased in some areas because an increase in net licence fees has resulted in reduced up-take of licences. In 1996, dry weather and low flows were reported in most areas during the summer months. Rod catches were poor and effort low in this period. Netting effort increased in one fishery in the southwest because a compensation arrangement lapsed; 12 seine nets resumed fishing and accounted for $67 \%$ of the total declared net catch in the region. Bag limits for rods also ceased on two rivers in 1996 and this may have increased the catch on those rivers.

The provisional salmon catch for 1996 is estimated at 193.8 t ( $63 \%$ of the catch in 1995), comprising 129.3 t by nets and fixed engines and 64.5 t by rods. The overall net and fixed engine catch was very poor (about half that recorded in 1995 and $37 \%$ below the average of the previous 5 years). The estimated catch by rods is thought to be similar to both the 1995 catch and the average of the previous 5 years. Catches were generally felt to be poor in the middle part of the season due to low flows and adverse fishing conditions, but were better in the early and late parts of the season. CPUE for nets was below the five-year average. There has been increasing use of catch-and-release by salmon anglers in recent years, but the impact of this on overall exploitation is difficult to quantify.

Anecdotal reports indicate that grilse still comprise the majority of the catch in most regions, but the proportion of multi-sea-winter fish is thought to have increased in a number of areas. There is no salmon farming and no ranching programmes in England and Wales. The catch of salmon in England and Wales is therefore thought to be made up entirely of wild and stocked fish, although no surveys have been conducted to confirm this in recent years.

Exploitation rate estimates are available for rod fisheries on six rivers indicating rates from 5 to $56 \%$. In some rivers (Itchen, Frome and Leven) these were markedly higher than in other recent years for which data are available.

## U.K. (Northern Ireland)

The number of commercial fishing licences issued in 1996 (195) was slightly lower than in 1995 (206). There were no changes in fishing season bye-laws or gear regulations. The provisional declared catch in 1996 fishery ( 77 t ) was lower than for the 1995 season ( 83 t ) and lower than the 5 -and 10 -year averages. Angling catches have been collected for the Foyle system, a total of 1444 fish being reported. Anglers reported only an average season although some rivers did well. Reliable rod CPUE estimates are available for the lower R Bush. CPUE was higher in 1996 ( 0.267 fish per rod day) than in 1995 ( 0.206 ), despite the lower adult run compared to the previous year.

Ranched fish, released from the R Bush experimental station, comprised 2.3 t of the nominal catch. Anecdotal evidence suggests that the incidence of farm escapees in the net catch was lower than in recent years. Only 2 fish ( $0.18 \%$ ) entering the R Bush trap were farm escapees.

In 1996, the exploitation rate in the net fishery on hatchery reared 1 SW fish $(81 \%$ for $1+$ smolts and $77 \%$ for $2+$ smolts) was considerably higher than the average for the previous 5 years. No estimates are available for other smolt groups.

## U.K. (Scotland)

In the last year, there have been restrictions implemented in two Salmon Fishery Districts with regard to the type of bait permitted. Prawns and shrimps have been banned on the rivers Ythan and Forth with the aim of reducing the effectiveness of angling. Effort indices for the net and coble and fixed engine fisheries in 1996 showed a $23 \%$ and $5 \%$ decrease respectively compared to 1995 . The final reported catch for 1995 was $587.9 \mathrm{t}, 2 \%$ greater than the previous 5 -year average (1990-1994) but $24 \%$ less than the previous 10 -year average (1985-1994). The partial 1996 figure (caught and retained) is 380.4 t . It is likely that the final figure for 1996 will not only be lower than that recorded in 1995 but, the lowest on record. In 1996, the fixed engine CPUE decreased by $26 \%$ and the net and coble CPUE decreased by $11 \%$ compared with 1995 . In $1996,38 \%$ of the reported catch was recorded as grilse. However, scale analyses of samples from major fisheries in each of the main statistical regions have indicated that the proportion of grilse is always greater than the reported figure as a result of 1 SW fish being misreported as MSW fish. The errors in classification are neither consistent between regions, nor between years. Of the 380.4 t caught and retained in $1996,379.8 \mathrm{t}$ was reported as wild salmon and 0.7 t was reported as farmed fish. The only fishery in Scotland for which there is a time series of exploitation rates is the North Esk net and coble fishery. In 1996, the exploitation rates for 1SW and MSW fish were $19 \%$ and $10 \%$ respectively. In general, exploitation rates have declined, particularly since 1991 when there was a major reduction in effort.

### 3.3.2 Gear

Regulations have been introduced in many countries in the NEAC area to reduce the efficiency of fishing methods in order to lower exploitation rates. In some rod fisheries, certain baits have been banned on some rivers or only certain methods (e.g. fly-fishing) are allowed at some times of year. In net fisheries, restrictions have been imposed on the materials from which nets may be constructed, and their dimensions and mesh sizes. No new restrictions on fishing gear were reported in 1996.

### 3.3.3 Effort

For the NEAC area, available data on effort, as described by numbers of gear units licensed or authorised, are listed in Table 3.3.3.1. In general, fishing effort has been declining substantially over the years for commercial fisheries although rod and line has been increasing in some areas. The number of gear units used in U.K. (England \& Wales), U.K. (Scotland), Ireland and U.K. (N. Ireland) has been declining fairly steadily. In almost all fisheries, the number of gear units licensed or authorised in 1996 was lower (by up to $53 \%$ ) than the 5 -year mean and also lower (by up to $66 \%$ ) than the 10-year mean. Increases on the 5 -year mean were only recorded for the Irish drift nets (3\%) and rods in Ireland (32\%) and on the R. Näätamö (Finland) (18\%). Further descriptions of the fishing effort for individual countries are provided in Section 3.3.1.

### 3.3.4 Catches

NEAC catch data are presented in Table 3.3.4.1. Figure 3.3.4.1 shows the percentage change of the 1996 NEAC homewater catch data relative the previous 5 -year mean (1991-1995) and the previous 10-year mean (19861995). For all 11 countries, the 1996 catch was below (by up to $57 \%$ ) the 1986-1995 mean and only the 1996 Ireland catch exceeded the 1991-1995 mean (by 8\%). Clearly, current catch levels are markedly lower than in the recent past. This is believed to reflect both reductions in fishing effort (Section 3.3.3) and reductions in stocks (Section 3.7.2).

Catch and release is being practised in a number countries. In some areas, fish that are released are still reported in the catch statistics. In other areas although they are not counted as part of the catch, no account is generally taken of fishery induced mortalities. The Working Group considered that efforts should be made to standardise the way that these catches are handled in the catch statistics.

### 3.3.5 Catch per unit effort (CPUE)

Catch per unit effort data where available for the NEAC area are presented in Tables 3.3.5.1, 3.3.5.2 and 3.3.5.3. A route regression analysis was used to examine trends in the data and the results are shown in Table 3.3.5.4.

Catch per unit effort in rod fisheries in Finland, France and on the River Bush (U.K., Northern Ireland) show no trend for catch per angler day for the last 10 years. However, there is a significant upward trend in CPUE for the whole season for rod fisheries in Finland and France for the same period ( $p<0.002$ ). This may reflect increasing rod effort. CPUE for fixed engine fisheries in England and Wales show no trend. For Scotland, there is a significant downward trend in CPUE in the net fishery ( $\mathrm{p}<0.001$ ). Changes in CPUE for different countries are described in Section 3.3.1.

### 3.3.6 Age composition of catches

The age composition of the catches are presented in Figure 3.3.6.1 for those countries where a time series of data exists. The proportion of 1SW fish in the 1996 catches is presented as a percentage, the 1991-1995 mean and the 1986-1995 mean proportions. In Finland and Russia, the proportion of 1SW fish in the catch has increased compared to the 1991-1995 and 1986-1995 mean proportions. In France, Norway and Sweden, the opposite is true with the proportion of 1SW fish having decreased. The current level of 1SW fish in the Scottish catch differs little from any of the standards it was compared to. Caution should be observed in interpreting these results as the split between the reported 1SW and MSW fish may be based on a weight categorisation as a proxy of sea age and may therefore not be accurate in all cases. However, even in these cases the data provide an index of real changes in growth and/or maturation.

### 3.3.7 Farmed and ranched salmon in catches

The contribution of wild, farm origin and ranched salmon to national catches in the North-East Atlantic in 19911996 is shown in Table 3.3.7.1. Farmed salmon continue to represent a large percentage of the national reported catch in both Norway ( $28 \%$ ) and Faroes ( $20 \%$ ) (see Section 3.2.3) and ranched salmon now account for $65 \%$ of the national catch in Sweden. Although Iceland produces a large tonnage of ranched salmon, practically all this is harvested at the production sites.

The occurrence of farmed salmon in several Norwegian net fisheries is shown in Table 3.3.7.2. Although the level has remained relatively stable over the period, in coastal fisheries, the incidence of farmed salmon (34$54 \%$ ) is consistently higher than that recorded in fjord fisheries ( $10-21 \%$ ). Furthermore, the incidence of farmed salmon in angling catches ( $4-7 \%$ ) is less than that in fjord fisheries. However, in broodstock samples, taken after the closure of the angling season, the incidence varied from $21-38 \%$ (Table 3.3.7.3).

Farmed fish formed less than $3 \%$ of the national catches in Ireland, U.K. (Northern Ireland) and U.K. (Scotland). The incidence of farmed salmon in the River Bush, U.K. (N Ireland), based on the operation of a total trap throughout the year, for the period 1991-1996 are given in Table 3.3.7.4. The occurrence of farmed salmon throughout the period has remained below $1 \%$ and the 1996 value of $0.18 \%$ is the second lowest recorded in this series.

The significance of these results is discussed further in Section 6.

### 3.3.8 National origin of catches

No new data on the national origin of salmon catches for the NEAC area were presented. While it is known that there are fish from neighbouring countries in homewater catches, no new analyses on the distribution or number of these fish has been carried out since 1994 (ICES 1994/Assess:16). These estimates were regarded as very approximate and so further effort should be made to provide a more accurate estimates of the level of catch by each country of stocks from other countries.

### 3.3.9 Exploitation rates in homewater fisheries

Exploitation rates for 11 wild stocks, 4 hatchery stocks and 3 mixed stocks are shown in Table 3.3.9.1. Increases in exploitation rates on stocks from Irish and U.K. (N. Ireland) rivers have been shown in recent years while a decrease is noted for one river in U.K. (Scotland) and one river in Russia. No other notable differences are shown. Although reported exploitation in some fisheries have changed, route regression analyses indicates that there has been no overall trend in exploitation in fisheries over the last 10-year or 5-year periods for either 1SW or 2SW stocks (Table 3.3.5.4).

### 3.3.10 Summary of homewater fisheries in the NEAC area

There has been a continuation in the trend to reduce commercial fishing effort in the Northeast Atlantic area in recent years, mainly reflecting conservation measures in the respective countries and the reduced value of commercially caught salmon. Minor changes in commercial and recreational salmon fishing effort were reported in 1996.

Provisional figures suggest that nominal catches of salmon in North East Atlantic countries in 1996 were generally below the 1995 values and for most countries they are still below the previous 5 - and 10-year averages. In general, fishing effort in terms of licences issued has been declining substantially over the years for commercial fisheries and increasing for recreational fisheries. CPUE was shown to increase in Finland and France for the rod fisheries and decrease for Scottish net and coble fisheries. No significant trend was noted for other fisheries in the NEAC area.

The proportions of 1SW fish in catches has increased for Russia and Finland, and decreased for Norway, Sweden and France. The proportion of 1 SW fish in national catches varied from $58 \%$ to over $90 \%$. The lowest proportions of 1SW fish in catches were reported in Norway, Finland and France (rod fishery) and the highest in Ireland, France (net fishery), Iceland and Russia.

Farmed salmon continue to represent a large proportion of the catch in Sweden (65\%), Norway ( $28 \%$ ) and Faroes ( $20 \%$ ). The incidence in catches is $<3 \%$ for samples taken in U.K. (N. Ireland) and is $<1 \%$ for catches in all other countries. Ranched fish continue to comprise the majority of the Icelandic catch (over $60 \%$ ) and some straying is observed into rivers. Ranched salmon comprise only a small proportion ( $<3 \%$ ) of the catches in Norway, Ireland and U.K. (N Ireland).

Reported exploitation rates in some fisheries have changed, but no trend in fisheries is noted over the previous 5or 10 -year periods.

### 3.4 Status of Stocks in the NEAC Area

### 3.4.1 Attainment of spawner reference levels

Progress with the development of biological reference levels for stocks in the NEAC area is discussed in Section 3.6.

Spawner requirement reference levels and time series of compliance data have been provided for seven rivers in the NEAC Area (Table 3.4.1.1). Most of these are monitored rivers where stock-recruitment data have been collected over a number of years. Where possible, threshold levels have been set at the MBAL for the stocks (max. gain on the appropriate stock-recruitment relationship) according to guidelines presented in Section 8.1.1 of the 1995 Working Group Report (ICES 1995/Assess:14). These should therefore be regarded as a threshold levels and not as targets. For the Tuloma river (Russia), however, the reference point is a target for the number of female spawners required to give optimal recruitment.

Spawning thresholds have only been exceeded in the rivers Scorff and Nivelle (France) and N Esk (U.K. (Scotland)) in 1996. No significant trend in attainment of spawner requirements has been noted for the last 10 years (Table 3.4.1.2). However, a significant downward trend is shown for the last 5 years for all rivers combined. This is principally due to decreases in the egg deposition for the Burrishoole (Ireland), Bush (U.K. (N. Ireland)) and the Tuloma (Russia).

It should be stressed that no information is available on the majority of the river stocks in the NEAC Area and those for which data are provided are not necessarily indicators of the status of stocks in other areas.

### 3.4.2 Measures of juvenile abundance

Counts or estimates of juvenile abundance are available for 23 rivers (Table 3.4.2.1) and full counts are shown for eight of these. Values in 1996 were lower than the means for the last 5 years for Icelandic, U.K. (Scotland), Norwegian and Swedish rivers while values were higher than the mean for the previous 5 years for French rivers.

There is no evidence that freshwater productivity has declined in the NEAC area from these data. Route regression analyses show no significant trends in juvenile production in these rivers over the last 10- or 5-year period (Table 3.4.1.2).

### 3.4.3 Measures of spawning escapement

Adult counts or estimates are available for 28 rivers in the NEAC area (Table 3.4.3.1). The counts in 1996 were generally lower than the mean for the last 5 years for rivers in Russia, Ireland, U.K. (Scotland) and U.K. (N. Ireland). Higher estimates were obtained for some U.K. (England and Wales) rivers.

Due to differences in the size of stocks considered and their migration patterns, route regression analyses were carried out separately for adult counts in Russian rivers and other NEAC rivers (Table 3.4.1.2). An increasing trend is shown for Russian adult counts over the last 30 - and 20 -year periods. A significant downward trend is indicated for the last 10 years while there has been no significant trend in the most recent 5 years in the data series.

There was no trend noted for the other rivers in the NEAC area over the last 10 - or 5 -year periods.

### 3.4.4 Survival indices

Estimates of marine survival for wild smolts from nine stocks returning to homewaters (i.e. before homewater exploitation) and for eight stocks returning to freshwater in 1996 are presented in Tables 3.4.4.1 and 3.4.4.2 respectively. In Table 3.4.4.2, indices of return rates are also provided from autumn $0+$ parr for the Nivelle river (France). This provides an approximation of marine survival as more than $80 \%$ of the juveniles emigrate after only 1 year in freshwater.

Marine survival rates for six hatchery stocks are given in Tables 3.4.4.3 and Tables 3.4.4.4. The Working Group noted that estimates of return to homewaters are likely to present a clearer picture of marine survival than returns to freshwater because of variation in exploitation in coastal fisheries. No clear trends in survival were noted for any individual stock. However, route regression analyses of combined river data showed a significant downward trend for the last 10 years for wild 1 SW and 2 SW fish and hatchery 1 SW fish, but no trend for the last 5 years (Table 3.4.1.2). For 2SW hatchery fish, there was no trend shown for either period.

### 3.4.5 Summary of status of stocks in the NEAC area

Estimates of spawner requirements were presented for seven rivers in the NEAC area. In 1996, spawning thresholds were only exceeded in the Scorff and Nivelle (France) and the North Esk (U.K. (Scotland)). A significant downward trend in egg deposition was noted for the previous five-year period for all rivers combined.

Examination of the general trends from the analyses carried out in the previous sections suggests that there has been no significant change in smolt production in the Northeast Atlantic as a whole. Adult runs in western European rivers showed no significant trend in run size over the last 10 years. An increasing trend in spawning escapement was noted for Russian rivers over the previous 20- and 30 -year period. Over the most recent 10 -year period a decreasing trend has been noted. No trend is apparent for the previous 5 -year period for these Russian rivers.

Survival indices for combined river data for the NEAC area indicate a downward trend in survival to homewaters for the last 10 years for 1SW and 2SW wild stocks and 1SW hatchery stocks. No trend was noted in the most recent 5-year period.

An assessment of pre-fishery abundance for stocks in the NEAC Area is provided in Section 3.7.2.

### 3.5 Evaluation of the Effects of the Suspension of Commercial Fishing Activity at Faroes

Since 1991 the Faroese fishermen have agreed to suspend commercial fishing for the salmon quota set by NASCO in exchange for compensation payments. The number of fish saved as a result of this suspension is the catch that would have been taken if the fishery had operated minus the catch in the research fishery (Table 3.1.2). The maximum catch that would have been taken is given by the quota, but in the three years prior to the suspension of fishing (1988-1990) the quota was not taken in full.

The Working Group has previously examined the likelihood of the full quota being taken at Faroes in the 1991/92-1993/94 fishing seasons if the fishery had operated (ICES 1996/Assess:11). It was felt that the quota might have been taken if there had been an increase in the availability of salmon in the area; an increase in the number of vessels operating or the amount of gear used; or more favourable fishing conditions permitting increased effort by each vessel. However there was no evidence that such changes had occurred. The Working Group therefore considered that the mean annual catch for the $1988 / 89$ to $1990 / 91$ seasons ( 87,484 fish) provided the best estimate of the expected catch in each of the subsequent four seasons. In the absence of any new data the Working Group considered that this was also the best available estimate of the likely catch in the 1995/96 season.

Data on the expected discard rate, the proportion of farm escapees in catches, the expected age composition of the catch, and the expected time to return were obtained from research vessel catches in the 1991/92 to 1994/95 seasons and previous published data (ICES 1996/Assess:11). No new values of these parameters were available for the 1995/96 season and so means for the previous four seasons were used. The assessment is shown in Table 3.5.1.

This suggests that between 1,600 and 10,000 extra 1 SW salmon and between 40,000 and 71,000 extra MSW salmon returned to homewaters each year from 1992 to 1996. In addition, nearly 107,000 extra farmed fish are expected to have been saved from the Faroes fishery in the five seasons of the suspension. It is not known whether these fish will have returned to the areas from which they escaped. If so, and assuming the number of escapees is proportional to the production in each country, about $70 \%$ of the survivors might be expected to return to Norway and $20 \%$ to Scotland.

Estimates (means of 1000 simulations) of the total numbers of MSW salmon returning to homewaters in the NEAC area and to countries in Northern and Southern Europe are provided in Table 3.7.2.1. The additional returns of MSW fish represent $3 \%$ to $7 \%$ of the estimated returns to homewaters between 1992 and 1996. However, analyses of smolt tagging data (e.g. ICES 1993/Assess:10) and results from the adult tagging studies (Section 3.2.2) show that the majority of the MSW salmon caught in the Faroes fishery would return to Scandinavian countries, Finland and Russia. The estimates from the adult tagging studies suggest that about $65 \%$ of the saved wild MSW fish might have returned to these countries; if this were the case they might have represented $4 \%$ to $9 \%$ of the returns of MSW fish between 1992 and 1996. If stocks and fisheries had remained stable, total catches would have been expected to increase by approximately the same proportions in the respective areas.

Catches in homewater fisheries in four areas of Europe (Table 3.5.2) were examined to see whether here had been a significant change following the suspension of fishing at Faroes in 1991. The only significant change was a reduction in catches of 1 SW salmon in Norway (Rcrit, $\mathrm{p}=0.004$ ) and in southern Europe (Ireland, U.K. (England \& Wales), U.K. (Scotland), and France) (Rcrit, p = 0.02). No detectable change was noted for 1SW catches in Northern Europe (Finland, Sweden and Norway) or for adult counts to Russian rivers in the same period. (It should be noted that catches of MSW salmon in Europe in 1994 and 1995 should also have been affected by the suspension of salmon fishing in Greenland). Although the additional returning fish are expected to have contributed to catches and spawning stocks, it appears that any increase in catches has been too small to be detected as a statistically significant change above the normal annual variation or has been masked by other factors such as changes in marine survival or exploitation rates in homewaters.

### 3.6 Development of Age Specific Spawning Targets

In its 1995 report to NASCO, the ICES Advisory Committee on Fishery Management (ACFM) recommended that "all countries should establish preliminary spawning targets for all their rivers as soon as possible" (NASCO 1995). Subsequently, NASCO requested ICES to "Provide estimates of age specific spawning targets" (NASCO 1995, p. 102). In order to be consistent with present ICES terminology, we have used the term conservation (or limit) reference points instead of "spawning targets" (see Section 2.5 of this report). Furthermore, the two requests were not identical. In the latter, a request for "age specific" reference points was specified. The Working Group advises against defining conservation points only on an age specific basis. In some catchments, genetically distinct populations inhabiting subcatchments within a river system have been identified. Age specific reference points are not sufficient to provide adequate protection for these populations, and other approaches will also need to be developed.

Member countries from the North East Atlantic Commission Area have generally accepted the need for developing biological reference points (MBALs and target fishing levels) for salmon, and some have made considerable progress toward this end (Table 3.6.1). However, certain countries are faced with complicating factors (see below) and do not foresee having significant numbers of reference points in place within the next 5 years.

Complicating factors include:

- Data bases for calculating stock-recruit relationships or long term trends are rare;
- Extrapolation of information from the limited number of rivers where relatively complete information is available, to other rivers of different physical characteristics or in different geographic areas is questionable in some areas;
- The salmon runs entering a river may be composed of discrete populations, which occupy spatially distinct areas within the system, differ in their biological characteristics and do not interbreed (e.g. spring salmon versus autumn salmon). Hence conservation limits may have to be set for each discrete population;

It will take time, additional resources and research to develop the necessary information to set population conservation points for all rivers. Section 2.6 of this report discusses these issues further.

Progress with the development of reference points for rivers in the NEAC area includes:
Russia: Target reference points have been established for the Tuloma River, based on a stock recruit relationship derived for this system and estimates of the production potential of the river. The reference points are being used to provide management advice in the Tuloma fisheries. In the next five years, it is hoped that points will also be established for the Ponoy and Kola rivers as well. All these systems are on the Kola peninsula.

Norway: Biological reference points are being developed for the River Imsa. Eventually, it is hoped to establish reference points for all Norwegian river, but this will take more than 5 years.

Sweden: An attempt is being made to establish reference points for the River Högvadsån. At present, there is no evidence that the spawning biomass regulates salmon production in the river. More work will be carried out on the system, as it is the only one where the necessary data can be obtained at present.

Iceland: Habitat surveys are currently being carried out to estimate the productivity of two Icelandic rivers, with the goal of developing spawner levels at least for these rivers. However, in the short term ( 5 years), it may not be possible to extrapolate from these sites to other Icelandic rivers and values from these sites are not appropriate for all Icelandic rivers.
U.K. (Northern Ireland): Biological reference points from a monitored river (Bush) are available and methods are being developed to extrapolate from this and other information to set reference points for all significant salmon rivers. Reference points will also be established for major tributaries within some river systems.

Ireland: Biological reference points from a monitored river (Burrishoole) are available, and methods are being developed to extrapolate from this and other information to set reference points for all significant salmon rivers. This has been called for in Ireland's new salmon strategy (Salmon Management Task Force 1996). To this end resources are available to establish accurate reference points for a further 16 rivers.
U.K. (England and Wales): The development of biological reference points for all salmon stocks is and established part of the Environment Agency's salmon management strategy (Environment Agency 1996), and methodologies have been developed to transfer reference point data from the River Bush (U.K. (N. Ireland)) (Environment Agency 1996). Preliminary MBAL levels have been set for all rivers (Table 3.6.2) and these will be reviewed and updated with the preparation of Salmon Action Plans for all salmon producing rivers over the next four years.

France: Methodologies have been developed to extrapolate reference points from a monitored river (Oir) to other systems (ICES 1996/Assess:11). In some cases, data collection has begun in other rivers so that stock/recruit relationships can be calculated (e.g. the Scorff). As more appropriate data become available,
existing reference points will probably be modified. Table 3.6 .3 summarises the present reference points for French rivers.

### 3.7 Catch Options with an Assessment of Risk

### 3.7.1 Introduction

It has previously been suggested that the Working Group would attempt to work towards developing a model for salmon stocks in NEAC countries (as one or more groups) similar to that for North American stocks which is used to provide catch advice for the WGC Area and NAC Area. This requires the development of spawning escapement reference levels for all stocks in the area and a capability to predict the pre-fishery abundance of the stocks prior to the fisheries commencing. Considerable progress is being made with setting MBAL levels for spawner escapement in a number of countries and others have indicated that they intend to develop such data in the next few years. However, this is an immense task in some areas; Norway for example will have to set reference levels for 669 rivers. In addition, some countries have indicated that the development of spawner reference levels is not currently planned; this includes major salmon producing countries in both southern and northern Europe. In the absence of such data it will not be possible to provide catch options for the NEAC area using similar methodology to the WGC.

Nevertheless, the Working Group considered that the description of trends and, if possible, prediction of prefishery abundance of stocks in the NEAC area was useful. The work commenced in 1995 and 1996 has therefore been further developed below. The Working Group has also considered additional information on levels of exploitation which may provide a rational basis for the consideration of quotas in the distant water fisheries.

### 3.7.2 Pre-fishery abundance estimates for the NEAC area

The Working Group considered developments in the methods to estimate the pre-fishery abundance of maturing and non-maturing 1SW salmon in the NEAC area. The model developed in 1995 estimated pre-fishery abundance from the catch in numbers of 1SW and MSW salmon in each country, which were then raised to take account of minimum and maximum estimates (or guess-estimates) of non-reported catches and exploitation rates on the two age groups. Finally they were raised to take account of maximum and minimum estimates of the natural mortality between the first sea winter and the mid-point of the national fisheries.

Thus the minimum and maximum estimates of pre-fishery abundance for each age class in each country were estimated as follows:
and $\quad \mathrm{PFA}_{\mathrm{i}(\max )}=\mathrm{C}_{\mathrm{i}} /\left(1-\mathrm{R}_{\mathrm{i}(\max )}\right) / \mathrm{E}_{\mathrm{i}(\min )} / \mathrm{S}_{\mathrm{i}(\min )}$
where: $\quad \mathrm{C}_{\mathrm{i}}=$ catch in numbers of salmon sea age group ' i ' (maturing 1 SW or non-maturing 1 SW )
$\mathrm{R}_{\mathrm{i}(\min )}$ and $\mathrm{R}_{\mathrm{i}(\max )}=$ minimum and maximum guess-estimates of the proportion of the total catch of age group ' i ' salmon that is unreported.
$\mathrm{E}_{\mathrm{i}(\min )}$ and $\mathrm{E}_{\mathrm{i}(\max )}=$ minimum and maximum estimates of the average level of exploitation on age group ' i ' salmon in the country.
$\mathrm{S}_{\mathrm{i}(\min )}$ and $\mathrm{S}_{\mathrm{i}(\max )=}$ minimum and maximum estimates of the survival from beginning of first sea winter to mid point of homewater fishery for age group ' i ' salmon (assuming values of M of 0.05 and 0.015 per month) and maximum and minimum times between homewater fisheries and the time of recruitment.

In 1996, minimum and maximum estimates of pre-fishery abundance were derived for all countries in the NEAC area for the period 1971-1995 (ICES 1996/Assess: ). These estimates were given in the report, although the Working Group expressed caution about using the mid point of the calculated ranges as reliable estimates of the pre-fishery abundance until further efforts had been made to improve the estimates.

The Working Group recognised that the minimum to maximum range shown previously overstated the uncertainty in the estimates as values near the extremes were less likely to occur than those nearer the mid-points.
(Values near the extremes will only occur if all parameter values are near one extreme, but values near the middle will occur both if parameter ' $a$ ' is near the maximum and parameter ' $b$ ' is near the minimum or vice versa).

The Working Group employed @Risk in Excel to generate estimated distributions of pre-fishery abundance values by simulating repeated runs of the model. The same parameter values were used as in 1996, except where these were updated or corrected; these values were considered likely to encompass the full range of true values. Each unknown parameter was entered as an @Risk function using the uniform distribution (RiskUniform). A single @Risk function was used for series of years where the min-max range of a parameter remained the same. The model was run separately to estimate the total numbers of maturing and non-maturing 1 SW recruits in the NEAC area and the numbers in the southern and northern European countries (see table below); each run was based on 500 simulations.

| Southern European countries: | Northern European countries: |
| :--- | :--- |
| Ireland | Iceland |
| France | Finland |
| U.K. (England \& Wales) | Norway |
| U.K. (Northern Ireland) | Russia |
| U.K. (Scotland) | Sweden |
| (Greenland catches) | (Faroes catches) |

The Working Group recognised that the split between northern and southern European salmon producing countries is somewhat arbitrary, although a greater proportion of the salmon from Scandinavian countries and Russia are believed to feed in the Norwegian Sea, and a greater proportion of fish from southern European countries migrate to West Greenland. In particular, it was emphasised that wherever a split is made the stocks from rivers on either side of this artificial boundary are likely to behave in a similar manner. This has been demonstrated by the correlation in smolt to adult survival for fish from the R. Figgio (southern Norway) and N. Esk (Scottish east coast) (Section 2.). Nevertheless, salmon stocks in the NEAC area are spread over a very wide range of habitat types and are exposed to differing environmental factors; they are therefore likely to exhibit different trends. The Working Group agreed that the division used in 1996 (based upon the oceanic divide of the North Sea) provided the simplest split at present, but recommended that other groupings should be considered in the future.

The results of the @Risk simulation model (mean and 95 percentiles values for 500 simulations) are shown in Table 3.7.2.1 and Figures 3.7.2.1 to 3.7.2.3. They appear to provide a clearer picture of the likely trends in the salmon stocks in the NEAC area. Trendlines have been inserted in figures where the relationship is significant ( $\mathrm{p}<0.01$ ), but these should only be regarded as indicative of likely trends as they are based only upon the mean figures).

It appears that the maturing component of the southern European stocks has declined by more than $50 \%$ from the early 1970s to the early 1990s, although stocks appear to have stabilised at a low level in recent years. It should be noted, however, that the early 1970 s was a period of high grilse abundance, and the data might, in part, be showing the decline from a peak. It is also possible to see the periods of slightly improved abundance in the mid1980s and the years of poor survival around 1990 which have been noted previously by the Working Group.

The non-maturing 1SW component of the southern European stocks has also declined. The mean estimate has fallen by around $60 \%$ over the 25 year time period, and the series is highly correlated with time ( $\mathrm{R}^{2}=0.77$ ). There is some evidence that the decline has stabilised since the late 1980s, although the 1997 value is the lowest in the time series. (These data are plotted on the same scale as the maturing recruit figures to aid comparison). This is the component of the NEAC stocks which is expected to contribute to the West Greenland fishery. The lack of additional variation in the data may make the task of developing predictive models very difficult.

The estimates of both maturing and non-maturing pre-fishery abundance for the northern European stocks show less clear trends (it should be noted that these figures are plotted on a larger scale than the data for southern European stocks). Nevertheless there appears to have been a steady decline in the maturing component of the stocks over the last nine years and in a similar period the abundance of non-maturing recruits has dropped to the lowest level in the series.

### 3.7.3 Levels of exploitation by Faroes fishery

The levels of exploitation in the Faroes fishery of salmon from various monitored rivers in the NEAC area have been estimated from microtag and external tag recoveries for a number of years (Table 3.7.3.1). No new tag recoveries were reported from the research fishery in 1995/96. The data sets for hatchery and wild 2SW salmon from the R. Imsa (Norway) and for wild 2SW salmon from the N. Esk (U.K. (Scotland)) show significant linear correlations between the level of exploitation and the catch in the Faroes fishery ( $\mathrm{R}^{2}$ values $0.69,0.77$ and 0.72 respectively; $\mathrm{p}<0.001$ in all cases) (Figure 3.7.3.1). The data for wild Imsa fish may indicate a non-linear relationship, with exploitation rates of $<10 \%$ for all catch levels below about 300 t ; however the choice of a linear relationships is supported by the existence of a very similar linear relationship for the hatchery fish.

There was no significant relationship for either the R. Drammen (Norway) or the R. Lagan (Sweden) 2SW salmon, but this may reflect the fact that many of the exploitation rate estimates were based on few tag recaptures and were therefore likely to be very imprecise. For 1SW salmon from the N.Esk (U.K. (Scotland)) and both 1SW and 2SW salmon from monitored sites in Ireland, U.K. (N. Ireland) and U.K. (England \& Wales) the levels of exploitation at Faroes have been too low (generally $<1 \%$ ) to demonstrate a relationship.

Clearly other factors will affect the level of exploitation of specific stocks. However, the three relationships shown can be used to provide rough guidance to managers on the likely impact of different levels of catch at Faroes on stocks from Norway and Scotland. The regression equations for 2 SW hatchery and wild salmon from the river Imsa are very similar, suggesting similar patterns of exploitation of these stock components at Faroes; this differs from patterns of exploitation in homewaters where hatchery fish tend to be more heavily exploited than wild fish in coastal fisheries because of delayed entry into fresh-water.

### 3.7.4 Development of catch advice

The assessment of pre-fishery abundance provides an indication of trends in stock abundance and suggests that numbers of maturing and non-maturing recruits in the NEAC area are around their lowest level in the past 25 years. The maturing components of the northern European stocks appears to show an alarming downward trend in recent years. The southern European stocks (maturing and non-maturing) and the non-maturing component of the northern European stocks may have stabilised at their current depressed levels.

Although these data cannot be compared with spawning requirement data for the relevant regions, they suggest that a precautionary approach is called for in the management of fisheries, particularly where they exploit mixed river stocks.

The relationship between catch at Faroes and levels of exploitation described above can be used to provide guidance on the approximate effects of different quota levels at Faroes on the exploitation of salmon stocks from Norway and Scotland (Table 3.7.4.1). Estimates for wild and hatchery fish from the Imsa have been averaged to provide a single data series. This suggests that the 1997 quota level of 425 t for the Faroes fishery represents a potential exploitation rate of the order of $22-25 \%$ on Norwegian (Imsa) stocks and $3-4 \%$ on Scottish (N. Esk) stocks. Exploitation rates on 1SW Norwegian and Scottish stocks and on 1SW and 2SW stocks from other southern European countries are likely to be lower ( $<3 \%$ ).

### 3.8 Catches of Post-Smolts in the Norwegian Sea

### 3.8.1 Results of post-smolt surveys in 1991-96

In 1996 the Working Group reported on a pair-trawling experiment for herring conducted in July/August 1991 in the northern Norwegian Sea which resulted in a by-catch of 34 postsmolts and 21 SW salmon (ICES 1996/Assess:11). This coincided with the development of a new pelagic research trawl designed to operate in 025 m depth. The Institute of Marine Research (IMR, Norway) has now included salmon sampling in their survey programme for pelagic species, which began on an experimental scale, but from 1995 onwards has been conducted on a regular basis as part of a large-scale ecology study in the Norwegian Sea, the so called "Mare Cognitum Programme" (MCP) (Holst et al. 1993, Valdemarsen and Misund 1995, and Holm et al. 1996b). The successful application of the surface trawl technique for capturing postsmolts led to the method being tested with a similar but smaller trawl by the SOAEFD, Marine lab. with equal success in the area between NW Scotland, the Shetlands and the Faroes in June 1996 (Shelton et al. 1996). As it has been anticipated that most of the larger fish (1SW and older) avoid being caught by the trawl, the IMR conducted experiments in 1995 and 1996 with
floating long-lines, driftnets and a specially developed otter board trolling device for use on board the 64 m research ship. Six 1SW salmon were caught, but these fishing methods did not catch post-smolts.

From 1991 to 1995, 507 surface trawl hauls have been made covering an area from the south-west of Ireland $\left(50^{\circ} \mathrm{N}\right)$ up to $75^{\circ} \mathrm{N}$, east of Bear Island. A total of 404 postsmolts and eleven 1 SW fish have been caught (Table 3.8.1.1 and Figure 3.8.1.1).

A large number of postsmolts have been recorded in some of the hauls west of the Hebrides and along the Wyville-Thomson Ridge suggesting that post-smolt salmon may form schools in the open sea and that the fish in these areas have been concentrated by a narrow northward flowing slope current along the north-west European continental shelf edge (Holm et al. 1996b; Shelton et al. 1996). The mean length of postsmolts increased northwards, possibly because the northerly surveys were conducted later in the summer and the fish had been feeding for a longer time. The proportion of 1 year smolts was significantly higher in the northern than in southern areas indicating that a relatively large proportion probably originated from more southerly areas. This observation is supported by the retrieval in 1995 and 1996 of two microtagged fish tagged the same year in south England and Ireland respectively. Both these fish were captured north of $70^{\circ} \mathrm{N}$ together with other untagged postsmolts (Holst et al. 1996).

Some of the post-smolt captures have been plotted in relation to salinity and water temperature. During a cruise in the eastern and northern Norwegian Sea (cruise 1995 b, Table 3.8.1.1) all post-smolts except two were captured in areas where the salinity exceeded 35 ppm (Holm et al. 1996a). A similar observation was reported from the Scottish surveys, where all smolts were caught in the warmest and most saline waters during a cruise 1996 along the Wyville- Thomson Ridge.

### 3.8.2 Potential of by-catch of post-smolts in pelagic fisheries

The fishery for mackerel and Norwegian spring spawning herring are the two major fisheries for pelagic species occurring in the Norwegian Sea during summer. The mackerel fishery uses mainly pelagic trawls similar to that used to sample postsmolts. The herring fishery on the other hand employs predominantly purse seines. The catches of mackerel off the Faroes (Division Vb) and in the Norwegian Sea (Division Ia) has varied from about 50,000-165,000 metric $t$ in the period from 1983-95 (ICES 1997/Assess:3). The fishery as a rule starts in the Faroese zone in early July and moves northward in the international zone with the northward migration of the western mackerel stocks. The fishery for Norwegian spring spawning herring in the Norwegian Sea started in 1994 and has increased rapidly. Only a small tonnage has been taken with pelagic trawls. In 1996 the catches of herring in the Norwegian Sea were more than $300,000 \mathrm{t}$.

Both the fishery for mackerel and herring in the Norwegian Sea overlap geographically with the anticipated routes of European post-smolts on their northward feeding migration. To some extent the fishery has been observed to coincide with the post-smolt migration paths as a large fleet was observed trawling in international waters just outside the Norwegian EEZ at around $66^{\circ} \mathrm{N}$ during cruise 1995 b (Table 3.8.1.1) in July. (Holm et al. 1996b). A Norwegian Carlin tag from a smolt release in the Trondheimfjord in May 1996 was retrieved by a fisheries control officer during a screening of the mackerel catch on a pelagic trawler in international waters in the Norwegian Sea in the summer 1996. No data on the possible by- catches of post-smolts in purse-seine catches is available.

The data for estimating the size of such by- catches is unavailable at the present. Provided the trawl methods used in the surveys were comparable with those used by the commercial fishery, the catch- rates from the scientific trawl fishery could be used for estimating smolt numbers from the commercial catches. However, so far almost no information about the trawls used, the fishing depth, towing time and speed etc. is available, and thus no estimates are possible. It is also thought that to catch post-smolts the trawl must be operated in the surface mode, i.e. from 0 m down, but it is not known whether the commercial trawls are used in this way.

The pelagic fishery in the area concerned is presently at a high level. Although these fisheries are anticipated to have reached their peak and are expected to decline slowly over the years to come, an effort to investigate the possible interception between those fisheries and post-smolt migrations would be of great importance for a proper assessment of post-smolt mortality.

### 3.8.3 Potential of by-catch in herring and redfish fisheries

An important trawl fishery for redfish occurs on the Reykjanes Ridge in the Norwegian Sea and there is anecdotal information that post-smolts have been observed among catches. The necessity to quantify possible post-smolt by-catches in this fishery therefore is as high as for the pelagic fisheries.

### 3.9 Data Deficiencies and Research Needs in the NEAC Area

1. The Working Group recognises the importance of the results generated from the research fishery programme in the Faroes area and would recommend a continuation of the research fishery.
2. Further information is required on the by-catch of post-smolts in marine fisheries. The Working Group strongly endorses the continuation of the post-smolt surveys in the North East Atlantic.
3. Efforts should be made to standardise the way that catch and release data are handled in the catch statistics in order to provide an unbiased estimate of mortalities due to fishing.
4. The Working requires guidance on the way that ACFM and NASCO would like production of ranched fish to be handled in the various catch tables.
5. Further work is required on the development of biological reference points for stocks in the NEAC area. Consideration should be given to the development of population specific concepts with respect to setting and using spawning reference levels.
6. Efforts should be made to provide more accurate estimates of the level of catch by each country of stocks originating from other countries.
7. Relationships between environmental parameters and marine survival of salmon stocks in the NEAC area need to be developed.

## 4 <br> FISHERIES AND STOCKS IN THE NORTH AMERICAN COMMISSION AREA

### 4.1 Description of Fisheries

### 4.1.1 Gear and effort

## Canada

The 23 areas for which DFO manages the salmon fisheries directly are called Salmon Fishing Areas (SFA); for Québec, the management is delegated to the Ministère de l'Environnement et de la Faune and the fishing areas are designated by Q1 through Q11 (Figure 4.1.1.1). Harvest (fish which are killed and retained) and catches (including fish caught and released in recreational fisheries) are categorised in two size groups: small and large. Small salmon in the recreational fisheries refer to salmon less than 63 cm fork length, whereas in commercial fisheries, it refers to salmon less than approximately 2.7 kg whole weight. Large salmon in recreational fisheries are greater than or equal to 63 cm fork length and in commercial fisheries refer to salmon greater than or equal to about 2.7 kg whole weight.

Three user groups exploited salmon in Canada in 1996: Native peoples, commercial fishers, and recreational fishers. The following management measures were in effect in 1996.

Native peoples fisheries: In Québec, Native peoples food fisheries took place subject to agreements or through permits issued to the bands. There are nine bands with food fisheries in addition to the fishing activities of the Inuit in Ungava. The permits generally describe gear and fishing effort and catch limits. In the Maritimes and Newfoundland (SFAs 1 to 23), food fishery harvest agreements were signed with several Native peoples in 1996. The signed agreements included allocations of small and large salmon. Data for harvests which occurred both within and outside agreements were obtained directly from the Native peoples. The Conne River (SFA 11) food fishery did not occur in 1994, 1995 and 1996 because the expected returns were below the conservation
requirement for the river. Harvest by Native peoples with recreational or commercial licenses are reported under the recreational and commercial harvest categories.

Commercial fisheries: The five-year moratorium which was placed on the commercial fishery in insular Newfoundland in 1992 continued in 1996. In Labrador, commercial fishing quotas assigned by SFA were reduced further from 1995 and the number of fishers declined minimally (Table 4.1.1.1). The opening of the Labrador commercial fishery was moved forward to June 20 from the delayed opening of July 3 in 1995. Previously, the Labrador commercial fishery opened on June 5. The delay in 1996 from the pre-1994 opening date was intended to reduce the exploitation rate on the large salmon and improve the escapement to the rivers. The season was to close on October 15 or sooner if the quota was caught. Commercial fisheries in Québec in 1996 occurred in zone Q9 (July 1 to August 23) and in Ungava Bay (zone Q11 by Native peoples). The quota for Q9 in 1996 was reduced by $20 \%$ from 1995.

Recreational fisheries: Management in 1996 differed by geographical area (Figure 4.1.1.2). Except in Québec and Labrador, only small salmon could be killed and retained in the recreational fisheries. The seasonal bag limits in the recreational fishery remained at eight small salmon in New Brunswick (SFA 15, 16) and Nova Scotia (SFA 18 and 21) with a daily limit of two retained. In SFA 17 (PEI), the season and daily bag limits were 7 and 1 respectively. Catch-and-release fishing for all sizes of Atlantic salmon was in effect in SFA 20 of Nova Scotia and SFA 23 of New Brunswick. SFA 22 was closed to salmon angling. For insular Newfoundland (SFA 2 to 14A), the seasonal bag limit was similar to 1994 and 1995: six fish of which three small salmon could be retained prior to July 31 and three small salmon after that date. After the bag limit of three was reached in each time period, catch-and-release fishing only was permitted. In Labrador (SFA 1, 2 and 14B), there was no seasonal division of the bag limit but the season limit for large salmon was set at one as in 1995 with a daily limit of two fish. In Québec, season and bag limits varied by zone: for Q1 to Q8 and Q10, the season limit was 7 fish of any size. For rivers in zone Q9 and Q11, the season limit was 10 fish. In most rivers of zones Q1 to Q7 and Q10, fishing for the day would end if the first fish kept was a large salmon. If the first fish kept was a small salmon, then fishing could continue until a second fish was caught, regardless of the size of the second fish. Daily limits in zone Q8 were two fish, Q9 it was three fish and in Q11 it was four fish.

## U.S.A.

Angling for sea-run Atlantic salmon in the U.S.A. is permitted only in the State of Maine, and in 1996 the sport fishery was again restricted to catch-and-release. Because of the restrictive management measures put into force in recent years license sales have declined by $50 \%$, from an average of 2,873 during the period 1989-1993 to 1,415 in 1996. The number of licenses sold is not a good indicator of angling effort however, since there is little incentive for anglers to purchase a license when salmon must be immediately released.

## France (Islands of Saint-Pierre and Miquelon)

For the Saint-Pierre and Miquelon fisheries in 1996, there were 10 professional fishermen using an estimated $10,400 \mathrm{~m}$ of surface gillnet, similar to values last reported in 1994. There were 42 licensed recreational gillnet fishermen using an estimated $7,560 \mathrm{~m}$ of surface gillnet. In 1994, there were reported to have been 26 recreational fishermen using $13,860 \mathrm{~m}$ of gear.

### 4.1.2 Catch and catch per unit effort (CPUE)

## Canada

The provisional harvest of salmon in 1996 by all users was 291 t , an increase of $12 \%$ by weight from the 1995 harvest of 260 t (Table 2.1.1). The 1996 harvest represented about 87,141 small salmon and 30,066 large salmon, an increase of $41 \%$ for small salmon but a reduction of $12 \%$ for large salmon from the 1995 harvests (Table 2.2.1).

The dramatic decline in harvested tonnage since 1988 is mostly the result of the large reductions in commercial fisheries effort and, since 1992, the closure of the insular Newfoundland commercial fishery (Figure 4.1.2.1). The abundance of salmon has also declined.

The 1996 harvest of small and large salmon, by number, was divided among the three user groups in different proportions depending on the province and the size group exploited (Table 4.1.2.1). Newfoundland reported the
largest proportion of the total harvest of small salmon and Québec reported the greatest share of the large salmon harvest. Recreational fisheries exploited the greatest number of small salmon in all the provinces and overall in Canada ( $81.3 \%$ ). Commercial fishers took the largest share of large salmon ( $49.7 \%$ by number). Native peoples harvested $4.5 \%$ (by number) of the total small salmon and $19.1 \%$ of the total large salmon harvests in eastern Canada.

Native Peoples Fisheries: In many cases, Native peoples food fisheries harvests in 1996 were less than the allocations. Harvests in 1996 (by weight) were $21 \%$ above the previous year's harvest and $10 \%$ above the previous 5-year average harvest. The proportion of the harvest composed of large salmon remained unchanged relative to previous years.

| Harvests | 1990 | 1991 | 1992 | 1993 | 1994 | 1995 | 1996 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Weight $(t)$ <br> \% Large <br> by weight | 31.9 | 29.1 | 34.2 | 42.6 | 41.7 | 32.8 | 39.8 |

Recreational Fisheries: Harvest in recreational fisheries in 1996 totalled 80,438 small and large salmon, $14 \%$ above the previous five-year average and $47 \%$ above the 1995 harvest level (Figure 4.1.2.2). Harvests of small salmon increased $19 \%$ from the previous five-year mean while harvests of 9,598 large salmon were a $10 \%$ increase. Harvests of small salmon were $20 \%$ above the harvests in 1995 and this size group has contributed more than $86 \%$ on average of the total harvests since the imposition of catch-and-release recreational fisheries in the Maritime and insular Newfoundland (SFA 3 to 14B, 15 to 23) fisheries in 1984.

Recreational catches (including retained and released fish) of small salmon in 1996 increased relative to the 1984 to 1993 mean in most fishing areas of Québec, Newfoundland and Labrador (Figure 4.1.2.3). Catches of large salmon were up in the Gulf shore of Nova Scotia (SFA 18) and the Québec/New Brunswick Chaleur Bay area (SFA 15, Q1 and Q2). Catches of large salmon in Labrador (SFA 2) were the highest observed since 1984. Catches in SFA 17 (PEI) were above average but more than $90 \%$ of the returns originate from smolt stocking programs.

Because of the changes which have occurred in the management of the recreational fisheries since 1984, the use of angling catches as indices of abundance has been seriously compromised. Therefore, the interpretation of trends in abundance relies mostly on rivers where returns have been estimated or completely enumerated. Numerous areas in the Maritimes Region of eastern Canada were closed to all retention of salmon, regardless of size (Figure 4.1.1.2). Caught-and-released fish are not considered equivalent to retained fish and their inclusion in catch statistics further compromises the reliability of interpretation of trends.

Commercial Fisheries: The commercial harvest in 1996 declined to 81.2 t from a peak of more than $2,400 \mathrm{t}$ in 1980 (Figure 4.1.2.4). Commercial harvest in Labrador was the lowest ever ( 48 t ) with large salmon representing less than $50 \%$ of the harvests (Table 4.1.1.1). For Québec, the harvest and the proportion of large salmon in the commercial fishery continued to decline in 1996, in part as a result of license retirements and reduced quotas.

## U.S.A.

There was no harvest of sea-run Atlantic salmon in the U.S.A. The estimated number of salmon caught-andreleased in 1996 was 542 fish, which was $46 \%$ higher than in 1995 and $154 \%$ higher than in 1994. Much of the increased catch occurred in the Penobscot River, and was attributed to increased salmon abundance and excellent angling conditions throughout the fishing season.

## France (Islands of Saint-Pierre and Miquelon)

The harvest of salmon by commercial nets in 1996 is estimated to have been 950 kg and 560 kg by recreational fishermen using gillnets. The commercial catch is approximately two times that reported for 1995. There was no estimate provided for the recreational catch in 1995.

### 4.1.3 Origin and composition of catches

In the past, salmon from both Canada and U.S.A. have been taken in the commercial fisheries of Labrador. No tags of U.S.A. origin were reported from this fishery in 1996 but there were no releases of external Carlin or coded-wire tagged smolts from U.S.A. rivers in 1995.

## Canada

## Origin of returns in 1996

Fish designated as being of wild origin are defined as the progeny of fish where mate selection occurred naturally (eggs not stripped and fertilised artificially) and whose life cycle is completed in the natural environment. Hatchery origin fish, designated as fish introduced into the rivers regardless of life stage, were identified on the basis of the presence of an adipose-clip, from fin deformations, and/ or from scale characteristics. Not all hatchery fish could be identified as such in the returns because of stocking in the early life stages. Aquaculture escapees were identified from hatchery fish on the basis of fin erosion (especially of the tail) and from scale characteristics.

The returns to the majority of the rivers in Newfoundland and to most rivers of the Gulf of St. Lawrence and Québec were comprised exclusively of wild salmon. Hatchery origin salmon made up varying proportions of the total returns and were most abundant in the rivers of the Bay of Fundy and the Atlantic coast of Nova Scotia (Figure 4.1.3.1). Aquaculture escapees were sampled from the returns to several rivers of the Bay of Fundy (St. Croix, Magaguadavic, Saint John in SFA 23) as well as in the Baddeck River (SFA 19). Other salmonid aquaculture escapees, rainbow trout and Atlantic salmon smolts from the Bay d'Espoir aquaculture industry, were observed at Conne River (SFA 11).

Aquaculture production of Atlantic salmon in eastern Canada has increased annually, exceeding 10,000 tin 1992 and rising to almost $17,000 \mathrm{t}$ in 1996 (Table 2.2.1.1). Escapes of Atlantic salmon have occurred annually. In 1994, escapes of Atlantic salmon in the Bay of Fundy area were estimated at 20,000 to 40,000 salmon, an amount greater than the total returns of wild and hatchery origin salmon (both small and large) ( 13,000 to 21,000 fish) to the entire Bay of Fundy and Atlantic coast of Nova Scotia area (SFA 19 to 23) in the same year. The level of escapes in 1993 was similar to that of 1994. Reported estimates of escapes for 1995 and 1996 are low.

Aquaculture escaped fish have increased in abundance in the Magaguadavic River (SFA 23) which is in close proximity to the centre of the aquaculture production area (Table 4.1.3.1). Escaped fish were not observed between 1983 and 1988. Since 1992, escaped fish have comprised between $33 \%$ and $90 \%$ of the total counts at the fishway.

## U.S.A.

Some salmon that were caught in the sport fishery in 1996 were escapees from aquaculture operations in Maine and New Brunswick (Canada). In addition, a few of those caught and released originated from 322 captive (wildorigin) broodstock released into three rivers in Maine in June. The incidence of aquaculture escapes was low in monitored rivers before 1994. Since 1994, the incidence of aquaculture escapes has increased in the Narraguagus River but has declined or remained high in the other two rivers in eastern Maine (Table 4.1.3.1).

### 4.1.4 Exploitation rates in Canadian and U.S.A. fisheries

## Canada

Within eastern Canada salmon were exploited by three user groups: Native peoples, recreational anglers, and commercial fishers. Exploitation rates can be estimated by dividing the harvests ( 87,141 small and 30,066 large salmon) by the sum of the estimated recruitment of small ( $287,664-620,741$ ) and large ( $108,256-203,416$ ) salmon to eastern Canada. Recruitment was estimated by summing returns of small and large salmon in the subareas (Appendix 5) with the harvest of small and large salmon in the Newfoundland and Labrador commercial fishery (Table 4.1.1.1). Calculated in this manner, the exploitation rate on the total recruitment to Canada of small salmon was between 0.14 and 0.30 and for large salmon, between 0.15 and 0.28 . The rates on both small and large salmon are down from the 1995 levels.

Overall marine conditions were more temperate in 1996 relative to those of the preceding several years (1990 to 1995). Ice coverage in the winter of 1996 was below the median distribution and ice retreat was earlier in the
spring of 1996 than in previous years. In northern Labrador, heavy ice persisted along the coast into August. The warmer conditions in 1996 resulted in adults entering rivers up to two weeks earlier than had been the case in the last few years, both in Newfoundland and in the Maritimes.

Freshwater environmental conditions affect the timing and availability of salmon to the fisheries. Discharges in 1996 were above normal in both winter and summer with no important low flow events. This contrasts with the 1995 water levels when summer flow conditions were exceptionally low. Warm water temperatures in 1996 were not as extreme as in the two previous years. Above-normal discharges and cooler water temperatures provided excellent angling opportunities in those areas where fisheries were open.

Native Peoples Fisheries: The harvest of salmon in eastern Canada by Native peoples in 1996 totalled 3,920 small salmon and 5,747 large salmon. The exploitation rate by Native peoples on small salmon in eastern Canada was about 0.01 and for large salmon between 0.03 and 0.05 of total recruitment to Canada. These rates are similar to those estimated for 1995.

Recreational Fisheries: The recreational harvest of salmon in eastern Canada in 1996 totalled 70,840 small salmon and 9,598 large salmon. The exploitation rate on small salmon was between 0.11 and 0.24 and for large salmon between 0.05 and 0.09 . These rates are an increase from 1995 for small salmon but a slight decline for large salmon.

Commercial Fisheries: The commercial harvest of salmon in eastern Canada during 1996 totalled 12,381 small salmon and 14,721 large salmon. The exploitation rate on small salmon was between 0.02 and 0.04 and for large salmon was between 0.07 and 0.14 . Both rates declined from the 1995 levels.

## U.S.A.

There was no exploitation of U.S.A. salmon in home waters, and no salmon of U.S.A. origin were detected in Canadian catches in 1996.

### 4.2 Status of Stocks in the North American Commission Area

There are approximately 550 Atlantic salmon rivers in eastern Canada and 21 rivers in eastern U.S.A. each of which could contain at least one population. Assessments are prepared for a limited number of specific rivers, mostly on the basis of the size of the Atlantic salmon resource within the river, the demands by user groups, and as a result of requests for biological advice from fisheries management. The status is evaluated by examining trends in returns and escapement relative to the conservation requirements.

### 4.2.1 Measures of abundance in monitored rivers

## Canada

The returns represent the size of the population before any in-river removals. Spawning escapement is determined by subtracting all the known removals, including food fisheries, recreational harvests, broodstock collections, and scientific samples from the total returns.

A total of 85 monitored rivers were assessed in eastern Canada in 1996. Estimates of total returns of small and large salmon were obtained using various techniques; 47 were derived from counts at fishways and counting fences, 7 were obtained using mark and recapture experiments, 18 using visual counts by snorkeling or from shore, 1 from an acoustic system, and 12 from angling catches or catch rate indices.

Of the 85 stocks for which returns of salmon were determined in 1996, comparable data were collected on 47 of these in 1995 (Table 4.2.1.1). Large salmon returns in 1996 increased from 1995. Small salmon returns were also improved from 1995.

Annual returns of salmon by size group are available for 26 rivers in Atlantic Canada since 1985. These returns do not account for commercial fisheries removals in Newfoundland, Labrador and Greenland and in some rivers include returns from hatchery stocking. Peak return years differed for regions within eastern Canada (Figure 4.2.1.1). The returns during the Newfoundland commercial fishery moratorium years (1992 to 1996) for all areas except Newfoundland are lower than the returns of 1986 to 1988 when there were commercial fisheries in

Newfoundland, Labrador and Greenland harvesting mainland Canada origin salmon. Returns of small salmon to the Gulf rivers have fluctuated annually but have declined between 1994 and 1996 to the lowest levels since 1985. Large salmon of the Gulf rivers have not fluctuated as greatly as the small salmon returns and seem to have levelled off at about 45,000 fish in the eight rivers assessed. Returns to Scotia-Fundy improved from 1994 to 1996 for both large salmon and small salmon but returns of both size groups remain well below the levels observed in the 1980s. Québec returns in 1996 were the third lowest since 1985. The returns to Newfoundland rivers have more than doubled since 1993 from the low levels observed during 1989 to 1991.

Trends in abundance of small salmon and large salmon within the geographic areas show a general synchronicity among the rivers. Although returns in 1996 were generally improved relative to 1995, the returns in all rivers were among the lowest observed since 1985 with the exception of the Newfoundland rivers (Table 4.2.1.1). For the rivers of Newfoundland (there are no rivers from Labrador in the time series), large salmon and small salmon returns were among the highest in the last 12 years as indicated by the high rank of the abundance level for the majority of rivers in 1996 within the 1984 to 1996 time period. Large salmon returns in the Gulf of St. Lawrence and Québec were among the lowest whereas small salmon returns were in the lower third of the time series.

Densities of juveniles have been monitored annually since 1971 in the Miramichi (SFA 16) and Restigouche (SFA 15) rivers. In these rivers, juvenile densities of young-of-the-year (fry) and parr (juveniles of one or more years old) have increased since 1985 in response to increased spawning escapements (Figure 4.2.1.2). Densities of parr remained high in 1996 in the Miramichi but fry densities declined. In the Restigouche River, both fry and parr densities declined. The observed declines in both rivers are not attributed to lower spawning escapements but may be related to overwintering conditions during 1995/1996.

High densities of juveniles have also been reported from Nova Scotia rivers along the Gulf of St. Lawrence (SFA 18) and in several Cape Breton Island streams (SFA 19). This is in contrast to juvenile densities from an inner Bay of Fundy river (Stewiacke River; SFA 22) which have declined since 1984, as a result of reduced spawning escapement. Fry densities in 1996, an index of spawning escapement in 1995, were the lowest in the time series (Figure 4.2.1.2). Except for the rivers along the eastern and southern shores of Nova Scotia (SFA 20 and 21) which have been impacted by acid precipitation and rivers of the inner Bay of Fundy (SFA 22 and part of 23), the freshwater production of the monitored rivers in Atlantic Canada has increased or remained constant at high levels since 1985. Rivers along the south and eastern shores of Nova Scotia remain vulnerable to acid precipitation. Populations of Atlantic salmon are considered extinct in 14 rivers and remnant populations survive in 19 other rivers as a result of water quality impaired by acidification.

## U.S.A.

Documented adult salmon returns to thirteen rivers in New England in 1996 amounted to 2,762 salmon (Figure 4.2.1.3), a $58 \%$ increase from 1995. Returns of 1 SW salmon increased by $210 \%$ ( 184 to 570 ), while MSW returns increased by $40 \%(1,567$ to 2,192 ) from the previous year. The documented adult returns are minimal estimates, since many rivers in Maine do not contain counting facilities and throughout New England not all counting facilities are $100 \%$ effective at capturing adult salmon.

Most of the U.S.A. salmon returns were recorded in the rivers of Maine, with the Penobscot River accounting for about $74 \%$ of the total. Returns to the Penobscot River ( 2,045 fish) were $52 \%$ higher than the previous year, and $23 \%$ higher than the previous 5 -year average. However, total returns were $17 \%$ lower than the previous 10 -year average.

About 9\% of the U.S.A. returns ( 260 salmon) were recorded in the Connecticut River, a $38 \%$ increase from the previous year. Returns to the Connecticut River in 1996 were $7 \%$ and $2 \%$ below the previous 5 -year and 10 -year averages, respectively.

Salmon returns to the Merrimack River numbered 76 fish. While this represented a $124 \%$ increase ( 42 salmon) from the previous year, the 1996 salmon run was $34 \%$ and $38 \%$ below the previous 5 -year and 10 -year averages, respectively.

### 4.2.2 Estimates of total abundance by geographic area

For assessment purposes, the following regions were considered: Labrador (SFA 1, 2, \& 14B), Newfoundland (SFA 3-14A), Québec (Q1-Q11), Gulf of St. Lawrence (SFA 15-18), Scotia-Fundy (SFA 19-23) and U.S.A.

Returns of 1SW and 2SW salmon to each region (Tables 4.2.2.1 and 4.2.2.2; Figures 4.2.2.1 and 4.2.2.2; and Appendix 5 ) were estimated by updating the methods and variables used by Rago et al (1993a) and reported in ICES 1993/Assess:10. The returns for both sea age groups were derived using a variety of methods using data available for individual river systems and management areas. These methods included counts of salmon at monitoring facilities, population estimates from mark recapture studies, and the application of angling and commercial catch statistics, angling exploitation rates, and measurements of freshwater habitat (Appendix 5). MSW returns were proportioned to 2 SW returns on the basis of sea-age composition of one or more indicator stocks.

In the context used here "returns" means the number of salmon that returned to the geographic region, including homewater commercial fisheries, except in the case of Newfoundland and Labrador regions where returns do not include commercial fisheries. The catches of Newfoundland and Labrador origin salmon in homewater commercial fisheries have been added to Newfoundland and Labrador returns to show the total "recruits" produced by these regions. Similar procedures to estimate recruits produced by Québec, Gulf of St. Lawrence, Scotia-Fundy and U.S.A. regions were not followed as it was not possible to annually estimate the region of origin of intercepted salmon in the Newfoundland-Labrador commercial fisheries.

## Labrador:

The mid-point of the 1SW salmon returns to Labrador rivers in 1996 was about 113,200, which is the third highest in the time series, 1971 to 1996 and approximately double that of 1995 (Figure 4.2.2.1, Appendix 5ii). The abundance (recruits) of 1 SW salmon, 1971-88, has been quite variable with low numbers returning in 1973, 1978, and 1984. The mid-point of the estimated number of recruits declined from about 150,000 1SW salmon in 1987 to about 45,000 in 1991 and remained between 43,000 and 57,000 from 1992 to 1995.

The mid-point of the 2 SW returns to Labrador rivers in 1996 is about 21,000, a $21 \%$ decline from 1995 yet the second highest since 1980 (Figure 4.2.2.2, Appendix 5i). There was a decline in recruits of 2 SW salmon from 1980 to 1991, and recruits (mid-points) have remained between 23,000 and 29,000 fish from 1992 to 1996. The low returns and recruits of 1 SW and 2 SW salmon in 1991 may be underestimates of the population size since severe ice conditions in that year affected the commercial catch which is used to estimate population size.

## Newfoundland:

The mid-point of the estimated returns $(214,400)$ of 1SW salmon to Newfoundland rivers in 1996 is $28 \%$ higher than 1995 and $25 \%$ higher than the average 1SW returns $(171,300)$ for the period 1992-94 (Figure 4.2.2.1, Appendix 5iii). The 1992-95 1SW returns are higher than the returns in 1989-91, but similar to the returns to the rivers between 1971 and 1988. The 1SW recruits to Newfoundland, before commercial fisheries, have declined significantly from about 500,000 in 1988 to 214,000 in 1996.

The mid-point $(5,600)$ of the estimated 2 SW returns to Newfoundland rivers in 1996 is slightly ( $15 \%$ ) higher than in 1995 and continues an upward trend since 1992 (Figure 4.2.2.2, Appendix 5iii). The 2 SW recruits in 1992-96 are the lowest observed in the time series (1969-96).

## Québec:

The mid-point $(28,900)$ of the estimated returns of 1 SW salmon to Québec in 1996 is a $59 \%$ increase from the returns observed in 1995 and is similar to the years 1992-94 (Figure 4.2.2.1, Appendix 5 iva \& ivb).

The mid-point $(29,900)$ of the estimated returns of 2 SW salmon to Québec is slightly $(5 \%)$ higher than 1995 and is the third lowest estimate of returns in the time series (1971-95) and continues a decline in returns that began in 1989 (Figure 4.2.2.2, Appendix 5 iva \& ivb).

## Gulf of St. Lawrence SFA 15-18:

The mid-point $(73,500)$ of the estimated returns in 1996 of 1 SW salmon returning to the Gulf of St. Lawrence was a $20 \%$ increase from 1995 and is the first year of an increase since the high levels estimated in 1992 (Figure 4.2.2.1, Appendices 5 v , via, vib, vii, viiia, viiib).

The mid-point $(31,600)$ of the estimate of 2 SW returns in 1996 is $27 \%$. lower than the estimate for 1995 (Figure 4.2.2.1, Appendices 5 v , via, vib, vii, viiia, viiib). The average return of 2 SW salmon for $1992-95$ is slightly higher than the average for 1987-91 and may reflect the reductions in fishing mortality due to the closure of the Newfoundland commercial fishery.

## Scotia-Fundy, SFA 19-23:

The mid-point $(23,600)$ of the estimate of the 1SW returns in 1996 to the Scotia-Fundy Region is $43 \%$ higher than the 1995 estimate and continues the increase from the low estimate of 1994; it is similar to values during 1991-93 (Figure 4.2.2.1, Appendix 5 ix). The decline in returns began in 1991.

The mid-point $(9,900)$ of the 2 SW returns in 1996 is $44 \%$ higher than the returns in 1995; however it is the third lowest observed in the time series, 1971-95 (Figure 4.2.2.2, Appendix 5xa, xb). A continual decline in returns has been observed from 1985 to 1995.

## U.S.A.

Total salmon returns and spawners for U.S.A. rivers in 1996 were calculated as in the previous year (ICES 1996/Assess:11). Since the harvest of salmon is not permitted in Maine and many rivers do not contain fish counting facilities, run sizes for several small rivers in Maine continue to be underestimated. Additionally, since it is not possible to determine the age and origin of salmon caught in the Maine sport fishery, the number of spawners is considered to be the same as the number of returns.

The total estimated 1SW returns and spawners to U.S.A. rivers in 1996 is 657 salmon. This was the highest estimate since 1992 (Table 4.2.2.1, Figure 4.2.2.1), and represented a $25 \%$ increase above the previous 5 -year average but a $12 \%$ decrease from the previous 10 -year average.

The estimated 2 SW returns and spawners to U.S.A. rivers is 2,316 salmon (Table 4.2.2.2, Figure 4.2.2.2). This, too, was the highest estimate since 1992, and represented a $41 \%$ increase above the previous 5 -year average but a $17 \%$ decrease from the previous 10 -year average.

## North America (combined Canada and U.S.A.):

The mid-point estimate of the total number of 1 SW salmon returning to North America in $1996(454,000)$ is $44 \%$ higher than the estimate for 1995 and higher than the average $(363,200)$ of the previous years $(1971-95)$ by $20 \%$. It is the fourth highest observed in the past 10 years and seventh highest in the 26 year time series, 1971-1996 (Table 4.2.2.1). The estimates of returns are quite variable over the time series with no trends indicated.

The mid-point of the estimated 2 SW returns $(100,300)$ is $10 \%$ lower than the total returns for 1995 and $10 \%$ lower than the average $(111,200)$ for the past 10 years. It is similar however to both 1993 and 1994 returns (Table 4.2.2.2). It has declined from a peak of almost 200,000 in the late 1970s.

### 4.2.3 Pre-fishery abundance estimates of non-maturing and maturing 1SW North American salmon

## North American Run-Reconstruction Model

The Working Group has used the North American Run-Reconstruction Model to estimate the fishery area exploitation rates for West Greenland. The data required to estimate exploitation rates are also used to estimate pre-fishery abundance, which serves as the basis of abundance forecasts used in the provision of catch advice. The catch statistics used to derive returns and spawner estimates have been updated from those used in ICES 1996/Assess: 11 (Table 4.2.3.1).

## Non-maturing 1SW salmon

The non-maturing component of 1 SW fish destined to be 2 SW returns is represented by the pre-fishery abundance estimator for year i designated as [ $\mathrm{NN} 1(\mathrm{i})]$. Definitions of the variables are given in Table 4.2.3.2. It is constructed by summing 2 SW returns in year $\mathrm{i}+1$ [NR2( $\mathrm{i}+1$ )], 2 SW salmon catches in Canada [ $\mathrm{NC} 2(\mathrm{i}+1)]$, and catches in year i from fisheries on non-maturing 1SW salmon in Canada [NC1(i)] and Greenland [NG1(i)]. An assumed natural mortality rate $[\mathrm{M}]$ of 0.01 per month is used to adjust the back-calculated numbers between the
salmon fisheries on the 1SW and 2SW salmon (10 months) and between the fishery on 2SW salmon and returns to the rivers ( 1 month) as shown below:

Eq. 4.2.3.1

$$
\mathrm{NN} 1(\mathrm{i})=(\mathrm{NR} 2(\mathrm{i}+1) / \mathrm{S} 1+\mathrm{NC} 2(\mathrm{i}+1)) / \mathrm{S} 2+\mathrm{NC} 1(\mathrm{i})+\mathrm{NG} 1(\mathrm{i})
$$

where the parameters $S 1$ and $S 2$ are defined as $\exp (-M * 1)$ and $\exp (-M * 10)$, respectively. A detailed explanation of the model used to determine pre-fishery abundance is given in Rago et al. (1993b).

This estimated pre-fishery abundance represents the extant population and does not account for the fraction of the population present in a given fishery area. The model does not take into account non-catch fishing mortality in any of the fisheries. This is because rates for non-catch fishing mortality are not available on an annual basis and are not well described for some of the fisheries harvesting potential or actual 2SW salmon. Thus, catches used in the run-reconstruction model for the West Greenland fishery (1993 and 1994) and Newfoundland fishery (199296) were set to zero in order to remain consistent with catches used in other years in both of these areas (see Section 4.1.1) There were no fisheries in these areas for the years indicated.

As the pre-fishery abundance estimates for potential 2 SW salmon requires estimates of returns to rivers, the most recent year for which an estimate is available is 1995 . The minimum and maximum values of the catches and returns for the 2SW cohort are summarised in Table 4.2.3.3. The 1995 abundance estimates ranged between 99,400 and 182,000 salmon. The mid-point of this range $(141,000)$ is only slightly higher than the 1994 value $(137,000)$ which is the second lowest in the 25 years time series (Figure 4.2.3.1). The results suggests at best a levelling off of the decline, and prefishery abundance remains at historic low levels. The Working Group expressed concern about the continued decline in the prefishery abundance and its impact on spawner levels.

The low numbers observed in 1978 and 1983-84 were followed by large increases in pre-fishery abundance. However, if the data are divided into sets above and below the 24 year mean, the likelihood of a poor year (i.e. below mean) being followed by a good year (i.e. above the mean) is low as illustrated in the following table:

|  | Pre-fishery abundance in year i+1 |  |
| :--- | :---: | :---: |
| Pre-fishery abundance in year i | Poor | Good |
| Poor | 8 | 2 |
| Good | 3 | 11 |

These results suggest that salmon abundance tends to persist in "poor" and "good" states for several years. Moreover, the likelihood of reversing from poor to good in a single year appears to be about $20 \%$.

## Maturing 1SW salmon (Grilse)

Estimation of an aggregate measure of abundance has utility for identifying trends, evaluating management measures, and investigating the influence of the marine environment on survival, distribution, and abundance of salmon. Since 1993, the Working Group has been providing estimates of pre-fishery abundance estimates of nonmaturing 1 SW salmon, and these have been used for providing catch advice and investigating the relationships between survival in freshwater and the sea, changes in population characteristics, and spawning stock levels.

The commercial catches in Newfoundland and Labrador are reported as numbers and weight of fish in "small" and "large" size categories. Salmon less than 2.7 kg whole weight are graded as small; salmon $>2.7 \mathrm{~kg}$ are graded as "large". All "small" salmon are assumed to be 1SW fish based on catch samples which show the percentage of 1 SW salmon to be in excess of $95 \%$. Large salmon are primarily MSW salmon but some maturing and nonmaturing 1SW are also present in commercial catches in SFAs 1-7, 14B. Estimates of fractions of non-maturing salmon present in the Newfoundland and Labrador catch were presented in ICES 1991/Assess:12. The "large" category in SFAs 1-7,14B consists of 0.1-0.3 1SW salmon (Rago et al. 1993; ICES 1993/Assess:10). Salmon catches in SFAs 8-14A are mainly maturing salmon (Idler et al. 1981).

The maturing component of 1SW fish destined to be grilse returns is represented by the pre-fishery abundance estimator for year $i[M N 1(i)]$. It is constructed by summing maturing 1SW returns in year i [MR1(i)] in Atlantic Canada and catches in year i from fisheries on maturing 1SW salmon in Newfoundland and Labrador [MC1(i)].

An assumed natural mortality rate [M] of 0.01 per month is used to adjust the back-calculated numbers between the fishery on 1SW salmon and returns to the rivers ( 1 month) as shown below:

Eq. 4.2.3.2. $\quad \mathrm{MN1}(\mathrm{i})=\mathrm{MR} 1(\mathrm{i}) / \mathrm{S} 1+\mathrm{MCl}(\mathrm{i})$
where the parameter $S 1$ is defined as $\exp \left(-\mathrm{M}^{*} 1\right)$.
Eq. 4.2.3.3

$$
\mathrm{MCl}(\mathrm{i})=\left[\left(1-\mathrm{f} \_\mathrm{imm}\right)\left(\mathrm{H}_{-} \mathrm{s}(\mathrm{i})_{\{1-7,14 \mathrm{~b})}+\mathrm{q}^{*} \mathrm{H} \_1(\mathrm{i})_{(1-7,14 \mathrm{~b})}\right)\right]+\mathrm{H}_{-} \mathrm{s}(\mathrm{i})_{\{8-14 \mathrm{a}\}}
$$

This estimated pre-fishery abundance represents the extant population and does not account for the fraction of the population present in a given fishery area. The model does not take into account non-catch fishing mortality in any of the fisheries. This is because rates for non-catch fishing mortality are not available on an annual basis and are not well described for the fisheries harvesting 1SW salmon. Thus, catches used in the run-reconstruction model for the Newfoundland fishery were set to zero for 1992-96 in order to remain consistent with catches used in other years in this area (see Section 4.1.1).

The minimum and maximum values of the catches and returns for the 1 SW cohort are summarised in Table 4.2.3.4 and the mid point values are shown in Figure 4.2.3.1. The mid-point of the range of prefishery abundance estimates for $1996(467,000)$ is larger than that of $1995(328,000)$. Estimates for 1995 and 1994 decreased markedly below the previous two years. The reduced values observed in 1978 and 1983-84 were followed by large increases in pre-fishery abundance. However, if the data are divided into sets above and below the 25 year mean, the likelihood of a poor year (i.e. below mean) being followed by a good year (i.e. above the mean) is low as illustrated in the following table:

|  | Pre-fishery abundance in year i+1 |  |
| :--- | :---: | :---: |
| Pre-fishery abundance in year i | Poor | Good |
| Poor | 10 | 3 |
| Good | 3 | 9 |

These results suggest that salmon abundance tends to persist in "poor" and "good" states for several years. Moreover, the likelihood of reversing from poor to good in a single year appears to be about $25 \%$.

## Total 1SW recruits (maturing and non-maturing)

Figure 4.2.3.1 shows the prefishery abundance of 1 SW maturing and 1 SW non-maturing salmon from North America for the period 1971 to 1995 and Figure 4.2.3.2 shows these data combined to give the total 1 SW recruits. The steady decline in recruits over the last 10 years is alarming. Although the declining trend appears common to both maturing and non-maturing portions of the cohort, non-maturing 1 SW salmon have been declining at a steeper rate. Causes for the differences in rate of decline are uncertain. Figure 4.2.3.1 also shows the steady increase in the proportion of the North American stock maturing as 1SW fish. This proportion has risen from about $45 \%$ at the beginning of the 1970 s to around $70 \%$ in the last three years. Environmental variation could have resulted in earlier maturation of the salmon or the historically higher exploitation rates on the non-maturing component could have reduced the recruitment of this component. The Working Group expressed concerns about these stock trends and recommended further investigation into their causes.

### 4.2.4 Spawning escapement and egg deposition

## Canada

Egg depositions exceeded or equalled the river specific conservation requirements in 32 of the 85 assessed rivers and were less than $50 \%$ of conservation in 22 other rivers (Figure 4.2.4.1). Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where 10 of the 20 rivers assessed had egg depositions which were less than $50 \%$ of conservation requirements. Several rivers in Newfoundland and Québec which were deficient in eggs are colonisation programs where salmon have gained access in recent years to previously inaccessible habitat.

Escapements over time relative to conservation requirements have improved in some areas of Atlantic Canada but have declined in others (Figure 4.2.4.2). The Bay of Fundy/Atlantic coast of Nova Scotia rivers status has severely declined, especially since 1991. For the Québec rivers, spawning escapements declined continually from a peak median value in 1988 but recovered in 1995. The Newfoundland rivers have shown the greatest improvement in the proportion of the spawning requirement achieved as a direct result of the commercial salmon and groundfish moratoria instigated in 1992.

## Run reconstruction estimates of spawning escapement

Estimates for 2SW spawners were derived in 1996 (ICES 1996/Assess:11) and updated at the current meeting for the six geographic regions referenced in Section 4.2.2 (Table 4.2.4.1). Estimates of 1SW spawners, 1971-96 are provided in Table 4.2.4.2. These estimates were derived by subtracting the in-river removals from the estimates of returns to rivers. A comparison between the numbers of spawners, returns and spawning requirements for 1 SW and 2 SW salmon are shown in Figures 4.2.2.1 and 4.2.2.2 respectively (there are no spawning requirements defined specifically for 1 SW salmon).

## Labrador:

The mid-point of the estimated numbers of 2SW spawners $(20,700)$ in Labrador in 1996 is the third highest estimated spawning escapement during the period 1971-96 and approximates $60 \%$ of the total 2 SW spawner requirements for all rivers in Labrador (Figure 4.2.2.2). It is however a $21 \%$ decline from the numbers estimated in 1995. The 2SW spawning escapement declined during the period 1980 to record low levels in 1991. Subsequent to 1991 the spawning escapement appears to have increased each year to 1995, which is consistent with increasing restrictive management measures in the commercial fisheries.

The mid-point of the estimated spawning escapement of 1 SW salmon $(109,800)$ in 1996 is the third highest value in the time series, 1971-96 and is $122 \%$ higher than the mid-point estimated in 1995. Spawning escapements of 1SW salmon have been quite variable over the time series but have generally increased since 1991, consistent with increasing restrictive management measures in the commercial fisheries (Figure 4.2.2.1).

## Newfoundland:

The mid-point of the estimated numbers of 2SW spawners $(5,500)$ in Newfoundland in 1996 is slightly higher ( $15 \%$ ) than estimated in 1995 and is $137 \%$ of the total 2 SW spawner requirements for all rivers. This year is the third time that the spawner requirement has been met or exceeded since 1984 (Figure 4.2.2.2).

The 1SW spawners in Newfoundland rivers in 1996 increased by $28 \%$ from 138,000 in 1995 to 176,000 in 1996. The 1992-96 1SW spawners are higher then the spawners in 1989-91 and similar to levels in the late 1970s and 1980s (Figure 4.2.2.1).

There has been a general increase in both 2SW and 1SW spawners during the period 1992-96 and is consistent with the closure of the commercial fisheries in Newfoundland.

## Québec:

The mid-point of the estimated numbers of 2SW spawners ( 12,000 ) in Québec in 1996 is higher ( $18 \%$ ) than estimated in 1995 and is about $20 \%$ of the total 2 SW spawner requirements for all rivers (Figure 4.2.2.2). The spawning escapement in 1996 is the second lowest number estimated since the mid-1980s. Estimates of the numbers of spawners in Québec have consistently been about one-fifth to one-third of the spawner requirement over the time series (1971-96).

The mid-point of the estimated 1SW spawners in $1996(14,400)$ was a $78 \%$ increase from 1995 (Figure 4.2.2.1) and was one-third higher than the average of the time series 1971-95. Spawning escapement of 1SW fish has generally been higher since the early 1980s than it was before this period.

## Gulf of St. Lawrence:

The mid-point of the estimated numbers of 2SW spawners $(29,000)$ in Gulf of St. Lawrence in 1996 is 30\% lower than that estimated in 1995 and is about $95 \%$ of the total 2 SW spawner requirements for all rivers in this
region (Figure 4.2.2.2). This is the first time in seven years that these rivers have not exceeded their 2 SW spawner requirements.

The mid-point of the estimated spawning escapement of 1 SW salmon $(46,100)$ increased by $21 \%$ from 1995 and is the first increase seen since 1992 (Figure 4.2.2.1). Spawning escapement has on average been higher since the mid-1980s than it was before this period.

## Scotia-Fundy:

The mid-point of the estimated numbers of 2 SW spawners $(9,500)$ in Scotia-Fundy area in 1996 is a $41 \%$ increase from 1995 and is about $45 \%$ of the total 2 SW spawner requirements for all rivers in this region (Figure 4.2.2.2). The 2SW spawning escapement has been generally declining since 1985.

The mid-point of the estimated 1 SW spawners $(20,300)$ in 1996 is also a $40 \%$ increase from 1995 and continues the upward trend from the low spawning escapement in 1994 (Figure 4.2.2.1).

## Canada:

The mid-point of the estimated 2SW spawners in 1996 in Canada was 76,219 and is $50 \%$ of the total requirement for 2 SW spawners of 151,296 . This is a decrease from the $59 \%$ attained in 1995.

The overall 2 SW spawner requirement for Canada could have been met or exceeded in only 3 (1974, 1977, 1980) of the past 25 years (considering the mid-points of the estimates), by adjustments to the terminal fisheries alone. In the remaining years, spawning targets could not have been met even if all in-river harvests had been eliminated.

## U.S.A.

The estimated 2 SW returns ( 2,316 salmon) to U.S.A. rivers in 1996 represents $8 \%$ of the spawner requirements for all rivers. There were an additional 657 1SW spawners in U.S.A. rivers in 1996. This represented the highest level of both 1SW and 2SW spawners observed in U.S.A. rivers since 1992.

The estimated spawning escapement in the Penobscot River in 1996 was similar to the previous year at about 5\% of the required number of 2 SW females. Spawning escapements for the Connecticut and Merrimack rivers were less than $1 \%$ of spawning requirements.

## Escapement variability in North America

The projected numbers of potential 2SW spawners that could have returned to North America in the absence of fisheries can be computed from estimates of the pre-fishery abundance taking into consideration the 11 months of natural mortality at $1 \%$ per month. These values, termed potential 2 SW recruits, along with total North American 2SW returns, spawners and requirements are shown in Figure 4.2.4.3 and indicate that the overall North American spawner requirement could have been met, in the absence of all fisheries, in all years except 1993, 1994, 1995 and 1996. The difference between the potential 2 SW recruits and actual 2 SW returns reflect the extent to which mixed stock fisheries at West Greenland and in SFAs 1-14 have reduced the populations. Similarly, the impact of the Greenland fishery can be considered by subtracting the non-maturing 1 SW salmon (accounting for natural mortality) harvested there from the total potential 2 SW recruits. These values, termed 2SW recruits to North America, are also shown in Figure 4.2.4.3. The difference between the 2SW recruits to North America and the $2 S W$ returns reflects the impact of removals by the commercial fisheries of Newfoundland and Labrador. The 2SW recruits to North America indicate that, even if there had not been a West Greenland commercial fishery, spawner requirements would not have been met in 1979 and since 1990. The difference between the actual 2 SW returns and the spawner numbers reflects in-river removals throughout North America and coastal removals in Québec, Gulf and Scotia-Fundy regions.

In 1994, the Working Group (ICES 1994/Assess:16) undertook a preliminary analysis of the effects of escapement on potential fishery yield. It was noted that the stock-recruitment relationship ultimately defines the sustainable level of harvesting and its expected variability over time, although spawning stock size is often not a significant variable in models relating recruitment to stock and environmental variables. The establishment of strong correlations between recruits and an environmental variable is sometimes used to support the notion that
spawning stock size is unimportant. However, it was concluded that if environmental variability regulates survival in a density-independent fashion, then the importance of stock size is enhanced.

Following on the technique outlined in previous reports (ICES 1994/Assess:16, ICES 1995/Assess:14), the spawners in each geographic area were allocated (weighted forward) to the year of the non-maturing 1SW component in the Northwest Atlantic using the weighted smolt age proportions from each area (Table 4.2.4.3). The total spawners for a given recruitment year in each area is the sum of the lagged spawners. Because the smolt age distributions in North America range from one to six years and the time series of estimated 2SW spawners to North America begins in 1971, the first recruiting year for which the total spawning stock size can be estimated is 1979 (although a value for 1978 was obtained by leaving out the 6 -year old smolt contribution which represents $4 \%$ of the Labrador stock complex (Table 4.2.4.3)). Since the 1996 2SW spawners to North America are known, the spawning stock contributing to the pre-fishery abundance up to 1999 is known for North America and up to 2000 for the stock areas in Canada (Table 4.2.4.4, Figure 4.2.4.4).

Spawning escapement to several stocks complexes has been well below the spawner requirement (Labrador, Québec, Scotia-Fundy, U.S.A.) and decreasing (Labrador, Québec and U.S.A.) since the late 1980s (Figure 4.2.4.4). The relative contributions of the geographic area stocks to the total spawning escapement of 2 SW salmon has varied over time (Figure 4.2.4.5). The reduced potential contribution of Labrador and the increased importance of the spawning stock from the Gulf of St. Lawrence rivers to future recruitment is most evident. Thus abundance of non-maturing 1SW salmon would not be expected to increase dramatically in most areas of North America even if the sea survival improves. Only the Gulf and Newfoundland stock complexes have received spawning escapements which have been close to requirements, all other complexes are well below requirement and some have declined even further.

### 4.2.5 Survival indices

## Canada

Counts of smolts provide direct measurements of the outputs from the freshwater habitat. Previous reports have documented the high annual variability in the annual smolt output: in tributaries, smolt output can vary by five times but in the counts for entire rivers, annual smolt output has generally varied in magnitude by a factor of two.

The number of wild smolts leaving the rivers depends upon the number of eggs deposited adjusted by variable survival rates throughout the juvenile stages. The production among river systems is also not necessarily synchronised and it is not possible to calculate how many smolts in total leave the rivers of Atlantic Canada for any given year. In the Québec rivers where smolt production has been monitored, the 1996 smolt production was similar to the average production during 1990 to 1995 (Figure 4.2.5.1). In Newfoundland rivers, smolt production increased in three rivers along the South and Southeast coasts of Newfoundland but for the river with the longest time series of smolt counts in Canada, the production of smolts from Western Arm Brook (WAB) was similar to the 1990-95 average.

Counts of smolts and adult salmon returns enable estimates of marine survival to be derived. Examination of trends over time provide insight into the impact of changes in management measures or other factors that can influence the production of salmon. Information from 12 rivers in Atlantic Canada with smolt counts and corresponding adult counts are available; four are hatchery stocks and eight are wild populations. Geographically, populations for which data were available ranged from the Saint John River (SFA 23 - Bay of Fundy) in the south, LaHave River (SFA 21) and Liscomb River (SFA 20) along the Atlantic coast of Nova Scotia, Saint-Jean (Q2) in the Gaspé region, de la Trinité and aux Rochers (Q7) in the Québec north shore, BecScie (Q10) in Anticosti Island, and other populations from southern (Conne, Northeast and Rocky: SFAs 9 and 11), eastern and northern Newfoundland (Campbellton: SFA 4 and Western arm Brook: SFA 14) (Figure 4.2.5.2).

In general, survival of hatchery stocks is lower and more variable than that of wild stocks (Figure 4.2.5.2). The three hatchery stocks from the Bay of Fundy / Atlantic coast of Nova Scotia show a declining trend over time which has become particularly acute in recent years although two of these stocks showed a marked improvement in sea survival to the 1SW stage in 1996. The single hatchery stock from Québec also shows a declining trend over the shorter time series with very low smolt survivals to both the 1 SW and 2 SW stages.

Sea survivals in the Québec wild stocks have also declined from the peak survivals of the 1989 smolt migration with a slight improvement in the sea survival of the 1995 smolt migration (Figure 4.2.5.2). Survivals of the 1995 smolt migration improved for all the Newfoundland stocks and have recovered to historical or near-historical levels.

Given the large scale reductions in marine exploitation that have occurred over the past several years, sea survival of the salmon populations from the Scotia-Fundy and Québec stocks has not increased in the manner expected.

Colder oceanic conditions both nearshore and in the Labrador Sea are negatively associated with marine survival of salmon in eastern Canada. Environmental conditions tend to be autocorrelated and the upward trend in warming of the water temperatures in 1994 to 1996 may represent a return to temperate marine conditions favouring salmon production.

## U.S.A.

The survival of hatchery-reared smolts released in the Penobscot River in 1994 was slightly higher than that observed for the 1993 smolt class (Figure 4.2.5.3). Both 1SW and MSW salmon returns exhibit a slight upward trend in recent years.

### 4.2.6 Summary of status of stocks in the North American Commission Area

The North American Run-Reconstruction Model was used to update the estimates of pre-fishery abundance of non-maturing and maturing 1SW salmon from 1971-1996. The 1994 estimate of pre-fishery abundance of nonmaturing 1SW salmon was the lowest on record. Increases from this low value were noted in both 1995 and 1996 (Figure 4.2.3.1) with the 1996 estimate about $8 \%$ above the low 1994 estimate. Similarly, the 1994 estimate of pre-fishery abundance of maturing 1SW salmon was also the lowest on record and improvement has been noted since then with the 1996 estimate increasing by $46 \%$ from the low 1994 estimate. The results suggest a levelling off of a decline to historical low levels and in the case of 1 SW maturing salmon, a clear increase. In addition to the steady decline in total recruits over the last 10 years, there has been a steady increase in the proportion of the North American stock maturing as 1SW fish. This proportion has risen from about $45 \%$ at the beginning of the 1970 s to around $70 \%$ in the last four years.

The estimate of the total number of 1 SW salmon returning to Labrador and Newfoundland rivers and coastal waters of other areas of North America in 1996 is $44 \%$ higher than the estimate for 1995 and higher than the average of the previous years (1971-95) by $20 \%$. It is the fourth highest observed in the past 10 years and seventh highest in the 26 year time series, 1971-1996 (Table 4.2.2.1). The estimates of returns are quite variable over the time series with no trends indicated.

The estimated 2SW returns are $10 \%$ lower than the total returns for 1995 but similar to both 1994 returns and the average for the past 10 years (Table 4.2.2.2). They have declined from a peak of almost 200,000 in the late 1970s.

The rank of the estimated returns in 1996 in the 1971-1996 time series for six regions in North American is shown below:

| Region | Rank of 1996 returns in 1971-96 Mid-point estimate of 2SW spawners as time series ( 1 =highest) proportion of escapement requirement <br> 1SW <br> 2SW <br> (\%) |  |  |
| :---: | :---: | :---: | :---: |
|  |  |  |  |
| Labrador | 3 | 3 | 60 |
| Newfoundland | 3 | 6 | 137 |
| Québec | 7 | 24 | 20 |
| Gulf | 16 | 22 | 95 |
| Scotia-Fundy | 17 | 23 | 44 |
| U.S.A. | 8 | 15 | 8 |

In most regions the returns of $2 S W$ fish are near the lower end of the twenty five year time series. However, returns of 2SW salmon to Labrador in 1995 and 1996 were the best in the time series (Table 4.2.2.2). Returns of 1SW salmon improved in all areas in 1996 relative to 1995 and in some regions (Labrador, Newfoundland, and Québec) were near the highest levels in the time series (Table 4.2.2.1).

The text table above also shows the estimated total spawning escapement of 2SW salmon in each region in 1996 expressed as a percentage of the spawning escapement requirement. Only in Newfoundland were requirements exceeded; in the Gulf of St. Lawrence requirements were approached. The overall 2 SW spawning escapement requirement for Canada could have been met or exceeded in only 3 (1974, 1977 and 1980) of the past 26 years (considering the mid-points of the estimates) by reduction of in-river fisheries. In the remaining years, spawning requirements could not have been met even if all in-river harvests had been eliminated.

The majority of the U.S.A. returns were recorded in the rivers of Maine, with the Penobscot River accounting for about $74 \%$ of the total. Salmon returns to the Penobscot River were $52 \%$ higher than the previous year, but were $23 \%$ higher than the previous 5 -year average and $17 \%$ lower than the previous 10 -year average. While U.S.A. salmon returns improved in 1996, returns to most rivers are hatchery-dependent and remain at low levels compared to spawning requirements.

Egg depositions exceeded or equalled the specific river requirements in 32 of the 85 rivers which were assessed in Canada and were less than $50 \%$ of requirements in 22 other rivers. Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where 10 of the 20 rivers assessed had egg depositions which were less than $50 \%$ of requirements (Figure 4.2.4.1).

North American salmon stocks remain at low levels relative to production in the 1970s. The 1SW non-maturing component continues to be depressed with river returns and total production amongst the lowest recorded. Returns, however, in 1996 of maturing 1SW salmon (grilse) to North American rivers are quite high in many areas, notably Labrador, Newfoundland Québec and U.S.A. which may indicate improved marine survival rates of this cohort. If this is the case, improvement in 2SW salmon returns and spawners may be expected in 1997. Only two areas achieved or came close to achieving their spawning requirements for 2 SW salmon in 1996. They were Newfoundland, where 2 SW salmon comprise only a small proportion of salmon production and the Gulf of St. Lawrence where 2 SW salmon are a high proportion of production and very important in terms of their contribution to both North American and Greenland fisheries.

### 4.3 Effects on US and Canadian Stocks and Fisheries of Quota Management and Closure after 1991 in Canadian Commercial Salmon Fisheries

In 1992, a five-year moratorium was placed on the commercial Atlantic salmon fishery in insular Newfoundland while in Labrador and Québec North-Shore and Ungava, fishing continued under quota or allowance catch. In conjunction with the commercial salmon moratorium, a commercial licence retirement program went into effect in insular Newfoundland, in SFAs 1, 2 and 14B of Labrador, and in Q7, Q8 and a part of Q9 in Québec; there were no changes in the management measures in Q11. The commercial quotas, number of licensed fishermen, and landings are presented in Table 4.1.1.1.

The opening of the commercial salmon fishing season in Labrador (SFAs 1, 2, 14B) of July 3, 1995 was moved forward to June 20, 1996. Before 1995, the fishery commenced on June 5. The quota was further reduced by $25 \%$ from 73.5 t in 1995 to 55 t in 1996.

The opening of the commercial salmon fishing season in Q9 in 1996, was delayed from June 24 to July 1 and the quota reduced by $20 \%$, which would further reduce the exploitation of large and small salmon. The moratorium on the commercial cod fishery in 1992-96 would also have reduced the by-catch of salmon.

Newfoundland: An index of salmon escapements was used to evaluate the impact of the moratorium relative to premoratorium periods (1984-1991) for various Newfoundland salmon stocks (rivers) and across rivers for certain zones (e.g. northeast, south, and west coasts); this index also allowed inference of past average levels of commercial fishery exploitation separately for small and large salmon. Year 1992 was designated as the reference year for all comparisons. The count of salmon in the reference year divided by itself then receives the value of one (1). Counts for all other years are normalised to the 1992 reference year by dividing respective escapement estimates by the reference year count. This produces a series of numbers relative to the unity value of the reference year. A number less than unity indicates the actual proportion that the year in question is below the
reference year. It was expected that the value of the index during the moratorium period would be greater than it was prior to closure of the commercial fisheries.

Indices were calculated for 14 fish counting facilities representing 13 separate salmon populations from the three areas. Regional changes in salmon abundance were derived by averaging index values across rivers for the three areas in a way that each river is given equal weight. To derive an estimate of commercial exploitation for each stock, yearly index values were averaged for the premoratorium and moratorium periods The percentage difference between the two periods provides an overall average exploitation rate.

## Small salmon

In general, rivers along the northeast and west coast of Newfoundland showed substantive increases in small salmon stock abundance during the commercial salmon fishery moratorium (Table 4.3.1). For all rivers considered, however, there were some years during the premoratorium period that were as high or higher than the 1992 reference year. The exception to these improvements are found in various south coast rivers; Biscay Bay River, Northeast Trepassey, and Conne River which all have average index values during the moratorium that are lower than the premoratorium period. At Northeast Placentia River, only the 1996 returns were higher than those of the 1992 reference year. This would suggest that overall adult stock production levels were substantially lower during the moratorium period.

Overall regional perspectives show that both the northeast and west coast have shown substantive improvements whereas south coast rivers, as a whole, are not up to even the premoratorium level. There is, however, some suggestion of improvement during the past few years. The 1991 year was the lowest overall for each of the three regional groupings.

## Large salmon

Rivers along the northeast and west coast of Newfoundland also showed substantive increases in large salmon stock abundance during the commercial moratorium (Table 4.3.1).

With respect to south coast stocks, only at Northeast Placentia River were there consistent improvements to large salmon escapements during the moratorium period. Dramatic declines were experienced at Northeast Trepassey and Conne rivers.

Returns of large salmon were again among the lowest or second lowest for many rivers in 1991. Exploits River, Salmon Brook, Middle Brook, Northeast Trepassey and Conne River all had significant declines in large salmon returns through to the 1991 period.

Overall regional perspectives for large salmon returns show that both the northeast and west coast have shown substantive improvements whereas south coast rivers, on average, are not up to the premoratorium level. As observed with the regional grouping of small salmon returns, 1991 was again the lowest overall.

## Exploitation rate

Estimates of commercial exploitation rates on small salmon during premoratorium years ranged from $29 \%$ to $66 \%$, averaging $49 \%$ for all areas combined. On large salmon they ranged from $64 \%$ to $98 \%$ and averaged $76 \%$ (Table 4.3.1).

Figure 4.2.5.2 shows increases in the smolt to adult salmon returns subsequent to 1992 to several rivers, which is consistent with a decline in marine fishing mortality. Quantification of changes in fishing mortality from these data is not possible since natural mortality may have changed over the time series.

Québec: Effects of the management changes in Québec North Shore are also difficult to evaluate. In zones Q7 and Q8, the mean annual commercial catches in 1984-91 were 389 (130-673) small salmon and 8893 (728811004) large salmon (Table 4.3.2). During these years, the annual mean recreational catch was 1596 small salmon and 3167 large salmon. The closure was in effect in 1993, 1992 being a transition year. For years 199396 , mean recreational fisheries landings were reduced by $20 \%$. Assuming that exploitation rates in commercial fisheries would have declined in the same proportion as the recreational fisheries if there had been no
management change, the closure of the commercial fishery in 1993 may have resulted in an annual landing reduction of 311 small salmon and 7195 large salmon.

In zone Q9, commercial quota by numbers was reduced by $20 \%$, from 15175 in 1995 to 12068 in 1996 and the opening date was delayed by seven days from June 24 to July 1 . The impact of the quota reduction is assumed to be a reduction of $20 \%$ of salmon catch, because more than $90 \%$ of the quota was reached in the four previous years and $95 \%$ of the quota was reached in 1996. Delays in the opening date could have contributed to reduce the proportion of large salmon in the catch; from 1984-1995 period, large salmon were on average $73 \%$ of the landings, the minimum being $68 \%$ in 1985. In 1996, the proportion of large salmon dropped to $61 \%$ in commercial fisheries, while it remained the same as it was for the five previous year in the recreational fisheries (Table 4.3.3).

Other Areas: ICES 1995/Assess:14 indicated that there was an increase in size-at-age and in the proportion of previously spawned 1 SW and 2 SW salmon in the returns to the Miramichi River. This observation is consistent with reduced commercial exploitation. Similar trends to those reported for the Miramichi have been reported for the Restigouche River. However, other factors such as natural mortality may have contributed to the decline in returns.

Although the Newfoundland and Labrador commercial salmon fisheries used to harvest small and large salmon with origins in Nova Scotia, New Brunswick, Québec, and U.S.A., the benefits in returns to these provinces cannot be quantified. The estimates of returns of 2SW salmon to SFAs 19-23, Q1-Q11, and U.S.A. from 199296 are lower than the returns 1987-91 (Figure 4.2.2.2) which is inconsistent with a reduction in marine fishing mortality.

### 4.4 Spawning Requirements

In previous years, the word target was used to describe the spawning requirements for rivers in North America. Following the discussion in Section 2.7 (precautionary principles), the spawning requirement is considered as a threshold reference point. In Canada, this threshold reference point has been synonymously defined as the conservation requirement. The conservation requirements for North America have been expressed in terms of the number of 2 SW fish required for all production areas of North America. The requirements for U.S.A. rivers were reviewed in 1995 (ICES 1995/Assess:14). A review of the spawner requirements for Canada was conducted in 1996 (ICES 1996/Assess:11). No new requirements for North American rivers have been proposed and therefore the spawners requirements by management zone for Canada and for U.S.A. total 180,495 2SW salmon (Table 4.4.1) as in ICES 1996/Assess:11. The Working Group again recommends that these requirements be refined as additional information on sea-age composition of spawners becomes available and as further understanding of life history strategies is gained.

### 4.5 Catch Options for the North American Commission Area

This is the first year that the Working Group has been asked to provide catch options for the North American Commission Area. The Working Group, as a preliminary approach, suggests that catch options for the North American Commission Area be considered commencing with the forecast for 1997 of prefishery abundance for 1SW non-maturing salmon. This would mean that, principally, the 1998 fisheries for 2 SW salmon in North America would be considered. Only a small proportion of the cohort would be expected to be harvested as 1 SW non-maturing salmon in 1997 in the Labrador commercial fishery, if exploitation and stock composition patterns continue as in recent years.

Catch histories for the years 1972-96 are provided in Tables 4.5.1 and 4.5.2 with fishing mortalities of the cohorts exposed to the Greenland fishery all expressed as 2 SW salmon equivalents. Maturing 1 SW salmon (grilse) are not considered. The Newfoundland-Labrador commercial fisheries have historically harvested both maturing and non-maturing 1 SW salmon as well as 2 SW maturing salmon. The harvest in these fisheries of repeat spawners and older sea-ages has not been considered in the run reconstructions. Harvests of 1SW nonmaturing salmon in Newfoundland-Labrador commercial fisheries have been adjusted by natural mortalities of $1 \%$ per month for 11 months and 2 SW harvests in these same fisheries have been adjusted by 1 month to express all harvests as 2SW equivalents in the year and time they would reach rivers of origin. Mortalities (principally in fisheries) in mixed stock and terminal fisheries areas in Canada are summed with those of U.S.A. to estimate total 2SW equivalent mortalities in North America (Table 4.5.1). Mortalities within North America peaked at almost

375,000 in 1976 and are now around $30,0002 \mathrm{SW}$ salmon equivalents. In the most recent two years estimated, those taken as non-maturing fish in Labrador comprise only $5 \%$ of the total in North America.

The percentage of the cohort destined to be 2 SW salmon which were taken in terminal fisheries during 1972 1996 in Canada and the U.S.A. has ranged from as low as $18 \%$ in 1973, 1975 and 1987 to the highest value yet of $75 \%$ in the 1996 fisheries (Table 4.5.1). The percentage increased significantly with the reduction and closures of the Newfoundland and Labrador commercial fisheries, particularly since 1992.

Table 4.5.2 shows the mortalities expressed as 2 SW equivalents in Canada, U.S.A. and Greenland for 19721996. Harvests within the U.S.A. of the total within North America approached $1 / 2 \%$ on a few occasions in the time series and as recently as in 1990. As well as these harvests in the US, U.S.A. origin salmon were also harvested in Canada during the time period indicated. The percentage of the total 2SW equivalents that has been taken in North American waters has ranged from 41-100 \%, with the most recent year estimated at $60 \%$. The two years when $100 \%$ of the mortality occurred in North America were the years when the Greenland commercial fishery did not operate.

The $50 \%$ probability level for the prefishery abundance forecast for 1997 1SW non-maturing salmon is 196,858 . (See Section 5.2 for more detailed derivation of the models used, etc.) The text table below, as an example, assumes a $40 \%$ Greenland/60 \% North America division of the surplus for harvest (after reserving the spawner requirement of 201,483 ) and expresses catch options as 2 SW salmon equivalents for 1998 (by considering 11 months of mortality at $1 \%$ per month). As is noted in Section 5.2, there is a wide variability in the forecast and caution is warranted in the use of the $50 \%$ level. Precautionary approaches would utilise probabilities much lower than $50 \%$.

| Catch Options for $\mathbf{1 9 9 8}$ North American Fisheries (Probability levels <br> refer to probability density function estimates of pre-fishery abundance) |  |
| :--- | :---: |
| Probability Level | Catch Options in 2SW Salmon Equivalents (no.) |
| 25 | 0 |
| 30 | 0 |
| 35 | 0 |
| 40 | 0 |
| 45 | 0 |
| 50 | 0 |
| 55 | 6,396 |
| 60 | 15,535 |
| 65 | 24,857 |
| 70 | 34,666 |
| 75 | 45,427 |

The above table provides catch options for 1998, currently about 15 months in the future. If required, information could be provided at this time next year that would refine the 1998 forecast of the returns of 2 SW salmon. Mortalities resulting from fisheries on 1SW non-maturing salmon at Greenland and in North America in 1997 could be subtracted from up-dated forecasts for the cohort using current sampling information. Projected remaining fish, with associated risk levels of achieving spawner goals advised by management, could then be determined.

It should be clear from the above that the numbers provided for catch options refer to the composite North American fisheries. On individual rivers, where spawning requirements are being achieved, there are not biological reasons to restrict the harvest. Managers may however consider doing so for socio-economic reasons.

### 4.6 Multi-Year Projections of Salmon Abundance

The Working Group was not able to provide quantitative forecasts for abundance beyond projecting pre-fishery abundance for 1SW non-maturing salmon in 1997, which already has wide confidence limits. This is already two years advanced from the most recent estimate (1995) of prefishery abundance. Considering the importance of the
habitat factor, projections of abundance to date have only been possible for the current year as we have no models yet for predicting the marine environment.

Juvenile densities in recent years in many monitored rivers have been at record levels and large increases in spawning by 1 SW salmon have been occurring in many areas, notably the island of Newfoundland. Spawning by 2SW salmon has increased also in some areas, notably Labrador. As a result of overall low exploitation rates in fisheries on North American stocks, egg deposition has either remained stable or increased in most areas. There seems to be signals that marine survival rates on smolts have increased from the low values seen in the last 5 years. There are therefore indications for optimism for coming years. Further details by country follow.

Recruitment per 2SW lagged spawner was suggested for insight into longer term predictions. As noted in Table 4.2.4.4, this value has ranged from almost 82 SW fish produced per 2 SW spawner for the 1986 prefishery abundance to values below 2 fish per spawner for the three most recently estimated years (1993-95). Lagged spawners producing recruits in 1998 and 1999 were low $(70,000-75,000)$. Based on past ranges of recruits per spawner (2-8), recruits in 1998 and 1999 could be as low as 150,000 but no higher than 600,000 .

## Canada long-term trends

## Newfoundland and Labrador stocks

Sea survival has improved for both Labrador and Newfoundland stocks, and if it continues to do so over the next couple of years, returns will also improve. Specifically, for Labrador the recruitment over the next couple of years will originate from spawners that were the lowest recorded; however, the projected returns may increase over those expected due to the improvement in marine conditions affecting sea survival. Returns from increased levels of spawning in the past two years will not recruit until after 2000. For Newfoundland stocks, particularly on the northwest and northeast coasts, improvement was recorded in spawners starting in 1992 and 1993 (at the start of the commercial salmon fishing moratorium). Recruits from these increases should be seen starting in 1997 and continuing through to 2000 . This will probably not be the case on the south coast where returns have actually been lower since the commercial moratorium.

## Maritime (Gulf and Scotia-Fundy) stocks

The long-term prospects for Atlantic salmon stocks of the Maritimes (Gulf and Scotia-Fundy) can be categorised geographically.

In the southern Gulf of St. Lawrence (SFA 15, 16 and 18), the abundance of wild salmon is at best at medium levels relative to historical or expected values. The juvenile abundance in the rivers are at medium to high levels and generally increasing over time. Juvenile abundance is high in these rivers for two reasons: 1) they have a high proportion of large salmon in the returns (produce large quantities of eggs), 2) a large portion of the run returns late in the season and are not as heavily exploited as early-run fish, especially in the homewater fisheries. High juvenile abundances have not always translated into high adult returns to date. The ocean environment appears to be an important factor in the low at-sea survivals of Atlantic salmon in eastern Canada because returns to rivers have not increased markedly following closure of fisheries in Newfoundland and reduced fisheries in Greenland. When sea survivals improve, the abundance of salmon is expected to increase above current levels. Atlantic salmon stocks from Prince Edward Island (SFA 17) depend upon hatchery stocking for the large share of the returns. The wild salmon populations are suspected of being negatively affected by land use practices (agriculture and roads) which results in excessive instream siltation and contamination.

Most Atlantic salmon stocks of the Atlantic Coast of Nova Scotia and the Bay of Fundy (SFA 19-23) are not expected to show any important improvements over the next five years. The abundance of wild adult salmon and juveniles is generally low and declining. Sea survival of the salmon from the inner Bay of Fundy stocks is the most important constraint. Returns of wild adult salmon which will meet the conservation requirements are not anticipated in the near future. Returns of hatchery origin salmon may produce returns which approach or even meet the conservation requirements but the long term sustainability of the hatchery initiative is uncertain (from logistic and biological standpoints). The populations of salmon in this area are also impacted by numerous industrial activities: acid rain deposition, fish passage constraints (upstream and downstream), water use practices (regulation of discharge asynchronous with seasonal movements of fish) and escapees from aquaculture facilities.

## Québec stocks

Spawning escapements of all sea-age classes in Québec have not increased in recent years hence, unless significant improvements are seen in sea survivals, recruitment of Québec stocks may be expected to remain at low levels compared to spawning requirements (see Section 2.4).

## U.S.A. long-term trends

A significant increase in the juvenile stocking program for U.S.A. rivers began in 1987 (Table 4.6.1 and Figure 4.6.1). This was due primarily to the increased planting of fry that occurred in the Merrimack and Connecticut rivers, although fry stocking has also increased in many Maine rivers in recent years. In 1996, as much as $19 \%$ of the documented adult returns to some U.S.A. rivers originated from fry stocking, reflecting the increased emphasis upon releases of fry. Additional increases in the level of hatchery fry plants are planned in 1997 and 1998 in the Connecticut River and in several rivers in Maine. A significant decrease in the production and release of hatchery smolts occurred in the U.S.A. in 1995, reflecting the elimination of the hatchery smolt stocking program for the Connecticut River.

The potential for increased smolt output from the fry releases that occurred beginning in 1993 is likely in the future, since fry stocking programs in U.S.A. rivers target vacant or under-utilised juvenile salmon habitat. Although increased MSW returns originating from fry releases were observed in 1996 (smolt migration year of 1994), overall returns to U.S.A. rivers in Southern New England are not expected to change a great deal in 1997 due to the elimination of the hatchery smolt stocking program in the Connecticut River in 1995. This is expected to offset expected increases related to the fry stocking program. However, since the Penobscot River accounts for more than $70 \%$ of the documented returns to U.S.A. rivers each year, and marine survival is increasing (Figure 4.2.5.3), overall MSW returns to U.S.A. rivers are expected to continue the gradual upward trend which is illustrated in Figure 4.2.1.3.

A number of new restoration initiatives have been instituted in several Maine rivers in recent years and these programs have the potential to produce marked increases in adult salmon returns in the late 1990s. These initiatives include increased salmon fry production from government and private hatcheries, and the pen rearing of adult salmon by the Maine aquaculture industry to augment spawning escapement.

### 4.7 Data Deficiencies and Research Needs in the North American Commission Area

1. In the description of methods used to estimate Labrador returns and spawners (Appendix 5i), inactive fishing effort was removed from the estimation procedures. Changes in licensed fishing effort since 1992 have been used to revise exploitation rate calculations and correspondingly, return estimates. The proportion of effort removed (which was inactive) was not uniform over all SFAs of Labrador. The Working Group considered that it would be informative to estimate returns and escapements of salmon to Labrador by summing the individual estimates for SFAs 1, 2 and 14B calculated from SFA-specific exploitation rates for fishing effort within each of the respective areas and compare to the current values used.
2. There is a need for improved habitat surveys for rivers in Labrador and Ungava so that spawner requirements can be developed based on habitat characteristics.
3. Review possible changes in the biological characteristics (mean weight, sex ratio, sea-age composition) of returns to rivers, spawning stocks, and total recruits prior to fisheries. As new information becomes available, refine estimates of spawning requirements in U.S.A. and Canada by incorporating new information such as on biological characteristics for individual stocks, habitat measurements and stock and recruitment analysis.
4. Annual estimates of wild smolt-to-adult salmon survival rates need to be obtained for rivers in Labrador, New Brunswick and Nova Scotia. As well, sea survival rates of hatchery and wild salmon should be examined to determine if changes in survival of hatchery releases can be used as an index of sea survival of wild salmon.

### 5.1 Description of Fishery at West Greenland

### 5.1.1 Catch and effort in 1996

In 1996, no agreement was obtained in the West Greenland Commission of NASCO on the size of the Greenland quota. However, the Greenland authorities permitted a salmon fishery of up to 174 t for the 1996 season.

The fishery was initiated on August 12, and the season ended on November 11 after a long period with very small catches. The total nominal catches amounted to 92 t (Table 5.1.1.1), the majority being landed in August and September.

The geographical distribution of the nominal catches by Greenland vessels is gives in Table 5.1.1.2 for the years 1977-96. As in recent years the majority of the catch was taken and landed in Divisions C and E (79\%). Only minor catches were taken in Divisions A and B.

As in later years only vessels less than 42 ft were permitted to participate in the commercial salmon fishery in Greenland coastal waters in 1996. The fishery was conducted under quotas, distributed at the community level and assessed through daily licensee reports to the Licence Control Office. Entry into the fishery was limited to professional fishers or hunters, fishing their own gear (single hook and line or 2,000 knot 140 mm stretched mesh fixed or drifting gill net of any length) within 40 nautical miles off the west coast or 12 nautical miles off the east coast. Licences for salmon fishing were not issued to vessels with licences for the shrimp fishery.

Fishing for private consumption was restricted to residents of Greenland, using hook and line or a single fixed, 2,000 knot 140 mm stretched mesh gill net, or a similar 30 fathom drift net, tended daily. Salmon taken by this fishery were not permitted to be sold and were not counted against the quota. No firm information on the magnitude of this fishery is available, but the catch has been estimated from local information to be less that 10 t .

Fishing permits may be issued for tourists to fish with hook and line only. There is no daily catch limit, but the catch may not be sold. Only very few tourist licences were issued in 1996.

### 5.1.2 Origin of catches at West Greenland

The Working Group examined the 1996 composition and origin of Atlantic salmon caught at West Greenland based on discriminant analysis of characteristics from 2312 samples from NAFO Divisions 1C (August 14 to September 2), 809 samples from Division 1D (August 14 to September 17), and 220 samples from Division 1E (August 21 to 27). A stratified random sampling design was used to obtain samples from salmon landed by commercial vessels fishing in these areas.

The database used to develop the discriminant function consisted of 790 North American and 789 European known-origin salmon collected at West Greenland from 1980 to 1992. These samples were used because there were no known-origin samples from the 1995-96 catches. Scale samples which were independent of the discriminant analysis, were used to test the discriminant functions. Assumptions of between-group difference for discriminators used in the analysis, homogeneity of variance of within-group discriminators and normality of the distributions of discriminator values were tested before analysis proceeded. Assessment of misclassification rate based on a known prior probability of 0.5 , indicated an overall misclassification rate of $14.9 \%$ with a bias in the error rate of $\pm 0.2 \%$ in favour of the European group classification.

Classification of salmon caught at West Greenland in 1996 by the discriminant function indicated that $42 \%$ ( $95 \%$ $\mathrm{CI}=45 \%, 38 \%$ ) were of North American origin (propNA) compared with $65 \%$ in 1995. The proportions of North American fish in catches in Divisions 1C, 1D, and 1E were $42 \%, 49 \%$, and $42 \%$, respectively. Similar data for 1978 to 1996 (no data for 1993-94) are summarised in Table 5.1.2.1. The proportion of North American salmon in catches in 1996 is one of the lowest in the data series.

Applying the results of the above analysis to the reported catch indicated that $37.5 \mathrm{t}(12,900 \mathrm{salmon})$ of North American origin and 54.7 t (19,100 salmon) of European origin were landed in West Greenland in 1996. The data for 1982 to 1996 (no data for 1993-94) are summarised in Table 5.1.2.2 and Figure 5.1.2.1.

Natural production is known to occur in one small river in Greenland (NAFO Division 10); fish from that population have not knowingly been detected by discriminant analysis. Nielsen (1961) indicated that the population was based on egg deposition in only about 60 redds.

A total of seven tags (six Carlin and one spaghetti type) of Canadian origin salmon was captured at West Greenland in 1996 and returned to Canada. The six Carlin-tagged recaptures were tagged as spawning adults in 1995; four originated from the Miramichi River (SFA16; three MSW salmon and one 1SW salmon), and two originated from the Margaree River (SFA18; both were MSW salmon). The spaghetti-tag recapture originated from River Pabos (Zone Q2; broodstock released in the spring 1996). In 1995, over 7,000 small and large salmon were tagged and released to the Miramichi River during the spawning migration. In the Margaree River, just over 500 small and large salmon were tagged and released. Less than 50 kelts were released from River Pabos in 1996.

### 5.1.3 Biological characteristics of the catches

Biological characteristics (length, weight, and age) were recorded from 3328 samples of commercial catches from NAFO Div. 1C, 1D, and 1E in 1996 using the results of discriminant analysis to divide samples into North American and European components. The data for 1996 are compared with those for previous years in Tables 5.1.3.1 to 5.1.3.3.

The downward trend in mean length of both European and North American 1SW salmon since 1969 changed in 1996, as mean length increased (Table 5.1.3.1). The mean length of European 1SW fish ( 63.4 cm ) was the highest observed mean length in the last five years. The mean length of North American 1SW fish ( 63.0 cm ) is the highest since 1987. Similar observations was made for the mean weights of 1 SW salmon at West Greenland in 1996. Mean length and weight of 2 SW salmon changed similar to those of the 1SW.

Distribution of the catch by river age in 1996, as determined from 1,297 scale samples, is shown in Table 5.1.3.2. The percentage of the European origin salmon that were river age 3 fish ( $31.5 \%$ ) was greater than the mean of $17.3 \%$. This may indicate a continued change in the stock composition in the area. River age 2 fish of North American origin salmon have declined appreciably from the 1968-95 mean of $36.5 \%$ to the current $23.5 \%$.

The proportionate distribution by weight categories ( $1.1-3.3 \mathrm{~kg}, 3.3-5.6 \mathrm{~kg}$, and $>5.6 \mathrm{~kg}$ ) of the landings to the fish plants in West Greenland 1996 was similar to the distributions from the period 1987-90 and indicated somewhat larger salmon than in 1991 and 1995 (Table 5.1.3.4).

The sea-age composition of the samples collected from the West Greenland commercial fishery showed a lower proportion of 1SW fish in 1996 ( $92.1 \%$ ) than in 1995 ( $97.3 \%$ ) in the North American component (Table 5.1.3.3). The proportion of 1SW salmon in the European component in 1996 was similar to proportions observed since 1985.

### 5.1.4 Status of the stocks in the West Greenland Commission area

The salmon caught in the West Greenland area are non-maturing 1SW salmon or older, nearly all of which would return to homewaters in Europe or North America as MSW fish if they survived.

The most abundant European stocks in West Greenland are thought to originate from the U.K. and Ireland. Survival indices for combined river data for the NEAC area indicate a downward trend in survival to homewaters for the last ten years for $2 S W$ wild stocks. No trend was noted in the most recent five year period. This is consistent with the estimates that have been made of the pre-fishery abundance of non-maturing 1 SW salmon from southern Europe; these have declined over the past 25 years and now appear to be at their lowest level in the time series.

Conservation reference points have been presented for only seven European stocks and these do not generally provide separate reference levels for 1 SW and 2 SW salmon. As a result they cannot be used to assess the status of the stock components contributing to the West Greenland fishery.

In general, there has been no significant change in smolt production in the Northeast Atlantic, and adult runs in western European rivers showed no significant trend in run sizes over the last ten years.

For the North American Commission Area the North American Run-Reconstruction Model was used to update the estimates of pre-fishery abundance of non-maturing and maturing 1SW salmon from 1971-1996. The 1994 estimate of pre-fishery abundance of non-maturing 1 SW salmon was the lowest on record. Increases from this low value were noted in both 1995 and 1996 (Figure 4.2.3.1) with the 1996 estimate about $8 \%$ above the low 1994 estimate. The results suggest a levelling off of a decline to historical low levels for 1SW non-maturing salmon. In addition to the steady decline in total recruits (both maturing and non-maturing 1 SW salmon) over the last ten years, there has been a steady increase in the proportion of the North American stock maturing as 1SW fish. This proportion has risen from about $45 \%$ at the beginning of the 1970 s to around $70 \%$ in the last four years.

The estimate of the total number of 1 SW salmon returning to Labrador and Newfoundland rivers and coastal waters of other areas of North America in 1996 is $44 \%$ higher than the estimate for 1995 and higher than the average of the previous years (1971-95) by $20 \%$. It is the fourth highest observed in the past 10 years and seventh highest in the 26 year time series, 1971-1996 (Table 4.2.2.1). The estimates of returns are quite variable over the time series with no trends indicated. The estimated 2 SW returns are $10 \%$ lower than the total returns for 1995 but similar to both 1994 returns and the average for the past 10 years (Table 4.2.2.2). They have declined from a peak of almost 200,000 in the late 1970s.

In most regions the returns of $2 S W$ fish are near the lower end of the twenty five year time series. However, returns of 2SW salmon to Labrador in 1995 and 1996 were the best in the time series. Returns of 1SW salmon improved in all areas in 1996 relative to 1995 and in some regions (Labrador, Newfoundland, and Québec) were near the highest levels in the time series.

The majority of the U.S.A. returns were recorded in the rivers of Maine, with the Penobscot River accounting for about $74 \%$ of the total. Salmon returns to the Penobscot River were $52 \%$ higher than the previous year, but were $23 \%$ higher than the previous 5 -year average and $17 \%$ lower than the previous 10 -year average. While U.S.A. salmon returns improved in 1996, returns to most rivers are hatchery-dependent and remain at low levels compared to spawning requirements.

Egg depositions exceeded or equalled the specific river requirements in 32 of the 85 rivers which were assessed in Canada and were less than $50 \%$ of requirements in 22 other rivers. Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where 10 of the 20 rivers assessed had egg depositions which were less than $50 \%$ of requirements (Figure 4.2.4.1).

North American salmon stocks remain at low levels relative to production in the 1970s. The 1SW non-maturing component continues to be depressed with river returns and total production amongst the lowest recorded. Returns, however, in 1996 of maturing 1SW salmon (grilse) to North American rivers are quite high in many areas, notably Labrador, Newfoundland, Québec and U.S.A. which may indicate improved marine survival rates of this cohort. If this is the case, improvement in 2 SW salmon returns and spawners may be expected in 1997. Only two areas achieved or came close to achieving their spawning requirements for 2 SW salmon in 1996. They were Newfoundland, where 2 SW salmon comprise only a small proportion of salmon production and the Gulf of St. Lawrence, where 2 SW salmon are a high proportion of production and very important in terms of their contribution to both North American and Greenland fisheries.

Despite some improvements in the annual returns to a number of rivers, both in European and North American areas the overall status of stocks contributing to the West Greenland fishery remains poor, and as a result, the status of stocks within the West Greenland area is thought to be low compared to earlier (historical) levels.

### 5.2 Catch Options with an Assessment of Risks Relative to the Achieving Spawning Requirements

### 5.2.1 Overview

The Working Group was asked to continue with the development and evaluation of methods to advise on catch levels based upon maintaining adequate spawning escapements. The problems of estimating the total allowable catch (TAC) for salmon have been examined by the Working Group in previous years (ICES 1982/Assess:19, 1984/Assess:16, 1986/Assess:17, and 1988/Assess:16) and were repeated in the four last Working Group reports (ICES 1993/Assess:10; 1994/Assess:16; 1995/Assess:14; and 1996/Assess:11). Although advances have been made in our understanding of the population dynamics of Atlantic salmon and the exploitation occurring in the fisheries, the concerns about the implications of applying TACs to mixed stock fisheries are still relevant. In principle, adjustments in catches in mixed-stock fisheries provided by means of an annually adjusted TAC would
reduce mean mortality on the contributing populations. However, benefits that might result for particular stocks would be difficult to demonstrate, in the same way that detriments to individual stocks are difficult to identify.

In 1993, the Working Group considered how the predictive measures of abundance could be used to give annual catch advice (ICES 1993/Assess:10; Sections 5.3 and 5.4). The aim of management would be to limit catches to a level that would facilitate achieving overall spawning escapement equivalent to the sum of spawning requirements in individual North American and European rivers (when the latter have been defined). In order to achieve the desired level of exploitation for a given level of predicted abundance, a TAC could be fixed or some form of effort adjustment introduced.

The advice for any given year is dependent on obtaining a reliable predictor of the abundance of non-maturing 1SW North American stocks prior to the start of the fishery in Greenland. Commercial gill net fisheries in Greenland and Labrador harvest one-sea winter (1SW) salmon about one year before they mature and return to spawn in North American rivers. This component is also harvested on their return as 2 SW salmon in commercial fisheries in Labrador and Québec, angling and native fisheries throughout eastern Canada and angling fisheries in the northeastern U.S.A. The fishery in Greenland harvests salmon from the non-maturing component while the fishery in Labrador harvests a mix from the non-maturing component as well as maturing 1SW and MSW salmon. The commercial fishery in Québec harvests maturing 1SW and MSW salmon.

The Working Group has advocated models based on thermal habitat in the northwest Atlantic to forecast prefishery abundance in order to provide catch advice for the West Greenland fishery. While the approach has been consistent since 1993, the models themselves have varied slightly over the years. The changes have been made to these models in attempts to improve the prediction and add more biological reality. The models of previous years included using the following predictor variables: 1993-thermal habitat in March; 1994-thermal habitat in March; 1995 - thermal habitat in January, February, and March, and 1996 - thermal habitat in February and lagged spawners from the Labrador, Newfoundland, Québec, and Scotia-Fundy regions of Canada.

## Biological rational for catch advice model

The Working Group had previously addressed in some detail the wide range of factors both abiotic and biotic that could influence survival of salmon in the sea (ICES 1993/Assess:10; ICES 1994/Assess:16). The first of these factors was the possible influence of the freshwater phase on subsequent size and condition of salmon smolts which would subsequently effect their marine survival when they enter the sea. Furthermore, factors at work in coastal areas and finally those that would influence survival in the open sea over their entire life history are also discussed. As can be seen by reference to Section 4.2.5, sea survival in several stocks remains at low levels despite reduced commercial exploitation from closed fisheries is considered (Section 4.2.5). However, in Newfoundland, sea survival improved considerably returning to near historic levels although the survival rates from pre-1992 years include removals from commercial fishing.

The Working Group reviewed the biological rational for the catch advice model first used in ICES (1993/Assess:10) and updated in ICES (1995/Assess:14). The hypothesis tested was that the amount of marine habitat available for salmon in the northwest Atlantic at some time prior to the end of their first winter at sea was directly related to the numbers of 2 SW salmon produced. In this analysis, a relative index of marine habitat thought suitable for salmon (termed thermal habitat) was determined for the months of January, February, and March by weighting salmon catch rates from experimental fishing and sea surface temperature data. Analysis of variance indicated that pre-fishery abundance was significantly related to thermal habitat in all of these months.

However, it is recognised that we have not identified biological mechanisms to account for the observed climate abundance relationship. Information reported at this meeting (Section 2.5.2) indicates that overall survival of salmon may be related to thermal conditions, this generally supporting the relevance of the forecast model.

## North American Run-Reconstruction Model

The Working Group has used the North American Run-Reconstruction Model to estimate pre-fishery abundance of 1 SW non-maturing and maturing 2 SW fish adjusted by natural mortality to the time prior to the West Greenland fishery (See Section 4.2.3). Region-specific estimates of 2SW returns are listed in Table 4.2.2.2. Estimates of 2SW returns in Labrador are derived from estimated 2SW catches in the fishery using a range of assumptions regarding exploitation rates and origin of the catch. For 1993-1996 returns, the estimates were further adjusted to account for reductions in licensed fishing effort and season in Labrador (See Section 4.2.2).

## Update of thermal habitat

The Working Group has been using the relationship between marine habitat and pre-fishery abundance to forecast prefishery abundance (ICES 1993/Assess:10; 1994/Assess:16; 1995/Assess:14; and 1996/Assess:11). Marine habitat is measured as a relative index of the area suitable for salmon overwintering, termed thermal habitat, and was derived from sea surface temperature (SST) data obtained from the National Meteorological Center of the National Ocean \& Atmospheric Administration and previously published catch rates for salmon from research vessels fishing in the northwest Atlantic (Reddin et al. 1993 and ICES 1995/Assess:14). The SST data were determined by optimally interpolating SSTs from ships of opportunity, earth observation satellites (AVHRR), and sea ice cover data. The area used to determine available salmon habitat encompassed the northwest Atlantic north of $41^{\circ} \mathrm{N}$ latitude and west of $29^{\circ} \mathrm{W}$ longitude and includes the Davis Strait, Labrador Sea, Irminger Sea, and the Grand Bank of Newfoundland.

Thermal habitat has been updated to include 1997 data. Two periods of decline in the available habitat are identified (1980 to 1984 and 1988 to 1995) in the February index (Table 5.2.1.1 and Figure 5.2.1.1). Available habitat has increased in 1997 over 1996 in the February data. The 1997 February value is the highest value in the previous seven years of the time series.

### 5.2.2 Forecast model for pre-fishery abundance of North American 2SW salmon

The Working Group reviewed the procedures used to forecast pre-fishery abundance and considered alternate model formulations that may be useful in future assessments. The current model is based on a combination of environmental and stock size variables. A review of potential thermal habitat and lagged spawner variables did not reveal any data relationships not previously detected, nor result in a new linear model significantly more robust than the one currently being used. Therefore, a change in model formulation did not appear warranted at this time. In addition to reviewing the formulation of the current linear model, the Working Group considered other model classes (Information on Other Prediction Procedures below).

The 1996 model used by the Working Group to forecast pre-fishery abundance was based on regression analysis to predict the pre-fishery abundance of non-maturing 1SW fish prior to the start of the Greenland fishery using thermal habitat for February and lagged spawners (sum of lagged spawners from Labrador, Newfoundland, Scotia-Fundy and Québec) as predictor variables (ICES 1996/Assess:11). This was justified on the basis of studies showing that salmon stocks over wide geographic areas tend to have synchronous survival rates and that the winter period may be the critical stage for post-smolt survival (Scarnecchia 1983; Reddin and Shearer 1987b; Friedland et al. 1993). Consequently, the model used in 1996 was updated to reflect the addition of the 1997 values to the time series of pre-fishery abundance estimates.

The linear fit to the model of pre-fishery abundance versus February thermal habitat and lagged spawners (SNLQ) produced a significant relationship between observed and predicted values at less than the $5 \%$ level ( F $(2,15)=18.7)$. The results show that with the 1995 data added there is an improvement in fit over that of last year ( $\mathrm{R}^{2}=0.71$ in 1997 versus 0.68 in 1996). The jackknife and deterministic predicted values for pre-fishery abundance for 1971-1995 are shown in Table 5.2.1.1 and Figure 5.2.2.1. The predicted values are shown to fit the observed data quite well except during the period of low abundance in 1978 and in the late 1980s and 90s when abundance was low. The high correlation between the observed and jackknife prediction ( $r=+0.744$ ) can be seen in Figure 5.2.2.2a. The residual pattern for the model shows a positive relationship with observed values $(\mathrm{r}=+0.509)$ although the positive residuals decrease at the end of the time series (Figure 5.2.2.2b). Also, the Working Group was encouraged by the low residual value shown in 1995, the last observed value in the time series. The residual pattern for the model shows no autocorrelation. The forecasted estimate of pre-fishery abundance for 1997 using the February thermal habitat and lagged spawner model are about 197,000 at the 50\% probability level (Table 5.2.2.1).

The advantage of this model is that it considers the influence of the spawning stock level in the predictive relationship for pre-fishery abundance. Thus, the prediction of pre-fishery abundance would be moderated during periods of high levels of habitat and low levels of spawning stock. The alternate case would be an increase in predicted pre-fishery abundance when stocks were high and thermal habitat was low. The former has occurred with the predicted value for 1997, as thermal habitat has increased considerably, the predicted pre-fishery abundance in 1997 is low due to the large decline in spawners producing them (Figure 5.2.1.1).

## Investigation of other prediction procedures

One class of model that may be useful in abundance prediction is neural networks which have been widely applied by physical and life scientists. The strength of this class of models is their ability to adapt to a variety of problems and to deal with non-linear relationships between variables (Chitra 1992). Models of physical systems often involve pattern recognition in complex and correlated data fields, much like the situation we face in predicting abundance from fields of thermal habitat data. Neural nets have been found to outperform linear models in predicting water column structure and air sea interaction effects. For example, salinity distributions in estuaries, which are dynamic mixing systems, can be predicted with greater accuracy using neural networks than comparable linear models (DeSilets et al. 1992). Dynamic behaviour on global scales can also predicted more effectively using neural networks as demonstrated by models predicting sea surface temperature structure associated with El Nino events in the Pacific Ocean (Derr and Slutz 1994).

Biologists were immediately attracted to neural networks because of their potential application in classification problems and as predictive tools. In a direct comparison between linear discriminate analysis and neural network, Withler et al. (1994) found that classification efficiency compared favourably between the two techniques. The predictive capability of these models is now being explored in the context of fishery independent survey predictions and catch forecasting from commercial datasets. Komatsu et al. (1994) developed a network model to predict post-larval stages of the Japanese sardine that outperformed linear regression models. Likewise, Hwang et al. (1996) forecasted jack mackerel catches also with greater prediction accuracy than simple linear models.

The Working Group examined the efficacy of predicting Atlantic salmon abundance with neural network models as opposed to linear regression models. A Ward, type 2 neural network (Ward Systems Group 1996) was developed using four independent variables or input neurons. Ward nets utilise multiple hidden network slabs with different activation functions. The four input neurons were thermal habitat for March (year i), May, June, and July (year i-1) and were selected based on contribution rates that can be computed from back propagation networks. The model was evaluated with a complete Jackknife, thus predicted values are unbiased. Each jackknifed network was trained for 1500 training epochs.

The neural network produced a significant relationship between observed and predicted values, and furthermore, the residuals were distributed without trend with abundance. Observed and predicted time series can be found in Figure 5.2.2.3a. The network model captured most of the features in the observed time series. Notably, the model estimates well at low abundance, but also fails to respond to the decline in 1978. The residual pattern for the network model shows no autocorrelation and residuals are generally balanced at the end of the time series (Figure 5.2.2.3b). The high correlation between observed and jackknife prediction can be seen in Figure 5.2.2.4a. Lower model residuals result in an absence of trend between residuals and observed values (Figure 5.2.2.4b). This neural network outperforms a linear model fit in respect to two criteria. The network model provides the best reconstruction of observed patterns using unbiased fits and showed no bias associated with the magnitude of residuals in the model. These characteristics are potentially critical at low population levels when estimation error puts the population at greater risk. But, the lack of any underlying distributions for the neural network model does pose a number of technical challenges. With neural network models we lack a closed form to estimate prediction intervals, and thus must rely on the computation or derivation of intervals empirically (Gardner 1988). The Working Group was not equipped to carry this model forward to produce precision estimates.

The management of salmon resources has become increasingly complex requiring scientific advice to meet interrelated conservation and economic goals. This has meant an expanding need for forecast models that are highly accurate and can characterise the risk of various management decisions. For the conservation of Atlantic salmon stocks in the northwest Atlantic, modelling efforts to date have been relatively simple and designed to meet a single conservation goal (Reddin et al. 1993). This goal has been to achieve requirement spawning in North American rivers the year after the fishery. This approach does not model economic impacts (Herrmann 1993) and is not truly in-season in that there is a full year to make other compensatory management decisions to meet the goals (Woodey 1987). Inseason management carries with it greater demands for accuracy and precision in forecast models. To meet the challenge of such management systems, an array of estimation procedures have been developed. The impact of non-linear relationships among model variables (Bocking and Peterman 1988), Bayesian probability approaches to predict run sizes (Fried and Hilborn 1988), nonparametic estimators (Noakes 1989), and time series approaches (Noakes et al. 1990) have been evaluated. This makes model evaluation and comparison that much more important and demonstrates the value of alternative model formulations. Such formulations should be pursued for Atlantic salmon assessments especially as datasets expand.

The Working Group considered the issue of model evaluation and formulation and weighed the competing issue of striving for biological realism versus the pragmatic goal of producing the model with the most predictive power. Model evaluation begins with setting clear goals and utilising tools equally effective on all modelling approaches. The use of jackknife and Monte Carlo techniques to evaluate forecast models has emerged as an important tool (Claytor et al. 1993). A school of thought in operation research suggests that models should be evaluated by a set of criteria that tests their predictive power. Thus, performance of a model should not be based on its ability to simply deal with historical data, but instead evaluate how it deals with actual out of sample data over the full contrast of potential responses (Makridakis 1990). This represents a shift of emphasis from strict adherence to fitting procedures to a more pragmatic approach of simply selecting the best predictor. Alternatively, models can be selected on the basis of documented biological relationship, thus variables would have to have specific biological meaning before they could be included in a model.

The Working Group seeks additional guidance from ACFM on these important issues of model formulation. These issues include the use of neural networks in development of catch advice. Secondly, what is ACFM's view of producing a model with the most predictive power versus an a priori model with a biological basis?

## Stochastic analyses

Although the exact error bounds for the estimates of NN1(i) are unknown, minimum and maximum values of component catch and return estimates have been estimated. Simulation methods, implemented in the software package SAS (SAS Institute, 1996), were used to simulate the probability density function of NN1(i).

Simulated values of NN1(i) assuming a uniform distribution were also used to evaluate the distribution of mean values for the regression models between pre-fishery abundance and February (H2) thermal habitat and lagged spawners (SNLQ).

To estimate the composite error distribution of the 1000 realisations, it was assumed that the forecast was distributed normally, with a mean equal to the forecast and variance equal to the mean square error of the estimate. The composite sampling distribution for the forecast was estimated as the sum of the underlying distributions for each stochastic realisation $\mathbf{j}$ :

Eq. 5.2.2.1

$$
\mathrm{F}_{\mathrm{C}}\left(\mathrm{NN}_{\mathrm{FOR}}(1997), \mathrm{s}_{\mathrm{C}}^{2}\right)=\mathrm{S}_{\mathrm{j}=1,1000} \mathrm{~F}_{\mathrm{j}}\left(\mathrm{NN}_{\mathrm{FOR}}(1997)_{\mathrm{j}}, \mathrm{~s}_{\mathrm{j}}^{2}\right) / 1000
$$

where $F()$ is the normal probability density function.
The sampling distribution of the composite stochastic forecast, i.e. $\mathrm{F}_{\mathrm{C}}\left(\mathrm{NN1}_{\mathrm{FOR}}(1997), \mathrm{s}_{\mathrm{C}}{ }^{2}\right)$ was used to compute forecast values in $5 \%$ percentile steps from $25 \%$ to $75 \%$. The $5 \%$ percentiles are used for computation of alternative quotas under varying levels of risk where risk refers to the probability that the spawning requirement will not be met.

The stochastic forecasts permitted the estimation of the cumulative distribution function (Table 5.2.2.1). These estimates can be used to quantify the probability that the actual stock is above the relative probabilities of attaining spawning requirements for the stock under different allocation schemes. Managers may also use this information to determine the relative risks borne by the stock (i.e. meeting spawning requirements) versus the fishery (e.g. reduced short-term catches).

### 5.2.3 Development of catch options for 1997

## Development of catch advice

To prevent recruitment overfishing, the goal in Atlantic salmon management is to ensure adequate numbers of spawners in each river population. In mixed stock fisheries, this is not possible owing to varying migration patterns and exploitation rates experienced by individual stocks. Nonetheless, it is possible to define a composite spawning requirement for the North American stock complex by summing the spawning requirements of Salmon Fishing Areas in Canada and river basins within the U.S.A. Details on the methodology to estimate and update the spawning thresholds are provided in (ICES 1996/Assess:11); values appear in Table 4.4.1 of this report. With these data, it is possible to compute an allowable harvest. This procedure is unchanged from the previous assessment and is shown in Appendix 7.

## Catch advice for 1997

The fishery allocation for West Greenland is for 1SW fisheries in 1997, whereas the allocation for North America can be harvested in 1SW fisheries in 1997 and/or in 2SW fisheries in 1998. To achieve the spawning management goal, a pool of fish must be set aside prior to fishery allocation in order to meet spawning requirements and allowing for natural mortality in the intervening months between the fishery and spawning migration. In last years report, a spawning requirement of 180,495 fish was reported for all North American rivers (ICES 1996/Assess:11). Thus, 201,483 pre-fishery abundance fish must be reserved ( $180,495 / \exp (-$ $.01 * 11)$ ) to ensure achievement of the requirement after natural mortality.

By using the probability density function of the pre-fishery abundance, the probability of the true stock abundance being greater or lower than the value selected can be estimated. This probability level also provides a measure of the probability of reaching spawning requirements assuming fishery allocations are taken without error. The mean estimate of the forecast represents a reference point at which there is a $50 \%$ chance that the true abundance is lower than required to achieve the spawning requirement. Likewise, the forecast value at the 25th percentile, or the value with a $25 \%$ chance that the abundance is lower and the forecast value at 75 th percentile, or the value with a $75 \%$ chance that the abundance is lower, characterise the range of decision with lower and higher risks, respectively.

Quota computation for the 1997 fishery requires an estimate of pre-fishery abundance [NN1], stock composition by continent [PropNA], mean weights of North American and European 1SW salmon [WT1SWNA and WT1SWE, respectively], and a correction factor for the expected sea age composition of the total landings [ACF]. Exponential smoothing model forecasts utilising data collected during the 1996 fishery and using interpolated values for 1993 and 1994, with approximate $50 \%$ confidence limits, are summarised below.

| Parameter | Forecast | Minus 1SE | Plus 1SE |
| :---: | :---: | :---: | :---: |
| PropNA | 0.557 | 0.465 | 0.649 |
| WT1SWNA | 2.647 | 2.488 | 2.806 |
| WT1SWE | 2.750 | 2.563 | 2.937 |
| ACF | 1.133 | 1.034 | 1.232 |

The Working Group recommends that as these parameters have changed in the past, they should be updated with new data from sampling programs to ensure the greatest possible accuracy in the quota calculation.

Greenland quota levels for H2-SNLQ forecast of pre-fishery abundance were computed. The quota values based on this forecast between interquartile limits of the probability density function are presented in Table 5.2.3.1. For the point estimate level and the stochastic regression estimate using NN1, the quota options ranged from 0 to 458 t , depending on the proportion allocated to West Greenland (FNA) and was bounded by the $25 \%$ to $75 \%$ probability levels. For the FNA level used in recent management measures for the West Greenland Commission (at the 0.4 allocation rate), the quota is 0 t at the $50 \%$ risk level.

The $50 \%$ risk level is intended to produce spawning escapements in North America that will meet the requirement level for all rivers combined $50 \%$ of the time. Even if this overall requirement is achieved, it is likely that some stocks will therefore fail to meet their individual requirement spawner requirements while others will exceed requirement levels. This may result from random variation between years or from systematic differences in the patterns of exploitation on fish from different rivers or regions. In the latter case, adoption of a $50 \%$ risk approach may result in some stocks failing to meet requirement levels over an extended period if the full TAC is harvested. This would be likely to result in the long-term decline in those stocks.

The Working Group reiterates the advice given in 1996, that it is evident from both the indicators of stock status and the extremely low quota levels computed, that the North American stock complex is in tenuous condition. We are close to record low abundance despite nearly complete closures of mixed and single stock fisheries, a continuing trend of below requirement spawning escapements for 2 SW salmon, and the low marine survival rates for some monitored stocks. The increasing advantage associated with each additional spawner in under-seeded river systems make a strong case for a conservative management strategy. However, the Working Group noted that thermal habitat and smolt survival rates in the northwest Atlantic are improving which will be expected to provide future benefits to returns and spawning escapements.

### 5.2.4 Risk assessment of catch options

The provision of catch advice in a risk framework involves the incorporation of the uncertainty in all the factors used to develop the catch options. The ranges in the uncertainties of all the factors will result in assessments of differing level of precision. The precision of the assessment has a potential effect on the risk approach used by managers. One approach considers the catch options relative to a $50 \%$ chance of the undesirable event occurring and ignores the uncertainty in the stock assessment. The reliability of the assessment has very different and profound consequences on the catch options for risk-averse compared to risk-prone approaches (Figure 5.2.4.1). In a theoretical example, two assessments provide the same point estimate ( $50 \%$ probability value) but the precisions are very different. Under a risk-prone management approach, the allowed catch would be greater for the imprecise assessment: at a $70 \%$ risk level, the advised catch under the precise assessment would be 500 t but the uncertain assessment would provide for a catch of 800 t (Figure 5.2.4.1). The risk-averse management approach would advise for lower catch options for the imprecise assessment: at a $20 \%$ risk level, the precise assessment would provide a catch option of about 400 t but for the imprecise assessment, no catch is advised. Under precautionary management principles (Section 2.7), a risk-averse approach would be favoured for imprecise assessments.

The analysis of risk involves three steps: 1) describing the precision or imprecision of the assessment, 2) the definition of a management strategy, and 3) the evaluation of the probability of an event (either desirable or undesirable) resulting from the fishery action. The management of Atlantic salmon in the North American and Greenland Commission Areas involves managing for a fixed escapement of salmon to rivers in North America. The spawning requirements to North America are considered to be a threshold reference point. All potential recruits in excess of the threshold requirement are considered to be available for harvest. The undesirable event to be assessed is that the spawning escapement to North America will be below the spawner requirements.

A risk analysis of catch options for Atlantic salmon from North America incorporates all the uncertainty in the estimates of the probable returns:

1. the spawning requirement risk plot, and
2. the uncertainty of the prefishery abundance forecast,
3. the uncertainty in the biological parameters used to translate catches (weight) into numbers of North American origin salmon.

Examples for the 1996 and 1976 fisheries are used to illustrate the outputs from this analysis.

## Spawner requirement risk analysis

The derivation of the spawning requirement risk plot for North America was similar to the method presented in ICES 1996/Assess:11. Briefly, North America is divided into six stock areas which correspond to the areas used to estimate returns and spawning escapements (Table 4.4.1; Table 5.2.4.1). Point estimates of the proportion female by stock area are from ICES 1996/Assess:11 (Table 5.2.4.1). The annual variability in the proportion female in each stock area was described in terms of a uniform distribution corresponding to values for each stock area. When values for annual variation were not available, the variation was assumed to be of a similar magnitude to other stock areas (Table 5.2.4.1). A total of 1000 simulations was run for each spawning escapement level. The sex ratio varied independently in each stock for each simulation. The risk plots were expressed as the probability of meeting or exceeding the spawning requirements concurrently in all six stock areas. In addition, plots of the probability of meeting or exceeding lower proportions of the spawning requirements were derived as an indication of the magnitude of under-escapement which would be expected for different levels of escapement to North American rivers (Figure 5.2.4.2).

Under the assumption of equal production from all stock areas (i.e. recruitment in direct proportion to the spawner requirement) just over 200,000 fish should escape to North America as spawners to achieve the spawner requirement in all six stock areas at a $50 \%$ probability level (Figure 5.2.4.2). This value is higher than the previously calculated $50 \%$ risk value of 182,250 fish (ICES 1996/Assess:11) because it includes the annual variation in proportion female and higher than the point estimate of total requirements to North America of 180,495 fish (Table 4.4.1). Substantially fewer fish are required for achieving only a portion (for example 50\%) of the spawner requirements in all six areas.

## Prefishery forecast abundance uncertainty

Model fitting and the confidence intervals for the prefishery abundance of non-maturing North American origin salmon are described in Section 5.2.2. The required elements for the risk analysis are the distributions of prefishery abundance and their associated probabilities. For purposes of these examples, prefishery abundance forecasts were obtained from the linear regression of winter habitat (sum of January, February and March habitat index) for the 1976 simulation and on February habitat and lagged spawners for the 1996 example (ICES 1996/Assess:11). The probability distribution of the point estimate for the prefishery abundance forecast was derived using the variance formulas for a single predicted value (Figure 5.2.4.3, upper panel).

## Uncertainty in the biological characteristics and predicted catches of North American origin salmon

In the previous year's working group report (ICES 1996/Assess:11), the quota options were calculated using a distribution of prefishery abundance forecasts and point estimates for the remaining parameters including: the spawner requirement for North America, proportion of the 1SW catch which would be of North American origin, weight of 1SW North American and European fish, and the age correction factor. The annual estimates of continent of origin and biological characteristics of salmon caught at West Greenland were taken from a previous report (ICES 1992/Assess:15, Tables 5.1.1.1, 5.1.2.1, and 5.1.2.3). The simple assumption that annual variation in characteristics follows a uniform distribution over the range of observed values was used. Using the biological characteristics and the catch options, the total returns to North America after the Greenland fishery were calculated by subtracting the catch of North American 1SW origin salmon from the prefishery abundance forecast and discounting for the 11 months of natural mortality between the time of the Greenland fishery and return to homewaters. An example of the distribution of harvest (numbers) of North American origin salmon for a given quota which incorporated the uncertainty in the biological characteristics is shown in the middle panel of Figure 5.2.4.3. The distribution of returns to North America after harvest at Greenland which incorporates the uncertainty in the prefishery abundance forecast and the uncertainty in harvest numbers is shown in the bottom panel of Figure 5.2.4.3.

## Catch options and risk summary examples

The final step in the risk analysis of the catch options involves combining the cumulative risk plots from the spawner requirement calculation with the probability distribution of the returns to North America for different catch options. The sum of the products of the cumulative distribution of spawner requirements and the probability distribution of the corresponding returns to North America equals the risk of meeting the conservation requirements. The risk of not meeting the desired spawner requirement in at least one of the six stock areas is obtained by subtracting from unity the probability of meeting the requirements in all the areas. An analysis of the risk of the severity of the underescapement (for example, the risk of not attaining $50 \%$ of the spawner requirement in at least one of the six stock areas) was derived in exactly the same way by substituting the cumulative distribution for a different spawner requirement proportion (Figure 5.2.4.4).

Using the 1996 data, it can clearly be seen that even under the assumptions of equal production rates in all stock areas of North America and no fishery in Greenland, there was a very high probability ( 0.60 ) of not meeting the spawner requirements in at least one of the North American stock areas (Figure 5.2.4.4). The relatively shallow rise in risk reflects the imprecision of the prefishery forecast and the variability in the biological characteristics of the salmon at Greenland. In terms of the magnitude of the underescapement which could be expected, there was a $>25 \%$ chance that the returns to North America would have resulted in an underescapement of $50 \%$ of the spawner requirements in at least one stock even in the absence of fisheries in Greenland and North America.

The prefishery abundance in 1976 was much higher than in 1996. For such a high abundance period, catch options of over $1,500 \mathrm{t}$ could have been considered at the risk neutral point ( $50 \%$ level) although risk-averse management would have considered catch options between 1,000 and 1,500 t presuming that no fisheries on the fish occurred in the homewaters of North America (Figure 5.2.4.4).

Such risk analysis could be used for directly assessing the consequences to the spawner requirements of harvest options in both Greenland and in North America. Given the large uncertainty in the prefishery abundance forecast and the annual variability and uncertainty in the biological characteristics of the fish harvested in Greenland, a risk-averse strategy would be advisable.

## Catch options and risk summary for 1997

The prefishery abundance forecast distribution for 1997 is described in Section 5.2.2. The expected biological characteristics of the non-maturing 1SW salmon were described from the exponential smoothing forecast (Section 5.2.3) and its associated variance for the predicted values. The variation in biological characteristics was used to generate the probability distribution of North American origin salmon in the West Greenland fishery relative to a range of catch options. The results of the risk analysis are summarised in Figure 5.2.4.5.

The abundance of salmon is expected to be low in 1997. There is a high risk ( $52 \%$ ) that the escapement in 1998 will be below the spawning requirement in at least one of the six stock areas in North America, even in the absence of any fisheries-induced mortality in Greenland and North America. There is a high probability ( $22 \%$ ) that at least one of the six stocks will be severely underescaped (by $50 \%$ ). Although the risk profile appears shallow over the range of catch options illustrated ( 0 to 1000 t ), the risk of not meeting spawning requirements provides options for risk-prone management approaches. Risk-averse management would close the fisheries. Considering the uncertainty in the assessment of the abundance of North American salmon in West Greenland in 1997, precautionary principles are advised.

The impact of the combined Greenland and North American fisheries must also be considered. The fisheries exploitation rates in North America in 1996 were estimated to be between 0.15 and 0.28 (Section 4.1.4). Assuming that fisheries management in North America in 1998 would be similar to that of 1996, then it would be expected that $15 \%$ to $30 \%$ of the 2 SW returns to North America would be removed prior to spawning. The impact of such a fishing scenario in North America on the salmon returning to homewaters in 1998, in the absence of any fishery at Greenland in 1997, results in a $65 \%$ risk of not meeting the spawning requirements in at least one of the six stock areas (Figure 5.2.4.5). This assumes that salmon will return to each geographic area in proportion to the relative spawning requirements in each area and that the exploitation rates in each of the six stock areas are similar. Although this is not true (see Section 4.2.4), it is the only scenario considered by the Working Group at this meeting.

The cumulative consequences of fisheries at Greenland (1997) and in North America (1998) on the potential spawning escapements to North American stock areas increases the risk of severe underescapement ( $50 \%$ of requirements) in North America. There is a $22 \%$ risk of severe underescapement with no fisheries and the risk rises to greater than $50 \%$ at a Greenland catch option of 400 t and exploitation rates between 0.15 and 0.28 in North America (Figure 5.2.4.5).

### 5.3 Data Deficiencies and Research Needed for the West Greenland Commission Area

1. The mean weights, sea ages and proportion of fish originating from North America and Europe are essential parameters to provide catch advice for the West Greenland fishery. As these parameters are known to vary over time, the Working Group recommends that the sampling programme which occurred in 1995 and 1996 be continued and improved to cover as much of the landings as possible.
2. Efforts should be made to improve the estimates of the annual catches of salmon taken for local consumption at West Greenland.
3. The catch options for the West Greenland fishery are based almost entirely upon data derived from North American stocks. In view of the evidence of a long-term decline in the European stock components contributing to this fishery (southern European non-maturing 1SW recruits) the Working Group emphasised the need for information from these stocks to be incorporated into the assessments as soon as possible.

## 6 ESCAPES FROM FISH CULTURE OPERATIONS

### 6.1 Background

In addition to full-scale commercial aquaculture, several classes of salmon culture operations exist including the hatching of eggs and the rearing of fry, parr and smolts for release into the wild in enhancement schemes. Intentional releases of juvenile stages have potential effects on wild populations in addition to intended effects on abundance. Unintended escapes of juveniles probably occur quite frequently although events like these are not generally documented. It should therefore be noted that two categories of aquaculture fish exist among those
liberated early in life - fish that are deliberately released at the fry, parr or smolt stages in enhancement or ranching schemes and fish that are released accidentally from aquaculture. In most cases, fish that have been intentionally released as juveniles cannot be distinguished from those which have escaped accidentally.

A number of techniques have been used to distinguish aquaculture fish among wild fish including assessment of morphological defects (Lund et al. 1989), scale patterns (Lund and Hansen 1991), otolith reading (Hindar and L'Abee-Lund 1992) and carotenoid pigment (Craik and Harvey 1987a) or genetic analysis (Crozier 1993). None of the methods are totally discriminatory and, in general, fish that escape very early in life cannot be recognised. In the U.S.A. and to a lesser extent Canada, intentional releases of adult fish to the wild are counted as part of the repertoire available to management. In Canada, the same techniques have been used but only on an experimental scale. In general, fish that have been liberated from sea-cages as post-smolts or adults belong to a single category of accidental release.

After escape, fish appear to resume a form of the natural life-cycle. Thus, fish that escape from sea-cages and fish that can be demonstrated to have been reared in hatcheries until near smolting have been shown to be present among wild fish on ocean feeding grounds in the Norwegian Sea (Hansen et al. 1987; 1993a) and at West Greenland (Hansen et al. 1993a), distant from any possible sources of release. Recently, cultured salmon released as smolts have been detected among wild post-smolts at intermediate latitudes in the north-east Atlantic and presumably in transit to more northern ocean feeding areas (Shelton et al. 1976). Later in the life-cycle, near sexual maturity, escaped farmed fish can be detected in coastal and fjord fisheries (Lund et al. 1991b; Webb and Youngson 1992) and in rivers (Lund et al. 1991b; Webb et al. 1991; Heggberget et al. 1993). Farmed fish have been observed to spawn among wild fish (Webb et al. 1991). The progeny of escaped female salmon have been identified among the progeny of wild fish at or near hatching time by using carotenoid pigment analysis to detect the presence of aquaculture flesh-colorants in the maternal pigment load of ova, alevins or recently emerged fry (Lura and Saegrov 1991a, 1993; Webb et al. 1993). Biochemical genetic analysis of juvenile salmon sampled from rivers indicates that, where spawning occurs, the progeny of escaped farmed fish survive among wild fish to contribute to juvenile salmon populations (Crozier 1993). Thus, the evidence from field studies indicates strongly that escaped salmon have the potential to exert permanent, genetic effects where they spawn.

Because of the tendency of many escaped fish to home to the general region of loss (Hansen and Jonsson 1991) those populations that are most exposed to any genetic effects of escaped salmon are in rivers and streams in the countries, regions or localities where salmon farming occurs. Reporting systems for losses from aquaculture exist among the producing nations, however, compliance is frequently lacking and these systems tend to record only large, catastrophic losses. Countries supporting Atlantic salmon aquaculture industries and current and historical production limits in each country are given in Table 2.2.1.1. Additional regional information on the frequency and distribution of escaped farmed fish is available as below. More information is expected to be made available during the Joint ICES/NASCO Symposium on Interactions of Wild and Introduced Salmon to be held in April, 1997 in Bath, U.K.

### 6.2 National Reports

National reports for the major aquaculture producing nations in the North East Atlantic and North American Commission area follow. Reports are not presented from lesser producing nations where the incidence of escapes is believed to be low.

## Norway

Salmon farms are located along the Norwegian coast from the southernmost to the northernmost part of the country. However, the highest density of farms are from the Stavanger area in the south to Lofoten area in the north. The number of fish farms is relatively low in northernmost Norway and in the area between Stavanger, south and eastwards to the Swedish border.

Salmon fisheries and spawning populations in Norway have been screened annually for escaped farmed salmon since 1989. Samples of salmon were obtained from marine bag-net and bend-net fisheries along the Norwegian coast and in fjords during the fishing season (1 June to 5 August). In freshwater, fish were collected during two periods - 1 June to 18 August which corresponds to the angling season in most rivers and 18 August to 30 November when samples were collected from brood stock fisheries. For 1995 and 1996, the figures are prepared separately for the periods before and after 31 August. August 31 corresponds to a change in the dates of the
angling season. Identification of escaped fish was by a combination of examination of external morphology and scale analysis (Lund et al. 1989; Lund and Hansen 1991).

In Norwegian coastal fisheries the proportion of farmed salmon has varied between $34 \%$ and $54 \%$ (unweighted means) in the period 1989 to 1996 (Table 3.3.7.2). No sampling was carried in 1996 at the locality in Finnmark county where the proportion of farmed fish in previous years was substantially lower than in other places. The proportions of farmed fish in coastal fisheries are significantly higher than in fjord fisheries where $10-21 \%$ of the catch have been of farmed origin. In freshwater the proportion of farmed salmon in angling catches is relatively low, and has varied between $4-7 \%$ during the same period. However, when examining catches of brood stock, the proportion is much higher varying between $21-38 \%$ (Table 3.3.7.3).

In outer coastal fisheries there was a significant negative correlation between the proportion of reared fish in the catches and mean distance to the ten nearest fish farms (Lund et al. 1991a). This correlation indicates that escapees at maturity will enter adjacent rivers near the site of escape. Samples from salmon fisheries on the outer coast showed a positive correlation between the number of smolts released into sea-cages and the proportion of farmed salmon in fisheries in the counties. On the other hand, the proportion of reared salmon in brood stock catches and marine fjord catches showed no correlation with this smolt release. This approach, geographically wider in scope, is less accurate when analysing the influence of the fish farming effort upon the proportion of reared salmon in river catches. Thus, the positive correlation in outer coastal waters provides further support for homing towards the geographical area of escape.

Additionally, Lund et al. (1991b) showed that in large fjords, like the Sognefjord and the Trondheimfjord the incidence of fish farm escapees is relatively small. There are very few fish farms in these fjords as a result of established zones restricted from farming.

## U.K. (Scotland)

Marine farming takes place in the western coast and islands, the Orkney Islands and the Shetland Islands (Figure 6.2.1). Rivers supporting runs of wild salmon are present on the western, northern and eastern coasts of mainland Scotland and in the western islands. Since 1981, coastal fisheries and rivers have been monitored using a variety of methods to detect the frequency and distribution of escaped farmed salmon (Table 6.2.1).

Samples were obtained from 12 coastal, estuary or rod fisheries at various locations around the Scottish mainland coast (Figure 6.2.2). Coastal and estuary catches were sampled mostly in the late spring and summer months during the main runs of fish. Sampling ceased around the end of August, the start of the legal close-time. However, day-catches on the rod-and-line fishery of the lower River North Esk were monitored after this date, until the beginning of the legal close-time for angling at the end of October. For each fishery, day-catches were sampled at intervals throughout the fishing period in the years indicated in Table 6.2.1. The status of sampled fish was assessed by inspection (Lund et al. 1989), scale reading (Lund and Hansen 1991) and/or carotenoid pigment analysis (Craik and Harvey 1987a) as indicated on Table 6.2.1. Additionally, trap catches of adult spawners were monitored at the Baddoch and Girnock Burns, in the upper catchment of the River Dee in eastern Scotland.

Before 1986 escaped fish were not detected at any of the fisheries examined - with the exceptions of very low frequency occurrences ( $<0.05 \%$ ) at Culkein in 1986 and Strathy on the north coast in 1982. In the years after 1986, reared salmon were detected regularly and at the greatest frequencies observed (ranging to $38 \%$ ) in fisheries in the coastal areas closest to, or shared with, marine aquaculture (i.e. Redpoint, Achiltibuie, Culkein and Strathy). Over the same period, reared fish were often detected at low frequencies ( $<1 \%$ ) in the fisheries at Bonar Bridge and the Spey, which are more remote from areas of aquaculture. In the Dee, North Esk, Tay and Tweed fisheries, which are most distant from sites of aquaculture, reared fish were detected only irregularly, only at very low frequencies $(<0.5 \%)$ and only after 1990. At the North Esk, reared fish appeared less frequent in the estuary fishery than in the rod-and-line fishery sampled later in the year. In general, the frequencies of reared fish appear to have declined in recent years, since peaking in the 1993 fisheries. No reared fish were detected in the eastern Scottish rivers after 1994. In the period 1981-1996, totals of 1663 and 1034 adult salmon were examined at the Girnock and Baddoch Burn fish-traps. No reared fish was detected at the Girnock Burn: a single escaped farmed fish was detected at the Baddoch trap in 1990.

The eastern Scottish coast and rivers have been substantially free of escaped farmed salmon since 1981 when monitoring commenced. Before this time, farmed salmon production in Scottish waters was less than 2,000 t per annum. By the early 1990s, when Scottish aquaculture production reached more than 30,000 t per annum,
escaped salmon were sometimes frequent among wild salmon in the western fisheries near the main sites of production. In contrast, escaped salmon were infrequent on the eastern coast and most infrequent on the southern part of the east coast which is most distant from aquaculture sites. This uneven distribution probably indicates partial homing to sites of loss from aquaculture, as reported by Hansen and Jonsson (1991).

The same pattern is indicated by the findings of a survey of western and northern Scottish rivers carried out in 1992 in which carotenoid pigment analysis (the presence of the feed-additive canthaxanthin) was used to detect the progeny of escaped female salmon (Webb et al. 1993). The progeny of escaped fish were most frequent in the central western and the northern Scottish rivers that are closest to the main sites of marine aquaculture. The geographical distribution of the progeny of farmed fish was in approximate parallel to the frequency distributions of escaped fish reported in the present study.

Fry containing canthaxanthin were detected in samples from 14 of the 16 rivers examined. Among all rivers the frequency of fry bearing canthaxanthin was ca. $5 \%$. All the rivers sampled were chosen to be free of hatchery development. Therefore the presence of escaped fish at spawning is a measure of opportunistic straying rather than homing to particular freshwater sites. Values were greatest in the River Kerry (a western river in the centre of the aquaculture industry) at ca. $18 \%$. All the values underestimate the contribution of escaped farmed fish because a) only $65 \%$ of a sample of escaped fish obtained from the western fishery contained canthaxanthin in the year of study and b) only female fish contribute to the carotenoid pigment loading of their progeny.

## Ireland

Inshore, coastal catches of salmon for both U.K. (Northern Ireland) and the Republic of Ireland are examined for escaped farmed salmon. Data for both countries (1991-1996) are presented together in Table 6.2 .2 because they constitute a continuous part of the species' geographical range.

All the frequency values are regarded as probable under-estimates because detection is by morphological features alone, sampling is limited to the period of the fisheries (summer) and because of local biases in the categorisation and reporting of escaped fish.

Salmon farming in Ireland is mainly concentrated in the Mayo and Galway regions with lesser concentrations in Donegal and the South West. Farming is absent from the South and East. The frequency with which escaped fish have been detected in the coastal fisheries suggests widespread, often low level frequencies of escapes across years. Data obtained in 1996 for the South and East, where salmon farming does not occur, indicated that escaped fish were absent from this region.

No systematic information has been collated for in-river frequencies of escaped fish in rivers of the Republic of Ireland, although numerous independent reports are available. However, the River Bush (U.K., N. Ireland) is monitored for escapees. These figures (1991-1996) are presented in Table 3.3.7.4. Escaped fish have been detected every year: the frequency in every year has been low ( $<1 \%$ ) with the exception of 1994 when the frequency was $2.6 \%$. As for the coastal catches, all frequencies for the River Bush are probably under-estimates, because detection is solely on the basis of morphological characters.

## Canada

Hatchery origin fish are identified on the basis of the presence of an adipose-clip, from fin deformations, and/or from scale characteristics. Aquaculture escapees were identified from hatchery fish on the basis of fin erosion (especially of the tail) and from scale characteristics.

The returns to the majority of the rivers in Newfoundland and Labrador and to most rivers of the Gulf of St. Lawrence and Québec were comprised exclusively of wild salmon (Figure 4.1.3.1). Hatchery origin salmon made up varying proportions of the total returns and were most abundant in the rivers of the Bay of Fundy and the Atlantic coast of Nova Scotia. Aquaculture escapees were sampled from the returns to several rivers of the Bay of Fundy (St. Croix, Magaguadavic, Saint John) as well as in at least one river from the Bras d'Or Lakes of Cape Breton (Baddeck River). Other salmonid aquaculture escapees, rainbow trout and Atlantic salmon smolts from the Bay d'Espoir aquaculture industry, were observed at Conne River (SFA 11).

Aquaculture production of Atlantic salmon in eastern Canada has increased annually, exceeding 10,000 tin 1992 and rising to almost 17,000 t in 1996. Escapes of Atlantic salmon have occurred annually. In 1994, escapes of

Atlantic salmon in the Bay of Fundy area were estimated at 20,000 to 40,000 salmon, an amount greater than the total returns of wild and hatchery origin salmon (both small and large) ( 13,000 to 21,000 fish) to the entire Bay of Fundy and Atlantic coast of Nova Scotia area (SFA 19 to 23) in the same year. The level of escapes in 1993 was similar to that of 1994. Reported estimates of escapes for 1995 and 1996 are low.

Aquaculture escaped fish have increased in abundance in the Magaguadavic River (SFA 23) (Table 4.1.3.1) which contains 3 smolt-rearing facilities and which is in close proximity to the centre of the aquaculture production area. Escaped fish were not observed between 1983 and 1988. Since 1992, escaped fish have comprised between $33 \%$ and $90 \%$ of the total counts at the fishway.

Other species cultured commercially in eastern Canada include Arctic charr and rainbow (steelhead) trout. The Arctic charr production occurs in Newfoundland, all in shore-based facilities. Rainbow trout are cultured in the Bay of Fundy, Bras d'Or Lakes (SFA 19), and in Bay d'Espoir Newfoundland (SFA 11). In 1996, production of rainbow trout was 750 t from New Brunswick, 530 t from Nova Scotia and over 315 t from Newfoundland. Escapees of both Arctic charr and steelhead trout have been recorded in many rivers in proximity to these production facilities.

## U.S.A.

Salmon aquaculture in the U.S.A. (Maine) began in the early 1970s, when coho salmon were cultured to pan size for the Northeast restaurant trade. These early ventures were unsuccessful due to adverse environmental conditions at pen sites, low market values, and a lack of adequate funding to support the industry. In the early 1980s, the successful culture of Atlantic salmon in New Brunswick was followed by rapid growth of the industry on both sides of the US-Canadian border. These operations in Maine were highly successful due to the quality of rearing sites available, warm winter water temperatures in the Passamaquoddy Bay area, favourable market prices, and the proximity to Canadian operations, which provided support in the areas of feed, cage technology, fish health and animal husbandry expertise.

The current industry is composed of 9 companies rearing Atlantic salmon, rainbow trout, and arctic char in Maine, down from 18 companies in 1989. These companies operate 6 smolt rearing facilities which produce about 4 million smolts annually for stocking into Maine marine rearing sites. There currently are about 800 cages that are operated at 25 sites in the eastern parts of the State of Maine. The preferred cage design is the 12 or 15meter steel net pen manufactured in New Brunswick; however, the use of small and large diameter HDPE circle cages of Norwegian manufacture is increasing.

The principal salmon stocks that are reared originated from the Penobscot and Saint John rivers. Both stocks are reared in about equal proportions, while the Norwegian Landcatch strain accounts for the remaining $10 \%$ of the total production. Production has risen from 2,000 mt. in 1990 to about $10,000 \mathrm{t}$ in both 1995 and 1996 (Table 2.2.1.1).

Salmon originating from farming operations have been observed in eight Maine rivers to date. Several other Maine rivers undoubtedly contain aquaculture escapees, although it is difficult to estimate their abundance since there are no fish counting facilities on these rivers. The first documented incidence of farmed salmon in Maine rivers occurred in 1990, when a minimum of $17 \%$ ( 14 of 83 fish) of the rod catch in the East Machias River was of farmed origin. There were few reports of salmon of farmed origin in Maine rivers in 1991 and 1992. In 1993, there were an estimated 20 aquaculture escapees in the Dennys River, which had a total run of about 50 salmon. Since 1994, however, the incidence of aquaculture escapes has been increasing in the three rivers of eastern Maine where there a provisions for fish counting. The incidence of farmed salmon in those rivers is reported in Table 4.1.3.1. Sexually mature escapees were identified in all three rivers in 1996.

### 6.3 Population Level Effects

Possible effects at the population level can be considered under three categories - disease/parasites, ecological and genetic. Disease and parasite interactions are self-evidently important: well documented effects exist for furunculosis and for Gyrodactylus salaris in Norway. Ecological effects relate to competition and environmental modification including predator attractions and fishery effects on mixed groups of wild and escaped fish. Genetic effects have been considered specifically by the Working Group on the Application of Genetics in Fisheries and Mariculture (ICES 1997/F:4).

Salmon populations are genetically heterogeneous for assumed neutral genetic markers (see e.g. Stahl 1987 and following) indicating that homing is sufficient to permit reproductive isolation. Reproductive isolation is a prerequisite for the development of geographical heterogeneity for genetically-based characters of adaptive significance. Phenotypic variation can be observed among populations for characters that are of possible adaptive significance (Taylor 1991). Although most of the evidence is circumstantial, the number, range and likely importance of the observed effects indicate that some part of total phenotypic variation among populations is likely to be attributable to local genetic adaptation.

Farmed salmon tend to differ genetically from local wild stocks because of their non-local genetic origin and/or because of deliberate and inadvertent selection during culture. Concern has been expressed that the spawning of escaped farmed fish, and the assimilation of their progeny (and genes) into wild populations, will result in losses of natural genetic diversity in wild salmon populations (Hindar et al. 1991). Similarly, ranching operations which do not result in a total harvest, or stocking programmes where the intention is to increase returns to rod fisheries and not to enhance spawning populations, may result in significant numbers of cultured fish in rivers interacting with wild populations in a similar manner to fish farm escapees. This is a difficult area - both conceptually and practically - that remains insufficiently explored, as indicated by the Working Group on the Application of Genetics in Fisheries and Mariculture (ICES 1997/F:4).

Nevertheless, some valid general points can be made. The outcome of any interaction between wild and escaped stock will be dependent on:

- the number of escaped fish,
- the genetic constitution of the escaped fish, as it reflects source and selection,
- the character of escaped fish, as it reflects their culture environment prior to release,
- the size of the wild population group,
- the genetic constitution of the wild population group and the individuals of which is composed,
- the character of the wild fish, as reflected in the nature of their interactions with escaped fish.

More generally, the scope for escaped fish to exert effects on wild populations will depend on the relative numbers of escaped and wild fish in the group and patterns of incursion. Small populations that are at risk of large incursions are likely to be most susceptible to change. Large populations may be robust to low rates of straying by escapes - as they are to low level straying among wild populations. The persistence of initial effects will be determined by the relative fitness of the progeny of escaped fish, native fish and hybrid progeny. Any initial genetic effect may be diminished or amplified over time in line with relative fitness. Single annual effects of any kind may be compounded by repeated incursions of escaped fish.

Considering only the general categories of effect listed above and their interactive effects, it seems likely that each interaction between escaped and wild and its outcome will be unique. This poses challenging questions for quantification and the development of generalised predictive models that will adequately describe the response of salmon populations to incursions by escaped farmed fish. However, the Joint ICES/NASCO Symposium scheduled for Bath, U.K. will include detailed, expert syntheses of current understanding of interactive effects at the population level.

## 7 PROGRESS ON THE IMPLEMENTATION OF SPAWNING TARGETS

The Working Group reviewed the progress in the NEAC area regarding the development and application of spawning requirement reference points. There has been substantial progress in the establishment of reference points in the NEAC area. There were no changes in the spawning requirements for rivers in North America. During a joint session with the Baltic Salmon Working Group (Appendix 1), a summary of the conclusions and recommendations from the spawning target workshop held in Pont-Scorff (FRANCE) in June 1996 was presented. One of the conclusions of the spawning workshop was that further progress in the development and transportation of reference points would occur with collection and analysis of additional data sets rather than refinements in analytical methods. There are few relevant data sets (long-term, large contrast in spawning escapement levels) in either the NAC or the NEAC areas. One of the recommendations of the workshop was the sharing of data sets to foster collaboration and share skills. As a first step, the Working Group compiled a preliminary list of individuals involved in the collection of data relevant to the development of reference points (Appendix 8). The list is preliminary and is intended to encourage the exchange of information and methods. The list could be updated by the Working Group in the future.

### 8.1 Fisheries

1. Considering the state of stocks in the Northeast Atlantic Commission area and trends in the pre-fishery abundance there should be no increase in levels of exploitation. Thus a precautionary approach is called for in the management of all fisheries, and particularly where they exploit mixed stocks.
2. The Working Group reiterates the advice given in 1996, that it is evident from both the indicators of stock status and the extremely low pre-fishery abundance forecasts for Greenland, that the North American stock complex is in tenuous condition. Stock abundance is low despite nearly complete closures of mixed and single stock fisheries. 2 SW salmon are experiencing low marine survival rates and in some monitored stocks are below spawning requirements. The increasing advantage associated with each additional spawner in under-seeded river systems makes a strong case for a conservative management strategy. However, the Working Group noted that thermal habitat and smolt survival rates in the northwest Atlantic are improving which will be expected to provide future benefits to returns and spawning escapements.
3. Although the analytical tools are not currently available to distinguish between native and wild salmon beyond the parental generation, the Working Group recommends that native salmon populations be given special management consideration.

### 8.2 Meetings

1. The Working Group recommends that it should meet in 1998 to address questions posed by ACFM, including those posed by NASCO to ICES. The length of the meeting will have to depend upon questions asked. Recent Terms of Reference have required a 10 -day meeting; a reduction in the number of meeting days would require a reduction in the Terms of Reference. In view of the fact that sea-surface temperature data required to provide catch advice for West Greenland is not expected before April 7, 1998, the Working Group should meet as soon as possible after that date.

### 8.3 Data Deficiencies and Research Needs

1. The Working Group requires guidance on the way that ACFM and NASCO would like production of ranched fish to be handled in the various catch tables.
2. Efforts should be made to standardise the way that catch-and-release data are handled in the catch statistics in order to provide an unbiased estimate of mortalities due to fishing.
3. Estimates of unreported catches should be improved for all fisheries.
4. The Working Group supports the continuation of the research programme in the Faroes area and recognises that the results from the project will improve the possibility of developing reliable assessment models in the North East Atlantic.
5. Information on fishing effort should be collected in more fisheries in the NEAC area in order to develop time series CPUE data.
6. The estimates of pre-fishery abundance of maturing and non-maturing 1 SW salmon in the NEAC area should be improved and possible relationships with environmental variables should be investigated.
7. Further information is required on the by-catch of post-smolts in marine fisheries. The Working Group strongly endorses the continuation of the post-smolt surveys in the North East Atlantic.
8. Further work is required on the development of biological reference points for stocks in the NEAC and NAC areas.
9. Efforts should be made to provide more accurate estimates of the level of catch by each country of stocks originating from other countries.
10. Relationships between environmental parameters and marine survival of salmon stocks in the NEAC area need to be examined.
11. In the description of methods used to estimate Labrador returns and spawners (Appendix 5 i), inactive fishing effort was removed from the estimation procedures. Changes in licensed fishing effort since 1992 had been used to revise exploitation rate calculations and correspondingly, return estimates. The proportion of effort removed (which was inactive) was not uniform over all areas of Labrador. The Working Group considered that it would be informative to estimate returns and escapements of salmon to Labrador by summing the individual estimates for SFAs 1,2 and 14 B by specific SFA exploitation rates adjusted for fishing effort within each of the respective areas and compare to the current values used. (Section 4.7).
12. There is a need for improved habitat surveys for rivers in Labrador and Ungava so that spawner requirements can be developed based on habitat characteristics. (Section 4.7).
13. Review possible changes in the biological characteristics (mean weight, sex ratio, sea-age composition) of returns to rivers, spawning stocks, and total recruits prior to fisheries. As new information becomes available, refine estimates of spawning requirements in U.S.A. and Canada by incorporating new information such as on biological characteristics for individual stocks, habitat measurements and stock and recruitment analysis. (Section 4.7).
14. Annual estimates of wild smolt-to-adult salmon survival rates need to be obtained for rivers in Labrador, New Brunswick and Nova Scotia. As well, sea survival rates of hatchery and wild salmon should be examined to determine if changes in survival of hatchery releases can be used as an index of sea survival of wild salmon. (Section 4.7).
15. Develop estimates of total recruits to all fisheries for each SFA in Canada for which estimates have not been made.
16. The mean weights, sea ages and proportion of fish originating from North America and Europe are essential parameters to provide catch advice for the West Greenland fishery. As these parameters are known to vary over time, the Working Group recommends that the sampling program which occurred in 1995 and 1996 be continued and improved to cover as much of the landings as possible. (Section 5.3).
17. Efforts should be made to estimate the annual catches of salmon taken for local consumption at West Greenland. (Section 5.3).
18. The catch options for the West Greenland fishery are based almost entirely upon data derived from North American stocks. In view of the evidence of a long-term decline in the European stock components contributing to this fishery (southern European non-maturing 1SW recruits) the Working Group emphasised the need for information from these stocks to be incorporated into the assessments as soon as possible (Section 5.3).
19. The Working Group continues to recognise the importance of in-season identification to continent of origin using genetic techniques to calibrate scale-based identification of the fishery catch at Greenland. The need for these data arose when it was found that scale-based growth features deposited during the post-smolt year that differentiate the continental groups can converge, thus making continent of origin identification less reliable. This problem can be rectified by in-season genetic sampling, however, the Working Group recommended that other methods be explored which may be used to evaluate the scale-based method without the added expense and difficulty of the present genetic sampling. Specifically, the Working Group recommends that an investigation of environmental predictors of the scale-based features used in the classification be undertaken. Further to the larger problem of accurately identifying larger segments of the catch to continent of origin, the Working Group encourages the development of new genetic techniques that can be applied to larger quantities of catch than present methods. The Working Group continues to support and encourage existing genetic monitoring programs identifying continent of origin of in-season samples from West Greenland.

Table 2.1.1.1 Nominal catch of SALMON by country (in tonnes round fresh weight), 1960-1996. (1996 figures include provisional and incomplete data).

1. Includes estimates of some local sales, and, prior to 1984, by-catch.
2. Since 1991, there has only been a research fishery at Faroes.
3. Includes catches made in the West Greenland area by Norway, Faroes, Sweden and Denmark in 1965-1975
4. New figures for entire series. Ranched salmon, previously included in the nominal catch have now been excluded and are reported separately in Table 2.2.2.1.
5. From 1994, includes increased reporting of rod catches.
6. Catch on River Foyle allocated $50 \%$ Ireland and $50 \%$ N. Ireland.
7. Before 1966 , sea trout and sea charr included ( $5 \%$ of total).
8. Weights prior to 1990 are estimated from 1994 mean weight

Weights from 1990 based on mean wt. from R. Asturias.
9. Not including angling catch (mainly ISW).
10. Includes catches in Norwegian Sea by vessels from De k, Sweden, Germany, Norway and Finland
11. Estimates refer to season ending in given year.

Table 2.1.1.2 Nominal catch of SALMON in homewaters by country (in tonnes round fresh weight), 1960-1996. (1996 figures include provisional and incomplete data).
$\mathrm{S}=$ Salmon (2SW or MSW fish). $\mathrm{G}=$ Grilse ( 1 SW fish). $\mathrm{Sm}=$ small. $\mathrm{Lg}=$ large. $\mathrm{T}=\mathrm{S}+\mathrm{G}$ or $\mathrm{Lg}+\mathrm{Sm}$

. Includes estimates of some local sales, and, prior to 1984, by-catch.
2. New figures for entire series. Ranched salmon, previously included in the nominal catch have now been excluded and are reported separately in Table 2.2.2.1
Catch on River Foyle allocated $50 \%$ Ireland and $50 \% \mathrm{~N}$. Ireland
4. From 1994, includes increased reporting of rod catches.
5. Before 1966 , sea trout and sea charr included ( $5 \%$ of total).

Weights prior to 1990 are estimated from 1994 mean weight
Weights from 1990 based on mean wt. from R. Asturias.
7. Not including angling catch (mainly ISW).

Table 2.1.2.1 Reported catch of SALMON in numbers and weight in tonnes (round fresh weight). Catches reported for 1996 may be provisional or incomplete. Methods used for estimating age composition given in footnotes.

1
MSW includes all sea ages $>1$, when this cannot be broken down.
Different methods are used to separate 1SW and MSW salmon in different countries:

- Scale reading: Faroe Islands, Finland (1996), France, Russia, UK (England and Wales), USA and West Greenland.
- Size (split weight/length): Canada ( 2.7 kg for nets; 63 cm for rods), Finland up until 1995 ( 3 kg ), Iceland (various splits used at different times and places), Norway ( 3 kg ), UK (Scotland) ( 3 kg in some places and 3.7 kg in others). All countries except Scotland report no problems with using weight to categorise catches into sea-age classes.
In Scotland, misclassification may be very high in some years. In Norway, catches shown as 3SW refer to salmon of 3SW or greater.

Guess-estimates of unreported catches in tonnes within national EEZs in the North-East Atlantic, North America and West Greenland Commissions of NASCO, 1986-1996.

${ }^{1}$ Common licence for salmon and seatrout.
${ }^{2}$ Introduction of quotas/fisherman, obligation to declare the catches.
${ }^{3}$ The number of licences indicates only the number of fishermen (or boats allowed to fish for salmon. It overestimates the actual number of fishermen fishing for salmon up to 2 or 3 times.
${ }^{4}$ Adour estuary only southwest of France.
$\infty \quad{ }^{5}$ Incomplete figures for 1993.
${ }^{6} 1996$ data for Ireland are provisional.

${ }_{7}^{6}$ Estimate of $0+$ parr population size in autumn.
${ }^{7}$ Juvenile surveys represent index of fry $(0+)$ abundance (number per 5 minutes electrofishing) at 137 sites, based on natural spawning in the previous year.
${ }^{8}$ These smolt counts show effects of enhancement
${ }^{9}$ Influenced by enhancement (fry releases).
${ }^{10}$ Minimum estimate due to severe flooding.
${ }^{11}$ Smolt counts too small for estimate.

${ }^{5}$ Minimum count.
In the UK(Scotl.)Girnock, the trap is located in the Girnock Burn, a tributary in the upper reaches of the River Dee (Aberdeenshire). In the UK(Scotl.) N . Esk, counts are recorded upstream of the in-river commercial fishery and most important angling fishery. Thus, the counts do not necssarily reflect the numbers of fish entering the river.
${ }^{2}$ River Faughan (UK, NI) count for 1996 not believed to be accurate.

Table 3.5.2 Results of Non-parametric Ratio analysis to examine changes in homewater catches between 1987-91 and 1992-96.

| Type of data | Area considered | Periods compared | p value | Effect |
| :---: | :---: | :---: | :---: | :---: |
| 1SW catches in Northern Europe | Finland, Sweden, Norway | 1987-91 vs 1992-96 | 0.013 | Lower catch |
|  | Norway only | 1987-91 vs 1992-96 | 0.004 | Lower catch |
| 1SW catches in Southern Europe | Ireland (total catch), UK(Scot), UK (E\&W), France | 1987-91 vs 1992-96 | 0.02 | Lower catch |
| MSW catches in Northern Europe | Finland, Sweden, Norway | 1987-91 vs 1992-96 | 0.304 | Not sig. |
|  | Norway only | 1987-91 vs 1992-96 | 0.279 | Not sig. |
| MSW catches in Southern Europe | UK (Scot), UK (E\&W), France | 1987-91 vs 1992-96 | 0.05 | Lower catch |
| Russian adult counts All ages | R. Varzuga, Ponoy, Kola, Yokanga, Zap Litca, Tuloma | 1987-91 vs 1992-96 | 0.162 | Not sig. |

Table 3.6.1 Area-by-area breakdown of the number of Atlantic salmon rivers, the number of rivers that presently have biological reference points (BRP), and the number of rivers which will probably have BRPs established in the next five years. (ND in the Table indicates we could not obtain the information.)

| Area | No. Rivers | No. with BRP | No. to have BRP <br> in next $\mathbf{5}$ yrs |
| :--- | :---: | :---: | :---: |
| Russia | $\sim 178^{\mathrm{a}}$ | 1 | 3 |
| Finland | $2^{\mathrm{b}}$ | 0 | $1^{\mathrm{c}}$ |
| Norway | $669^{\mathrm{d}}$ | $1^{\mathrm{e}}$ | 1 |
| Sweden | $\sim 10^{\mathrm{f}}$ | 0 | 1 |
| Iceland | $\sim 100$ | 0 | 2 |
| UK(Scotland) | $\sim 400$ | 1 | 1 |
| UK(N Ireland) | $\sim 11^{\mathrm{g}}$ | 1 | 11 |
| Ireland | 133 | 1 | 133 |
| UK(England/Wales) | 76 | $76^{\mathrm{h}}$ | 76 |
| France | 43 | 37 | 43 |
| Spain | 18 | ND | ND |
| Totals | $\mathbf{1 6 4 0}$ | $\mathbf{4 2}$ | $\mathbf{2 7 2}$ |

a. Rivers with main stem channels $>5 \mathrm{~km}$
b. Both rivers are shared with Norway.
c. Reference points for a tributary within one of the 2 systems will be established.
d. Includes 41 rivers where populations are extinct, 54 rivers with threatened populations, 147 rivers with vulnerable populations, 242 rivers with small ( $<100$ adults returning) populations, 98 rivers with healthy, large populations, 9 Gyrodactylus impacted rivers, 68 rivers where populations are present but nothing is known of their status, and 10 which may have transient populations.
e. Values are preliminary
f. Includes 1 river whose population is maintained exclusively by stocking reared fish, and $8-10$ wild rivers along Sweden's west coast, some of which are enhanced. Rivers draining to the Baltic are excluded.
g. This includes 3 major catchments which are jointly managed by UK(N Ireland) and Ireland, 4 major Glen rivers, the Bush where reference points have been established, and a number of other significant salmon rivers. We have not counted as separate rivers all of the tributaries within major catchments which will be managed with their own reference points. However, this tributary approach is a major thrust of the management effort.
h. Preliminary reference levels have been established and will be reviewed and updated in the next 4 yrs.

Table 4.2.3.2 Definitions of key variables used in continental run-reconstruction models for North American salmon.

## Variable Definition

| 1 | Year of the fishery on 1SW salmon in Greenland and Canada |
| :---: | :---: |
| M | Natural mortality rate (0.01/month) |
| t1 | Time between the mid-point of the Canadian fishery and return to river $=2$ months |
| S1 | Survival of 1 SW salmon between the homewater fishery and return to river $\{\exp (-\mathrm{Mt} 1)\}$ |
| H_s(i) | Number of "Small" salmon caught in Canada in year i; fish <2.7 kg |
| H_l(i) | Number of "Large" salmon caught in Canada in year i; fish $>2.7 \mathrm{~kg}$ |
| f_imm | Fraction of 1SW salmon that are immature, i.e. non-maturing; range $=0.1$ to 0.2 |
| q | Fraction of 1SW salmon present in the large size market category; range $=0.1$ to 0.3 |
| MN1 | Pre-fishery abundance of maturing 1SW North American salmon |
| $\mathrm{MCl}(\mathrm{i})$ | Harvest of maturing 1SW salmon in Newfoundland and Labrador in year i |
| i+1 | Year of fishery on 2SW salmon in Canada |
| MR1(i) | Return estimates of maturing 1SW salmon in Atlantic Canada in year i |
| NN1(i) | Pre-fishery abundance of non-maturing 1SW + maturing 2SW salmon in year i |
| NR(i) | Return estimates of non-maturing 1SW + maturing 2SW salmon in year i |
| NR2(i+1) | Return estimates of maturing 2SW salmon in Canada |
| $\mathrm{NC1}(\mathrm{i})$ | Harvest of non-maturing 1SW salmon in Nfld + Labrador in year i |
| $\mathrm{NC} 2(\mathrm{i}+1)$ | Harvest of maturing 2SW salmon in Canada |
| NG(i) | Catch of 1SW salmon in Greenland |
| S2 | Survival of 2SW salmon between Greenland and homewater fisheries |

Table 4.2.3.3. Run reconstruction data inputs and estimated pre-fishery abundance
for non-maturing 1SW salmon (potential 2SW salmon) of North American origin. (terms defined in table 4.2.3.2)

## Labrador: SFAs 1,2\&14B

Newfoundland: SFAs 3-14A
Gulf of St. Lawrence: SFAs 15-18
Scotia-Fundy: SFAs 19-23 (SFA 22 and a portion of SFA 23 are not included as they do not produce 2 SW salmon)
Quebec: Q1-Q11

Table 4.2.4.2 Estimated numbers of 1SW spawners in North America by geographic regions, 1971-96.

| Year | Labrador |  | Newfoundland |  | Quebec |  | Gulf of St. Lawrence |  | Scotia-Fundy |  | USA | North America |  |  |

Table 5.2.3.1 Quota options (mt) for 1997 at West Greenland based on H2-SNLQ regression forecasts of fishery abundance. Proportion at West Greenland refers to the fraction of harvestable surplus allocated to the West Greenland fishery. The probability level refers to the pre-fishery abundance levels derived from the probability density function.

| Prob. level | Proportion at West Greenland (FNA) |  |  |  |  |  |  |  |  |  |  |

## APPENDIX 1

## Minutes of Joint Session of the North Atlantic Salmon Working Group and the Baltic Salmon and Sea Trout Assessment Working Group

At its 1996 Statutory Meeting, ICES resolved (C.Res. 1996/2:14:13) that a half day joint session be held between the North Atlantic Salmon Working Group and the Baltic Salmon and Sea Trout Assessment Working Group to:

- discuss current progress with the implementation of spawning targets with reference to the conclusions of the Workshop on Spawning Targets held in France in 1996 (a).
- define the term 'wild salmon' (b).

Also, a formal request was made by the International Baltic Sea Fisheries Commission to the ICES to consider guidelines for establishing 'potential salmon rivers'. This was referred to the Baltic Salmon and Sea Trout Assessment Working Group for their consideration, with the suggestion that they discuss this with the North Atlantic Salmon Working Group at the joint session.
a) Current progress with the implementation of spawning targets with reference to the conclusions of the Workshop on Spawning Targets for the Assessment and Management of Atlantic Salmon Stocks (Pont-Scorff, France, June 24 to 28, 1996)

A summary of this Workshop was presented. Four main themes of interest were identified at the Workshop on Spawning Targets held in France and reviewed at the joint session:

- stock and recruitment analysis for deriving spawning targets with special reference to precision of estimates and methodological pitfalls,
- transfer and validation of spawning targets between river systems,
- use of time series data such as catches, juvenile densities and other indirect indices of stock and recruitment for defining spawning targets and evaluating the status of stocks, and
- managing the resource on the basis of spawning targets and incorporating uncertainty (concepts of risk analysis).

The intention of the workshop was to provide a teaching/exchange forum, to discuss objectives and distribute techniques currently available for the derivation and use of escapement reference points. The workshop was not intended to recommend procedures which individuals should follow or to recommend data to be collected. It was not intended to define specific reference points for particular rivers.
It was agreed at the workshop that the word "target" was an unfortunate choice as it implied that once the target was reached any extra fish were surplus. A more appropriate term suggested was "reference point" which would include the spawning target which was only one of several possible reference points. Clear definitions were required for other reference points (optima, thresholds, observation, MBAL and others).
A threshold level of escapement (synonymously referred to as conservation reference points) were defined based on the principles of genetic diversity and stock integrity. These levels should ensure the fitness of stocks (ability to sustain itself, rebuild, and not be threatened by insufficient escapement); no exploitation should occur below these reference points. It was also concluded that the definition of optimum spawning reference points requires clarification of the decision rules for resource use and that fixed exploitation rate management is the best policy for maximising benefit (yield) from the resource.

It was established that the derivation of reference points goes beyond fitting classical Stock - Recruitment curves and the examination of the goodness of fit. Currently available analysis tools incorporate the uncertainty around the average relationship and most of these methods can be applied using standard spreadsheet software. Generally, methods for assessing uncertainty are likely to be too optimistic and observation error (errors in estimation of spawning stock) result in underestimation of the policy parameters and overestimation of precision. This uncertainty should be acknowledged when advising managers on policy planning in the following manner:

- advice should be elaborated under a risk analysis framework
- and expressed in terms of probabilities of achieving a pre-defined goal or of probabilities of an undesired event.

The approach should take into account:

- knowledge on the nature of the $\mathrm{S} / \mathrm{R}$ relationships,
- strategy of exploitation (e.g. catch levels),
- uncertainty about the $S / R$ relationship, and
- uncertainty in implementation of the exploitation strategy.

The incorporation of risk analysis is the major area for improving the quality of the advice to managers by a scientific organisation such as ICES.

A further area examined in some detail by the Workshop was the transport of Stock - Recruitment relationship and derived reference points. Two extreme approaches are:

1. no extrapolation across rivers because every system is unique.
2. generalisation over very broad areas because all systems should behave roughly the same.

Neither of these are satisfactory. In the first instance transport is necessary as collection of stock and recruitment data is justifiable if the results can be generalised across a group of rivers and secondly there is no readily useable "recipe" to assess and ensure the validity of transport across rivers. Scientists must have at their disposal data sets to test and develop new tools. Good Stock-Recruitment series (long duration and with appropriate contrast) are not common and they should be shared within the scientific community for maximum benefit.

Progress was made at the Workshop in the derivation of reference points and transportability. This issue is considered to be of extreme importance considering that in most countries there were no short-term possibilities for developing individual Stock - Recruitment relationships for all rivers (there are over 500 rivers in Canada and 600 in Norway). A Canadian life history model (ASRAM) was developed to examine management strategies for stocks threatened by acidification in rivers of varying productivity. Definition of spawning requirements for several rivers in Brittany (France) based on a donor stream were established and the Environment Agency (Wales) has been exploring habitat based approaches to define spawning targets for rivers in England and Wales.

Further progress is more dependent on good data than on the development of tools to process data. Special attention must be devoted to:

- the precision of the stock and recruitment estimates, and
- experimental designs (i.e. direct manipulation of stock abundance to observe the response of the recruitment) to maximise learning from the data gathered.

The Working Groups acknowledged the advances which the Workshop had made to the understanding and clarification of many of the issues relating to spawning targets.

In discussion a number of valuable points were raised.
MBAL should not be seen as a target. For example, in the UK (England/Wales) MBAL has been set at the Maximum Gain. However, the assessment of compliance is based on an analysis of spawner escapement over a number of years. In Canada MBAL was seen as a point below which fishing should not take place.

While it was acknowledged that new information can be used to refine the reference points, caution was also expressed that substantially altering these reference points or changing too often may make the advice appear inconsistent or unstable. It was also noted that improvements to some Stock-Recruitment relationship can be made by incorporating extra parameters (relationships between river length and age composition, gradient classified approaches, altitude and productivity). The Baltic Group indicated that much of their work in future will be based on theoretical approaches and methodologies adapted to the Baltic from other areas. They were seeking to establish new monitored rivers to help with the establishment and management of wild stocks by the year 2010 .

A number of recommendations were made by the participants of the joint session:

1. Data series which were being used to provide reference points should be continued.
2. Risk analyses and similar approaches to quantify uncertainty should be used on existing Stock - Recruitment relationships.
3. The development of new data series and Stock - Recruitment relationships should be encouraged.
4. A list of rivers where sufficient information is available to establish reference points should be collated. Contact individuals should be identified who are involved in the collection of data or involved in the development of methods/models forwarding the progress of transporting reference points for Atlantic salmon stocks should also be compiled to encourage the dissemination of data, information and methodologies. A preliminary list is provided in Appendix 8 which will be expanded in due course.

## b) Define the term wild salmon

In 1995, ACFM requested that both groups provide definitions of "Wild salmon". Different definitions were produced.
i. The North Atlantic Working Group defined Atlantic salmon "types" as follows:

Native salmon are wild salmon which are members of a population with no known effects from intentional or accidental releases.

Wild salmon are fish that have spent their entire life cycle in the wild and originate from parents which were also spawned and continuously lived in the wild.

Naturalised salmon are fish that have spent their entire life cycle in the wild and originate from parents, one or both of which, were not wild or native salmon.

Stocked salmon are fish that have had artificial spawning and/or rearing techniques applied at some point of their life cycle and/or originate from intentional releases to the wild.

Escaped salmon are fish that have spent some or all of their life cycle undergoing artificial propagation and originate from accidental or unplanned releases into the wild.

These definitions recognise a "continuum" of salmon, based upon the degree to which each fish and its parental generation have been continuously subjected to natural selection. Natural selection acts over time upon individuals within populations, which then evolve to match their members biological characteristics to their environment. The presence of well adapted individuals confers characteristics like resistance, resilience, and the ability to sustain itself upon populations. Native salmon are the most valuable from biological perspective. They are self sustaining, and any losses are irreversible. Wild and naturalised salmon have the potential to develop self-sustaining populations.

## ii. The definition provided by the Baltic Salmon Working Group was:

A wild salmon is the result of natural spawning and has spent its entire life cycle in nature.
Underlying the Baltic group's definition was a concern about conserving wild stocks. The group emphasised that " A wild population was not simply a collection of wild salmon because the definition of wild lacks the genetic and adaptive contexts that are major biological characteristics of locally adapted spawning populations". These "genetic and adaptive contexts" are the end product of natural selection acting on individuals, and ultimately permit populations to be self sustaining. Under the Baltic Group's definition, "Native", "Wild" and "Naturalised" salmon could all be termed "wild".

ANACAT met in September 1996 and concluded that the North Atlantic Group's definition of wild salmon was more acceptable than that of the Baltic group because it considered the need for salmon to be subjected to natural selection for at least one generation before they were called "wild". During the joint meeting of the two groups in April 1997, members of the North Atlantic Working Group reiterated their need to maintain the present definitions. The recognition of the continuum of salmon types is very important, for theoretical and practical (management) reasons. However, both the North Atlantic Working group and ANACAT recognised that since
there is no easy way to determine if salmon's parents were wild, for certain management purposes the Baltic definition might have to be used.

During the Joint Meeting of the Working Groups, the WGBAST agreed to adopt the definitions proposed by the WGNAS. They also agreed that the goal of present wild salmon management practices is to maintain self sustaining populations, and to strive for the fish in them to have characteristics as similar to "Native" salmon as possible. As an expedient, especially for management purposes, biologists are forced to define a variety of salmon types as "wild". Both Working Groups agreed that the term is best used to describe populations which are (or are progressing towards becoming) self-sustaining. In a management context, all categories of "wild salmon" require a precautionary approach with appropriate measures as necessary being taken to protect them.

Estimates are based on:
EST LARGE RETURNS - (COMM CATCH*PROP LAB ORIGIN/EXP RATE, PROP SFAS1,2\&14B=.6-.8, EXP RATE-SFAS1,2\&14B=.7-.9(69-91),.58-.83(92),.38-.62(93),.29-.50(94), .15-.26(95), $.13-23(96)$
EST 2SW RETURNS - (EST LARGE RETURNS*PROP 2SW), PROP 2 SW SFA $1=7-9$, SFAS $2 \& 14 \mathrm{~B}=.6-8$
WG - are North American 1SW salmon of river age 4 and older of which $70 \%$ are Labrador origin
EST RET TO FRESHWATER - (EST 2SW RET-2SW CATCHES)
EST 2SW SPAWNERS = EST 2SW RETURNS TO FRESHWATER - 2SW ANGLING CATCHES
*Catches for 1969-73 are Labrador totals distributed into SFAs as the proportion of landings by SFA in 1974-78.

Appendix 5(ii). Estimated numbers of 1SW salmon recruits, returns and spawners for Labrador. 1996 catches are preliminary.

Estimates are based on:
EST SMALL RETURNS - (COMM CATCH*PROP LAB ORIGIN)/EXP RATE, PROP SFAs1,2\&14B=.6-.8, EXP RATE-SFAs1,2\&14B=.3-.5(69-91), 22-. $39(92), .13-.25(93), .10-.19(94), .07-.13(95), .03-.06(96)$
EST GRILSE RETURNS CORRECTED FOR NON-MATURING 1SW - (SMALL RET*PROP GRILSE), PROP GRILSE SFAS1,2\&14B=0.8-0.9
EST RET TO FRESHWATER - (EST GRILSE RET-GRILSE CATCHES)
EST GRILSE SPAWNERS = EST GRILSE RETURNS TO FRESHWATER - GRILSE ANGLING CATCHES
*Catches for 1969-73 are Labrador totals distributed into SFAs as the proportion of landings by SFA in 1974-78.
Furthermore small catches in 1973 were adjusted by ratio of large:small in 1972\&74 (SFA 1-1.4591, SFA 2-2.2225, SFA 14B-1.5506).

| Year | Small catch Small returns to river |  |  | Small recruits |  | Small spawners |  | Large returns to river |  | Large recruits |  | Large catch Retained | Large spawners |  | 2SW returns to river |  | 2SW spawners |  | 2SW recruits |  |

SRR (Small returns to river) are the sum of Bay St. George small returns (Reddin \& Mullins 1996) plus Humber R small returns (Mullins \& Reddin 1996) plus small returns in SFAs 3-12 \& 14A.
SR (Small recruits) $=$ SRR/(1-Exploitation rate commercial (ERC)) where ERC=0.5-0.7, 1969-91 \& ERC=0, 1992-95
SS (Small spawners) $=$ SSR-(SC $+\left(\mathrm{SR}^{*} 0.1\right)$ )
SR = salmon catch released
L (RATIO large:small) are from counting facilities in SFAs 3-11, 13 \& 14A, angling catches in SFA 12.
RR (Large returns to river) $=$ SRR *RL
R (Large recruits) $=\operatorname{LRR} *$ ( 1 -Exploitation rate large (ERL)), where ERL=0.7-0.9, 1969-91; \& ERL=0, 1992-95.
S (Large spawners) $=\mathrm{LRR}$-large catch retained (LC)-(0.1*large catch released)
SW-RR (2SW returns to river) $=$ LRR*proportion $2 S W$ of 0.4-0.6 for SFAs 12-14A \& 0.1-0.2 for SFAs 3-11

Appendix 5(ivb) Total return estimation of salmon in Québec, 1969-1996.

Low estimation
landings (recreational+comm.+First people) $+\operatorname{spawner}\left(=1^{*}\right.$ recreational) + unreported $\left(=.15^{*}\right.$ total landing

Appendix 5(v). Small, large and 2SW return and spawner estimates for SFA 15.

Return and spawner estimates for SFA 15 are based on Restigouche River data, scaled up for SFA 15 using angling data
Restigouche stock assessment is based on angling catch with assumed exploitation rates between $50 \%$ (min.) and $30 \%$ (max).
The proportion of 2SW in large salmon numbers is based on aged scale samples from angling, trapnets, and broodstock.
No scale samples were available for 1970, 1971, 1995: the mean value of 0.65 is used here. (Note: Mean of 1984-1994 was 0.62).
Salmon in the Quebec portions of the Restigouche River were subtracted from the total for the watershed.
The returns and spawners estimates thus derived for the SFA 15 portion of the Restigouche were then multiplied by the minumum (1.117) and maximum (1.465) ratios of angling catch in SFA15:SFA 15 portion of Restigouche catch to obtain estimates for SFA 15.

Returns to the Miramichi are from the assessment. Min. and max values are based on capture efficiencies of Millbank trapnet which gave a lower Cl of $-20 \%$ of estimate and upper Cl of $33 \%$ of estimate.
For 1992 and 1993, lower and upper Cl are based on estimate bounds of $-18.5 \%$ to $+18.5 \%$.
For 1994 to 1996, min and max are 5th and 95th percentiles from the assessment.
Prop. 2SW are from scale ageing. For 1996, prop. 2SW is from an age-length key.

Miramichi makes up 91\% of total rearing area of SFA 16.
Returns to SFA 16 are Miramichi returns / 0.91 or (Min., Max.) 2SW returns to Miramichi / 0.91
Same procedure for escapements as used to calculate returns.

Notes
Number of small retained salmon in 1993 was not recorded. The number given is the mean for 1986-1992
For 1970-1980, percent small is calculated from numbers of small and large salmon in the retained catch in each year. For 1981-1995, percent small is calculated from numbers of small and large salmon taken at the Leard's Pond trap.
Small recruits are calculated as small retained salmon/exploitation rate. Angler exploitation was calculated as $0.34,0.347$, and 0.2 of estimated returns in 1994, 1995, and 1996, respectively. For other years the mean of these values is used. The min and max max numbers of small recruits are calculated using exploitation + or -0.1 ; e.g. $0.34+$ or -0.1 gives 0.24 and 0.44 .
Small spawners = number of small recruits - number of small retained
Large recruits = (number of small recruits/( $0.01^{*}$ percent small))-number of small recruits
Large spawners $=$ number of large recruits - number of large retained
It is asssumed that large salmon and 2SW salmon are equivalent
During the years of the commercial fishery, commercial landings were far greater than estimated local runs, and commercial catches were widely distributed along the north shore of PEI. For these reasons it appears likely that most fish taken by the commercial fishery were destined for mainland rivers.

Appendix 5 (viiia). Total 2SW returns and spawners to SFA 18, 1970-1996.

Margaree returns, 1970-84, equal catch $/ \mathrm{min}(0.215)$ or $\max (0.37)$ exploitation rate.
Return of large salmon (MIN) and (MAX)to all SFA 18 equals Margaree returns * ratio Margaree catch to SFA 18 catch
Margaree returns 1984-1996 based on various Margaree CAFSAC Research Documents.
Margaree catch to SFA 18 catch; MIN _MAX 2SW based on the ratio 0.77-0.87 2SW fish among MSW fish.
Margaree escapements 1970-1983 = returns minus removals; 1984-1996 from various Margaree CAFSAC
Research Documents by Claytor and Chaput; 2SW equal 0.77-0.87 of MSW fish; Margaree raised to SFA by respective ratios in sport catch.

Appendix 5(viii b). Total 1SW returns and spawners to SFA 18, 1970-1996.

Margaree returns, 1970-83, equal catch divided by MIN (0.215) and MAX (0.37) exploitation rate.
Return of small salmon to all SFA 18 equals Margaree returns * MIN and MAX ratio of
Margaree catch to SFA 18 catch. Margaree returns, 1984-1996, based on annual assessments
in CAFSAC and DFO Atl. Fish. Res. Docs, eg., Claytor et al. MS 1995.
Spawners for 1970-1983 equal returns minus removals; 1984-1996 from various Margaree CAFSAC and Atl. Res. Doc. series, eg., Claytor et al. MS 1995.

Appendix 5 (ix). Total 1SW returns and spawners, SFAs 19, 20, 21 and 23, 1970-1996.

SFAs 19,20,21: Returns estimated as run size (1SW recreational catch / expl. rate [ 0.2 t0 0.45 ];
where MIN and MAX selected as 5th and 95th percentile values from 1,000 monte carlo estimates) + estimated 1SW fish in commercial landings 1970-1983 (Cutting et al. MS 1985).
SFA 22: Inner Fundy stocks and inner-Fundy SFA 23 (primarily 1SW fish) do not go to the North Atlantic.
SFA 23: Similar approach as for SFAs 19-21 except that estimated wild 1SW returns destined for Mactaquac Dam, Saint John River, replaced values for recreational catch; and estimated proportions that production above Mactaquac is of the total (0.4-0.6) river replaced exploitation rates, Marshall MS 1992 (commercial harvest, bi-catch etc., incl. in estimated returns);
hatchery returns attributed to above Mactaquac only; 1SW production in remainder of SFA (outer Fundy) omitted
Spawners equal river returns minus in-river removals.

Appendix 5 (x a). Total 2SW returns to SFAs 19, 20, 21 and 23, 1970-1996.

## APPENDIX 7

## COMPUTATION OF CATCH ADVICE FOR WEST GREENLAND

The North American Spawning Target (SpT) for 2SW salmon has been revised to 180,495 fish in 1996.
This number must be divided by the survival rate for the fish from the time of the West Greenland fishery to their return of the fish to home waters ( 11 months) to give the Spawning Target Reserve ( SpR ). Thus:

Eq. 1. $\quad \mathrm{SpR}=\operatorname{SpT}^{*}(\exp (11 * \mathrm{M}) \quad($ where $\mathrm{M}=0.01)$
The Maximum Allowable Harvest (MAH) may be defined as the number of non-maturing 1SW fish that are available for harvest. This number is calculated by subtracting the Spawning Target Reserve from the pre-fishery abundance (PFA).

Eq. 2. $\mathrm{MAH}=\mathrm{PFA}-\mathrm{SpR}$
To provide catch advice for West Greenland it is then necessary to decide on the proportion of the MAH to be allocated to Greenland ( $\mathrm{f}_{\mathrm{NA}}$ ). The allowable harvest of North American non-maturing 1 SW salmon at West Greenland NA1SW) may then be defined as

Eq. 3. $\mathrm{NA} 1 \mathrm{SW}=\mathrm{f}_{\mathrm{NA}} * \mathrm{MAH}$
The estimated number of European salmon that will be caught at West Greenland (E1SW) will depend upon the harvest of North American fish and the proportion of the fish in the West Greenland fishery that originate from North America [PropNA] ${ }^{1}$. Thus:

Eq. 4. $\mathrm{E} 1 \mathrm{SW}=(\mathrm{NA} 1 \mathrm{SW} /$ PropNA $)-$ NA1SW
To convert the numbers of North American and European 1SW salmon into total catch at West Greenland in metric tonnes, it is necessary to incorporate the mean weights ( kg ) of salmon for North America [WT1SWNA] ${ }^{1}$ and Europe [WT1SWE] ${ }^{1}$ and age correction factor for multi-sea winter salmon at Greenland based on the total weight of salmon caught divided by the weight of 1 SW salmon $[A C F]^{1}$. The quota (in tonnes) at Greenland is then estimated as

Eq. 5. $\quad$ Quota $=($ NA1SW $* W T 1 S W N A+E 1 S W * W T 1 S W E) * A C F / 1000$

[^0]:    "landing of salmon caught in fisheries targeting other species was illegal in most countries of the North East Commission except France, where it is authorised, and Sweden, where landing is allowed during the regular fishing season (March -September). In some of the countries where the by-catch cannot be landed legally, and in France where they are not consistently requested, these catches are included in the estimates of unreported catches.

[^1]:    * samples including 1-3 individuals of sea age 4,5 and 6 .

[^2]:    *) Samples only from latter part of the season (Jan-Mar); **) Only one month sampled that season.

[^3]:    ${ }^{1}$ Fish released for mitigation purposes and not expected to contribute to spawning.
    ${ }^{2}$ Provisional figures.
    ${ }^{3}$ Data from 1994 onwards is figure reported in national catch statistics; previous years' data calculated from sampling programmes.
    4 " + " indicates a small but unquantified catch.
    ${ }^{5}$ Smolts released for enhancement of stocks or rod fisheries are included in wild.

[^4]:    ${ }^{1}$ Microtags.
    ${ }^{2}$ Carlin tags, not corrected for tagging mortality.
    ${ }^{3}$ Minimum estimate.
    ${ }^{4}$ Before in-river netting.

[^5]:    Faroes: $\quad 0.75$ in 1981/82-1990/91; 1.00 in 1991/92-1992/93
    Scotland (N. Esk and Montrose Bay): 1.0
    Norway: 0.5
    Sweden: 0.65
    Elsewhere: 0.5
    灾

[^6]:    ${ }^{1}$ Native peoples in Conne River Newfoundland (SFA 11) did not fish in 1996 because of low returns.

[^7]:    Spawners lagged by:

[^8]:    ${ }^{1}$ Figures not available, but catch is known to be less than Faroese catch.
    ${ }^{2}$ The fishery was suspended.
    ${ }^{3}$ Including 7 t caught on longline by one of two Greenland vessels in the Labrador Sea early in 1970.
    ${ }^{4}$ For Greenland vessels: all catches up to 1968 were taken with set gillnets only; after 1968 , the catches were taken with set gillnets and drift nets. All non Greenland catches from 1969-84 were taken with drift nets.
    ${ }^{5}$ Quota corresponding to specific opening dates of the fishery.
    ${ }^{6}$ Quota for $1988-90$ was $2,520 \mathrm{t}$ with an opening date of 1 August and annual catches not to exceed the annual average ( 840 t ) by more than $10 \%$. Quota adjusted to 900 t in 1989 and 924 t in 1990 for later opening dates.

[^9]:    ${ }^{1}$ ) The fishery was suspended
    +) Small catch $<0.5 \mathrm{t}$
    -) No catch

[^10]:    ${ }^{1} \mathrm{CI}$ - confidence interval calculated by method of Pella and Robertson (1979) for 1984-86 and by binomial distribution for the others.
    ${ }^{2}$ During Fishery.
    ${ }^{3}$ Research samples after fishery closed.

[^11]:    1 New sampling data from the 1995 fishery at West Greenland were used to update the forecast values of the proportion of North American salmon in the catch (PropNA), mean weights by continent [WT1SWNA, WT1SWE] and the age correction factor [ACF] in 1996.
