## REPORT OF THE

# NORTHERN PELAGIC AND BLUE WHITING FISHERIES WORKING GROUP 

ICES Headquarters

29 April-7 May 1997

This report is not to be quoted without prior consultation with the General Secretary. The document is a report of an expert group under the auspices of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council.

### 1.1 Terms of Reference

The Northern Pelagic and Blue Whiting Fisheries Working Group [WGNPBW] (Chairman: Mr I. Røttingen, Norway) will meet at ICES Headquarters from 29 April to 7 May 1997 to:
a) assess the status of and provide catch options for 1998 for the Norwegian spring-spawning herring stock, and catch options for the 1997-1998 season for the Icelandic summer-spawning herring stock;
b) provide any new information on the present spatial and temporal distribution of Norwegian spring-spawning herring;
c) assess the status of capelin in Sub-areas V and XIV and provide catch options for the summer/autumn 1997 and winter 1998 seasons;
d) assess the status of and provide catch options for capelin in Sub-areas I and II (excluding Division IIa west of $5^{\circ} \mathrm{W}$ ) for the summer/autumn 1997 and winter 1998 seasons;
e) consider further possibilities for the incorporation of biological interactions into the assessments of capelin, herring, and cod stocks;
f) assess the status of and provide catch options for 1998 and 1999 for the blue whiting stock;
g) update the information on the spatial and temporal distribution of the stock and fisheries on blue whiting;
h) propose a definition of safe biological limits using target reference points based, where appropriate, on biomass, fishing mortality, maturity, growth, age structure, exploitation pattern, geographical distribution and other relevant parameters; based on the above parameters, propose limit reference points to be avoided with high probability;
i) prepare medium-term forecasts of yield and SSB, taking into account uncertainties in data and assessment and assuming a stock-recruitment relationship, to indicate the probability of attaining target reference points and avoiding limit reference points;
j) provide information on quantities of discards by gear type and area for commercially-exploited stocks of fish and fisheries considered by this group [OSPAR 1997/5.3] and report to WGECO.

The above terms of reference are set up to provide ACFM with the information required to respond to the requests for advice from NEAFC, the EC and OSPAR.

The following items were added on receipt of a request from NEAFC dated 22 January 1997:
k) indicate new developments in the seasonal and area distribution of the total Norwegian spring-spawning herring stock;

1) assess for Norwegian spring-spawning herring the development of catches and the probability that the spawning stock biomass will fall in the medium-term below the MBAL level of 2.5 million tonnes under the harvesting strategy of a catch ceiling of 1.5 million tonnes and a maximum fishing mortality of 0.15 ;
m ) assess for blue whiting the probability that the spawning stock can sustain a harvesting strategy of a constant value of 650 thousand tonnes.

Following an additional meeting in March 1997, NEAFC also requested ICES (letter dated 30 April 1997) to:
n) provide short- and medium-term levels of catches and spawning stock biomass, taking into account the stock specific recruitment pattern and the risk of reduced recruitment at low stock sizes and using the longest possible time series of recruitment. In particular, for the medium-term analysis, ICES is requested to provide $1-10$ years stochastic projections of the spawning stock at levels of $F$ of $0.1,0.15$ and 0.2 subject to catch
ceilings of $1.0,1.5$ and 2.0 million tonnes. The percentiles given of the distribution of $5,10,20,30,50,80$ and 90 per cent;
o) provide appropriate reference points for fishing mortality and spawning stock biomass. In addition to nominal absolute values, biomass reference points may also be based on a reference year in order to demonstrate problems of changes in scale;
p) provide appropriate management regimes (i.e. "harvest control laws") including reference points at which immediate remedial action should be taken and appropriate time scale for actions, which might be used in future management of the stock and which takes into account sustainable exploitation rates and appropriate biomass thresholds.

## 2 <br> ICELANDIC SUMMER-SPAWNING HERRING

### 2.1 The Fishery

The catches of summer-spawning herring from 1977-1996 are given in Table 2.1.1. No estimate of discards was made for the 1996/97 season. The fishery took place off the east coast of Iceland, considerably farther to the north than in previous seasons. The proportion used for reduction has continued to decrease from the 1992/93 maximum of $74 \%$ to $23 \%$ last season. The remainder of the catch was either salted or frozen for human consumption. While most of the catch was taken by purse seiners, some $8.7 \%$ were taken with pelagic trawl. Until 1990 the herring fishery took place during the last three months of each calendar year, but after that the autumn fishery has continued in January and early February of the following year. Therefore, all references to the years 1990-1996 refer to the season starting in October of that year. Landings, catches and recommended TACs since 1984 are given in thousands of tonnes in the text table below.

| Year | Landings | Catches | Recommended TACs |
| :--- | ---: | ---: | ---: |
| 1984 | 50.3 | 50.3 | 50.0 |
| 1985 | 49.1 | 49.1 | 50.0 |
| 1986 | 65.5 | 65.5 | 65.0 |
| 1987 | 73.0 | 73.0 | 70.0 |
| 1988 | 92.8 | 92.8 | 100.0 |
| 1989 | 97.3 | 101.0 | 90.0 |
| $1990 / 1991$ | 101.6 | 105.1 | 90.0 |
| $1991 / 1992$ | 98.5 | 109.5 | 79.0 |

| $1996 / 1997 *$ | 95.9 | 95.9 | 100.0 |

* Preliminary

### 2.2 Catch in Numbers, Weight at Age and Maturity

The catches in numbers at age for the Icelandic summer-spawners for the period 1977-1996 are given in Table 2.1.1. As usual the age is given in rings where the age in years equals the number of rings +1 .

In the first years after the fishery was reopened in 1975 the 1971 year class was most abundant. During the period 1979-1982 the 1974 and 1975 year classes predominated in the catches. During the period 1983-1986, the fishery was dominated by the strong 1979 year class. On the other hand, the fishery in 1987 and 1988 was based on a number of year classes ranging from 3-10 ringed herring.

In the period 1989-1991, the 1983 year class predominated in the catch. The 1988 year class was also well represented in the 1991 catches and predominated during the 1992 season. In 1993 the age distribution was dominated by the strong 1989 year class although the 1988 year class was also well represented. In 1994/95 the catches were distributed on 4 year classes, i.e. those of 1988-1991. The catch in numbers of 2-ringers has never been higher and yielded some $25 \%$ of the total numbers in the 1994/95 season.

In the 1995/96 and 1996/97 seasons, the catches were again mainly distributed on the 4 year classes from 19881991. In the 1996/97 season the total catch numbered some 384 million herring, while in the two previous seasons the numbers caught exceeded 500 million. The reason for this reduction is the lower total catch in tonnes, consisting of larger herring and a smaller proportion of age groups 2 and 3 than in the preceding seasons.

The weight at age for each year is given in Table 2.2.1 and the proportion mature at age is given in Table 2.2.2. The most striking feature of these parameters in this stock is that, despite inter-annual variations, the weights at age as well as other biological parameters have remained relatively stable over a wide range of stock size and fluctuations in environmental conditions of Icelandic waters.

### 2.3 Acoustic Surveys

The Icelandic summer-spawning herring stock has been monitored by acoustic surveys annually since 1973. These surveys have been carried out in October-December or January, usually after the fishery had been closed. During surveys, which took place in October-December 1996, an estimate was obtained of the adult stock in open waters and of 1 year old herring in the fjords of the west and north coast of Iceland. The adult stock was mainly located in an area off the east coast of Iceland, but a small proportion was found southwest of Iceland. The abundance of the 1992 and 1993 year classes was low and the 1993 year class was first registered acoustically last autumn. The abundance of the 1994 year class was found to be above average, and it is followed by another year class of some promise.

Jakobsson et al. (1993) formally tested whether it was feasible to maintain a one-to-one relationship between acoustic and VPA estimates of stock size. This was done by fitting regression lines between these estimates and testing for slope $=1$ and intercept $=0$. Although this provides an adequate model, it was further found that a modification of the target strength gave a better fit between the two data sets. The resulting target strength was used in this report, a value of $\mathrm{TS}=20 \log \mathrm{~L}-72 \mathrm{~dB}$ was used to calculate the stock estimates. The results of the
autumn 1996 acoustic surveys have been used as a basis for the present assessment of 4-ringed and older herring (Table 2.3.1).

### 2.4 Stock Assessment

Like in previous years the estimation procedure from Halldórsson et al. (1986) was used to estimate the stock size in the final year, based on all available acoustic data for the older part of the stock ( $5+$ ringers on 1 January each year). The procedure minimises the sum of squares of log-transformed rather than untransformed data, since there is increased variability in later years concurrent with increasing stock size.

The results are given in Table 2.4.1 as $\mathrm{F}_{\mathrm{ac}}$. In this analysis, 5-ringers and older fish have been grouped for estimating the fishing mortality on the oldest herring, whereas the fishing mortality for the younger age groups is calculated for each year class. For F on the oldest age group an average of F for 6-13 ringers was used.

A series of VPAs was run using varying terminal F 's on $5+$ ringers. For each terminal F a sum of squares (SSE $(\mathrm{F})$ ) of differences between the $5+$ group from the VPA and from the acoustic estimates was computed. A plot of these values is shown in Figure 2.4.1. From this series of VPAs it is clear that the best (giving the minimum value of SSE) one-to-one relation between the acoustic estimates and virtual population analysis is obtained with an input $F$ of 0.203 . The confidence intervals $(0.16,0.26)$ for the fitted terminal $F$ values are obtained as described by Halldórsson et al. (1986) and Stefánsson (1987) by using the tabled F-distribution to set limits on the SSE and finding the terminal F values corresponding to these limits (Figure 2.4.1).

Using the catch data given in Table 2.1.1 and the fitted values of fishing mortalities given in Table 2.4.1, a final VPA was run using a natural mortality rate of 0.1 for all age groups and the proportion of M before spawning as 0.5 . Fishing mortality at age for 1977-1996 and stock in numbers at age and spawning stock biomass on 1 July 1977-1997 are given in Tables 2.4.2 and 2.4.3 respectively. In addition, another VPA was run, extending backwards to 1947. The standard stock summary, based on the longer VPA, is given in Table 2.4.4 and the standard plots of the time series of spawning stock biomass and recruitment and trends in yield and fishing mortality are shown in Figure 2.4.2. The resulting stock trend from VPA is plotted together with the acoustic estimates in Figure 2.4.3 and the relationship between the two estimates is shown in Figure 2.4.4. In the absence of reliable abundance estimates for the 1993 year class, the size of this year class was set at 400 million as 1ringers. This number is close to the lower quartile of the recruitment observed since 1980.

According to the present assessment the spawning stock biomass was about 510,000 tonnes on 1 July 1996 as compared to the projected spawning stock from last year's assessment of 480,000 tonnes.

### 2.5 Catch and Stock Projections

The input data for the projections are given in Table 2.5.1. Although the variations of mean weight at age are relatively small with regard to the extreme variations of environmental conditions and changes in stock size observed during the past decades, an earlier working group found that a simple model of the interannual variation explains a statistically significant portion of the variance in weight at age (ICES 1993/Assess:6).

As in previous years, a regression of increase in weight on mean weight the previous year has been used to predict the weight at age for $2-8$ ringers, using as input the weight at age for $1-7$ ringers in the year before.

Data for the regression included, as starting years, the period 1987-1996. For 1-ringers and $9+$ ringers, a simple average of mean weights at age for the period 1986-1996 was used for the prediction. Weights at age for 2-8 ringers in the catch were obtained using the relationship:
$\mathrm{W}_{\mathrm{y}+1}-\mathrm{W}_{\mathrm{y}}=-0.2161 \cdot \mathrm{~W}_{\mathrm{y}}+85.453(\mathrm{~g})$
where $W_{y}$ and $W_{y+1}$ are the mean weight of the same year class in year $y$ and $y+1$ respectively.
Output of the prediction, assuming catches corresponding to a fishing mortality rate of $\mathrm{F}_{0.1}=0.225$, are given in Table 2.5.2, and projections of spawning stock biomass and catches (thousand tonnes) for a range of values of F are given in Table 2.5.3.

Due to the low abundance estimates of the year classes from 1992 and 1993, i.e. age groups 3 and 4, the catch during the 1997/98 fishing season will consist mainly of herring belonging to the 1989-1991 year classes. In addition, there will still be some contribution by the 1988 year class. It is estimated that approximately $70 \%$ of the catch will consist of 6 years and older herring.

Like in previous assessments and in agreement with the increased level of recruitment during the 1980s and early 1990s, a value of 600 million l-ringers has been assumed for 1997. For 1-ringers in 1996 a value of 845 millions was used.

Yield per recruit and spawning stock per recruit, and short-term yield and spawning stock biomass are shown in Figure 2.5.1, using the long-term average values given in Table 2.5.4.

### 2.6 Management Considerations

During the last 20 years the Icelandic summer-spawning herring stock has been managed at levels corresponding fairly closely to fishing at $\mathrm{F}_{0.1}$. Exploiting the stock at a fishing mortality rate of $\mathrm{F}_{0.1}=0.22$ during the 1997/98 season would result in a catch of about 100,000 tonnes (Table 2.5.3). The spawning stock biomass in 1998 would be similar to that in 1997, i.e. about 480,000 tonnes. Harvesting at higher fishing mortality rates than $\mathrm{F}_{0.1}$ would give a correspondingly higher short-term yield but would reduce the stock sharply when the effect of the strong year classes presently in the stock has been further reduced.

The Working Group points out that managing this stock at an exploitation rate at or near $\mathrm{F}_{0.1}$ has been successful in the past. The stock is in a healthy state and well above any "alarm level". Thus, for the time being, further precautionary measures seem not to be needed in the management of this stock.

### 2.7 Stock and Recruitment

Part of the analysis by Jakobsson et al. (1993) was repeated for the time series of spawning stock biomass and recruitment in the period 1947-1994 from this assessment. The Beverton-Holt, Ricker, Cushing and Schnute models for the SSB-R relationship were fitted to the data by minimising the residual sum of squares from each log-transformed relationship. A summary of the basic results is given in Table 2.7.1 and the resulting graphs on Figure 2.7.1, along with the lines used to identify the parameters $\mathrm{F}_{\text {high }}, \mathrm{F}_{\text {med }}$ and $\mathrm{F}_{\text {low }}$. The relationship between the SSE from the model fits is unchanged from Jakobsson et al. (1993), who found that the data fit best to the Cushing model and used it for further analysis.

### 2.8 Medium-Term Prediction

In 1995 the Working Group carried out a medium-term prediction for the Icelandic summer-spawning herring, based on a fixed F strategy ( $\mathrm{F}_{0.1}$ ). As the input parameters for the medium-term projections have not changed substantially since the last Working Group meeting in April 1996, no runs were made this year. There was some probability, within the model used, of the stock increasing to very high levels. This is due to the handling of uncertainty in the parameters of recruitment from the Ricker curve and is a consequence of the fact that the present state of the stock is at the highest known historical level.

### 2.9 Sampling

| Investigation | No. of <br> samples |  | Length meas. <br> individuals |
| :--- | ---: | ---: | ---: |
| Fishery | 30 | 3214 | Aged <br> individuals |
| Acoustic, wintering area | 15 | 3363 | 2295 |

### 3.1 The Fisheries

### 3.1.1 1996

The Faroes, Iceland, Norway and Russia agreed at a meeting in Oslo in May 1996 to limit their catches to a total catch of 1.1 million tonnes in 1996 . EU set a quota of 150,000 tonnes for their fishery.

The landings in 1996 amounted to $1,217,224$ tonnes.

## EU

The EU fishing fleet operated in international waters in April-June. The EU catch amounted to 181,028 tonnes.

## The Faroes

The Faroese fishery started in the latter half of April. The fishery in spring took place in the Faroese EEZ, in international waters, and in the Jan Mayen EEZ. This fishery terminated in the middle of June. In autumn the Faroese fishery took place in the Norwegian EEZ where 12,500 tonnes were caught. The Faroese catch amounted to 52,788 tonnes.

## Iceland

The Icelandic fishery started 9 May on the border area between the Icelandic and Faroese EEZ and the international waters on the Norwegian Sea. Some of the Icelandic catches were taken in the Jan Mayen EEZ. The Icelandic fishery was terminated around mid-July. The Icelandic catch amounted to 164,957 tonnes.

## Norway

The Norwegian fishery on Norwegian spring spawning herring is carried out throughout the year, and the main activity is linked to the migration pattern of the herring. The fishery started in the beginning of January in the wintering areas of northern Norway. About 158,500 tonnes were taken in this area by the end of February. 158,000 tonnes were taken during the spawning migration and on the main spawning areas in the period January throughout February. In the latter part of March and in April about 70,000 tonnes were taken of spent herring at the start of the feeding migration. In the Norwegian Sea, during late spring and summer, there was a total catch of 18,000 tonnes. Finally 298,000 tonnes were caught during autumn in Vestfjorden, the wintering area. The total Norwegian catch was 699,161 tonnes. Approximately $85 \%$ of the Norwegian catch was used for human consumption, the rest was utilised for reduction purposes.

## Russia

The Russian catch in the spawning area in February to April amounted to 79,000 tonnes. In addition 40,000 tonnes of herring were taken in the Vesterålen area in autumn. The total Russian catch was 119,290 tonnes.

### 3.1.2 1997

At a meeting in Oslo in December 1996, the main participants in the fishery for Norwegian spring-spawning herring reached an agreement to limit their total catch in 1997 to 1.5 million tonnes and on the allocation of this TAC.

By 1 April the Norwegian catch was approximately 325,000 tonnes and the Russian catch approximately 87,000 tonnes.

### 3.2 Catch Statistics

The total annual catches of Norwegian spring-spawning herring for the period 1972-1996 (1996 preliminary) are presented in Tables 3.2.1 (by fishery) and 3.2.2 (by country). Catch in number and mean weights per age group
by nation are given in Tables 3.2.3 and 3.2.4. The amount of samples used for converting landings to number by age group is listed in Section 3.1.3.

The Working Group noted that in this international fishery an additional mortality caused by fishing operations probably exists. In general, it was not possible to assess the magnitude of these extra removals from the stock, and taking into account the large catches taken in recent years, the relative importance of such additional mortality is probably low. Therefore no extra amount to account for these factors have been added in 1994, 1995 and 1996. In previous years, when the stock and the quotas were much smaller, an estimated amount of fish was added to the catches (Table 3.2.1).

For 1996 age compositions and weight at age were provided for all age groups by Norway and Russia. The Icelandic catches were split using Norwegian age compositions and weight at age from the Norwegian fishery taking place in the same area and time. The Netherlands provided such data up to age $9+$. This + group was split in the same way as in the Norwegian, Russian and Icelandic catch combined. The catch at age and weight at age in the catch taken by Denmark, the Faroes and UK was calculated by combining length distributions provided by these countries with Norwegian age-length keys. For the catch by Ireland, Sweden and Germany, the Dutch data were used. The mean weight at age in the catch was calculated as a weighted average of the weight at age in the catch for all the countries. Minor changes in the 1995 catch data have been accounted for.

The method used to calculate catch in number in the Norwegian fishery is described in a working document by A. Slotte. Each herring landing utilised for human consumption is registered with the following: catch size in kilograms ( kg ), catch position in terms of area and location and date of delivery for production. In addition the majority of the catches that are used for consumption are divided into 5 size groups as follows:

| Group | Weight $(\mathrm{g})$ |
| :---: | :---: |
| 1 | $>333$ |
| 2 | $200-333$ |
| 3 | $125-200$ |
| 4 | $83-125$ |
| 5 | $<83$ |

The percentage of the total catch in kg is calculated for each size group, by taking out subsamples of the catch during the production process. These percentages are registered by the sales organisation. The per cent age composition within each size group can be found from sampling, and the total catch in number calculated.

### 3.3 Surveys

### 3.3.1 Spawning areas

A survey was carried out under very bad weather conditions, and as described in the Working Document by A. Slotte and A. Dommasnes it was not possible to obtain an estimate on the spawning areas in 1997 (Table 3.3.1).

### 3.3.2 Wintering areas

The wintering area was surveyed acoustically in December 1996 (Working Document by K. Foote et al.) and in January 1997. The results from December 1996 are given in Table 3.3.2, but due to bad weather it was not possible to obtain an estimate in January 1997 (Table 3.3.3). In addition, results from the December 1995 acoustic survey were available (Table 3.3.2). These results were not available during the Working Group meeting last year.

### 3.3.3 Feeding areas

The feeding areas in the Norwegian Sea were mapped in a multinational acoustic survey in May 1996 (Working Document by Jakupsstovu et al.). The results showed that a survey in the feeding area will probably give relevant information on stock size and structure (Table 3.3.4). The survey will be repeated in May 1997 (ICES CM 1997/H:3) and it will be decided at the 1998 WGNPBW meeting if this survey should be incorporated into the tuning series.

### 3.3.4 Nursery areas

The nursery areas of the Norwegian spring-spawning herring are Norwegian fjord and coastal areas, and the southern part of the Barents Sea. Since 1988, when the 1983 year class spawned for the first time, the latter area has increased in importance as a nursery area for the herring.

The results from the acoustic survey in the Barents Sea in May/June 1996 are given in Table 3.3.5. This survey had previously been a joint Norwegian/Russian cruise but this year the two nations conducted the survey separately. The results from the 0-group survey in fjord and coastal areas in November 1996 are given in Table 3.3.6. Furthermore, the abundance indices for herring from the joint Norwegian/Russian 0 -group trawl survey in August/September 1996 are given in Table 3.3.7.

### 3.3.5 Herring larval survey

The distribution area of herring larvae was covered by a cruise with R/V " Michael Sars" during the period 5-21 April 1997 (Figure 3.3.1) High numbers of herring larvae ( $>1000 \mathrm{~m}^{-2}$ ) were recorded outside the Lofoten area, at Haltenbanken, outside Møre, outside Bremanger and Sognefjorden and outside Jæren. The herring larval indices for the period 1981-1997 are shown in Table 3.3.8. The number of larvae found in 1997 is the highest since the collapse of the herring stock and more than twice the previous recorded maximum in 1996.

The spawning areas of the NSSH have had a tendency to spread out in northern and southern direction the last years. This was easily seen in 1997 with high numbers of larvae both at the Røstbank and the Siragrunn. However, the numbers of larvae in the central areas have also increased, and the highest density of larvae was found at the Haltenbank with more than 20,000 larvae in one haul of approx. $60 \mathrm{~m}^{3}\left(0.3\right.$ larvae $\left.1^{-1}\right)$, a concentration not usually found in nature.

Low densities of microzooplankton were recorded on the cruise, however many of the larvae were feeding and algae and copepod eggs were found in their guts.

### 3.4 Tagging Experiments

The Norwegian tagging experiment on herring, which was initiated in 1975, has been continued, and recaptures from commercial catches have been screened for tags using tag detectors installed at sea food processing factories. In 1996, 48.7 million herring were screened for tags, and 98 tagged herring were recaptured. Recaptures have also been reported from other Norwegian factories, mainly meal plants, which use herring entrails from the herring filleting industry in the production. These tags originate from an unknown catch, and have not been used in the assessment.

From the 1995 catches, Iceland reported 630 tags retained on magnets in Icelandic fish meal plants. A magnet efficiency test carried out at one of the plants gave a screening efficiency of $47.5 \%$. The herring used in the test experiment was, however, in very poor condition, which may have caused error in the efficiency estimate. A total of 402 tags were recovered at 5 Icelandic reduction factories from total landings of about 92,000 tonnes in 1996. Attempts to obtain measures of efficiency of the magnets used at those factories were unsuccessful. It was decided not to use the data from the Icelandic recaptures in the assessment.

In the 1996 assessment, the length of the fish when tagged was used to separate the recaptures of the 1983 year class from recaptures of tagged herring of younger age groups. This procedure was acceptable as long as the recruiting year classes were small compared to the 1983 year class. In recent years, new strong year classes have been recruited, and a more reliable method of ageing the recaptures and calculating the corresponding number of released fish is suggested. The recaptures of tagged herring were aged individually by scale reading, and the grouping by age for each batch of release was available. The corresponding number of tagged herring by age in the batch was calculated from an age determined random sample of the catch from which the tagging was executed.

The number of releases in 1987-1996 and corresponding recaptures in the years 1989-1996 for the year classes 1983 and older are given in Table 3.4.1. In order to avoid error due to non-random mixing of the tagged fish, the recaptures in the year of tagging and in the year after tagging have been excluded. In addition 4 batches of tagged herring in 1987 and 1988 are excluded because they may have contained herring belonging to local stocks.

Similar data of screened catch and recaptures of tagged herring of younger year classes (1986-1989 and 1990 separately) are shown in Table 3.4.2.

The use of these data in the assessment is described in Section 3.5.2.3.

### 3.5 Stock Assessment and VPA

### 3.5.1 Models for stock assessment

A brief review was carried out of options and choices made for stock assessment and modelling, with the intention of developing a more formal assessment model structure that brings together the previously separate spreadsheet-tuning and VPA-running exercise. The Working Group reviewed choices made for the previous assessment of this stock, and attempted to define an appropriate model based on conventional assumptions and several Working Documents. The more important changes were then implemented step by step and the Working Group considered whether to accept or to reject each of the proposed alterations. In this case, the time series of survey information was too short to perform a retrospective analyses. Due to time constraints at the meeting, attention was focused on developing a model for the year classes that had recruited to the fishery, and recruitment forecasting was treated as a separate issue for the present. The following Section describes this process of $a$ priori model definition and subsequent testing and review.

The Working Group considered that the preferred assessment model would ideally include all possible survey information in a single framework with a single fitting procedure based on least-squares or a maximumlikelihood approach, i.e. a maximum-likelihood 'ADAPT' formulation, with the addition of a model component describing tagging experiment releases, survival and recapture.

### 3.5.2 Input data

### 3.5.2.1 Year and age range

Age-structured information on catches, and biological information from 1950 to 1996 were available for use and were to be included. Historical information from 1936 onwards is being re-evaluated at the IMR, Bergen and it is expected eventually to include these years in the time series.

Previously, the age-range 3 to $14+$ was used for the purposes of calculating age-structured assessments. Two problems were noted: (1) excluding younger ages meant excluding the significant exploitation of juvenile fish in the 1950s until the early 1970s, which may have implications for the estimation of stock-recruit relationships, and (2) the persistence of the 1983 cohort in the catches resulted in the Working Group having to increment the oldest age in the assessment year by year in recent years.

To overcome these problems it was decided that the full age-range of available information should be used, and the analysis should be run for ages 0 to 15 with a $16+$ group.

### 3.5.2.2 Missing values

There is a large number of observations with missing values in the catch-at-age matrix, due to periods of very low abundance of some cohorts. In previous assessments, missing observations had been replaced with arbitrary values of 1000 fish, which (when assuming a reasonable terminal population) results in an arbitrary, and often excessively high fishing mortality being estimated at the oldest age with catch observation in the cohort. In some years when the stock was depleted the problem is severe as there are very few observations at older ages. It was not known how sensitive the perception of stock size was to this arbitrary treatment of terminal fishing mortalities.

One proposed solution was to replace the missing observations with values predicted by fitting a log-transformed separable model (Shepherd and Nicholson, 1991).

### 3.5.2.3 Natural mortality

Values of natural mortality assumed by the Working Group previously (ICES 1996/ASSESS: 14) for ages 3 and older were 0.16 for the years 1950 to 1970 and 0.13 for the years 1971 and subsequently. In the previous
assessment of this stock it was assumed (on the basis of observations of many diseased and dying fish in catches) that the fish of the 1987 cohorts and older had suffered a higher natural mortality in the years 1991 to 1994. An additional disease-induced natural mortality of 0.1 was assumed. However, interim studies (Patterson, WD 1997; Tjelmeland WD 1997) directed at estimating disease-induced mortality have failed to provide compelling evidence for values above zero. Attempts to estimate natural mortality from tagging information (Hamre, WD 1997; Patterson, WD 1997a; Tjelmeland, WD 1997) were highly consistent with values in the range 0.13 to 0.16 , but the Working Group did not consider that this parameter could be estimated with sufficient precision to justify a discrimination between levels of 0.13 and 0.16 . Consequently it was decided to predicate the assessment model estimates on an arbitrarily-chosen $\mathrm{M}=0.15$ for ages 3 and older, and no attempt was made to include additional disease-induced mortality in the maximum-likelihood assessment model. However, uncertainty in possible levels of this additional mortality was retained when estimating uncertainty in stock size.

Values of natural mortality for juvenile fish (ages 0-2) used by the Working Group in 1996 were 0.9 for all years in the historic VPA, but for forecasting purposes values of 1.56 for age 1 and 0.54 for age 2 were used for the 1993-1995 year classes. These values were based on an unpublished Ph.D. Thesis by de Barros (1995); this work was not available for evaluation by the Working Group, and hence it was decided to retain the assumption of $\mathrm{M}=0.9$ for ages 0 to 2 in all years. This value is consistent with the mean of de Barros' estimates.

### 3.5.2.4 Calculation of fishing mortality at the last true age

For VPA calculations the fishing mortality at the last true age was chosen to be calculated as the populationweighted mean fishing mortality from ages 8 to 13 , on the basis that historical selection patterns have been approximately flat over this age-range.

### 3.5.2.5 The plus-group

It was decided to calculate historic populations in the plus-group independently of the VPA populations based on the catch equation, the fishing mortality on the last true age and the estimated catch at age in the plus-group in conventional fashion.

### 3.5.2.6 Calculation of reference $F$

Following the advice given by ACFM at its November 1995 meeting, it was decided to use $\mathrm{F}_{5-13}$ weighted by the population number (hereafter denoted as $\mathrm{F}_{5-13, \mathrm{w}}$ ) as the reference F for this stock.

### 3.5.2.7 Proportion of $F$ and $M$ before spawning

As in last year's assessment, the proportion of F and M before spawning was set to 0.1 .

### 3.5.3 Choice of survey data and tagging data to use in the assessment

It was decided to use the following acoustic survey information, on the basis that survey efficiency was assumed constant over the years and age-ranges as below:

Surveys on the spawning stock in February-March, ages 5 to 13 and years 1988 to 1996. (1992, 1993 and 1997 missing due to bad weather conditions).
Surveys on the wintering area in December, ages 4 to 13 and years 1992 to 1996.
Surveys on the wintering area in January, ages 5 to 13 and years 1991 to 1996 (1997 missing).
Surveys on juvenile fish in the Barents Sea, age 1, years 1984 to 1996.
Surveys on juvenile fish in the Barents Sea, age 2, years 1984 to 1996.
It was argued that all available information from the surveys (including the very weak cohorts) should be included in the assessment, rather than just the information from the abundant cohorts that was used for the previous stock assessment.

It was decided to include information on tag marking mortality and subsequent recaptures of fish of the 1983 cohort in the assessment model. Data on recaptures of the 1986 and younger year classes were not used because few observations were available (Table 3.4.2).

The larval survey was not used in the assessment because there seems to be no evidence of a relation between those survey indices and the year class strength.

### 3.5.4 Treatment of acoustic surveys and tagging data in the assessment model

### 3.5.4.1 Survey structural relationships

As in the previous assessment of this stock, a simple age-independent proportionality relationship was assumed for the estimates of stock abundance $U_{a, y, i}$ from the ith survey in year $y$ at age a on the adult stock. Denoting the constant of proportionality for the ith survey as $Q_{i}$ the structural relationship to the VPA population abundance $N$, natural mortality M and fishing mortality F is:

$$
U_{a, y, i}=Q_{i} N_{a, y} \exp \left(\left(-F_{a, y}-M_{a, y}\right) t_{i}\right)
$$

Where $t_{i}$ represents the timing of each survey relative to 1 January in years. Values of $t_{i}$ are $3 / 12$ for the FebruaryMarch survey, $11 / 12$ for the December survey and 0 for the January survey (stock assumed surveyed on 1 January).

The juvenile survey in the Barents Sea was treated similarly except that a separate Q for ages 1 and 2 was estimated. For this survey, $\mathrm{t}_{\mathrm{i}}=5 / 12$.

### 3.5.4.2 Choice of survey error model

Prior to 1996 the Working Group assumed a normal distribution of errors for acoustic survey residuals. Subsequently, a lognormal error distribution was chosen. Making this change resulted in a change in the perception in the size of the 1983 year class in the beginning of 1995 from 1.8 to 3.5 billion individuals. However, simple scatter plots suggest that distributional assumptions of both normal and lognormal error distributions may be violated. In the case of the normal error model, the variance of residuals appears to increase with expected values, whilst in the case of the lognormal error model the variance appears to decrease with expected value (Figure 3.5.1). In order to overcome this problem a gamma error distribution (being intermediate between normal and lognormal in the relationship of variance and expected value) was deemed a plausible alternative choice.

### 3.5.4.3 Tagging

A known number of tagged fish $\mathrm{K}_{\mathrm{j}, \mathrm{a}, \mathrm{y}}$ were released into the sea in each of j experiments and then assumed to suffer an initial tagging mortality S . The number of tagged fish in the sea T is estimated by:

$$
T_{j, a, y}=K_{j, a, y} S
$$

and in subsequent years as:

$$
T_{j, a t+, y+1}=T_{j, a, y} \exp \left(-F_{a, y}-M_{a, y}\right)
$$

Recaptures of tagged fish $\left(\mathrm{G}_{\mathrm{j}, \mathrm{a}, \mathrm{y}}\right)$ are then modelled as rare Poisson events whose expectation $\left(\mathrm{H}_{\mathrm{j}, \mathrm{a}, \mathrm{y}}\right)$ is given by the catch equation and the number of tagged fish in the sea. Expected recaptures of tagged fish of age a in year $y$ given that $m_{y}$ fish are screened out of a catch of $\mathrm{C}_{\mathrm{a}, \mathrm{y}}$ untagged individuals is approximately:

$$
H_{j, a, y}\left(\frac{m_{y}}{\sum_{a} C_{a, y}}\right) T_{j, a, y} \frac{F_{a, y}}{F_{a, y}+M_{a, y}}\left(1-\exp \left(-F_{a, y}-M_{a, y}\right)\right)
$$

### 3.5.4.4 Likelihood function

Given the above structural relationships, the log-likelihood function for the above model (assuming gamma errors) was:

$$
\begin{aligned}
& \sum_{j, a, j} G_{j, a, j} \ln \left(H_{j, a, y}\right)-H_{j, a, s}-\ln \left(G_{j, a, y}\right)+ \\
& \sum_{i, a, y}-U_{i, a, y} / \beta_{i, a, y}+\left(\alpha_{i, a, y}-1\right) \ln \left(U_{i, a, j} / \beta_{i, a, y}\right)-\ln \left(\beta_{i, a, y} \Gamma\left(\alpha_{i, a, y}\right)\right)
\end{aligned}
$$

where the scale parameter estimate is:

$$
\beta_{i a, y}=\sigma^{2} /\left(Q_{i} N_{a, y} \exp \left(\left(-F_{a, y}-M_{a, y}\right) t_{i}\right)\right)
$$

and shape parameter estimate is:

$$
\alpha_{i a, y}=\left(Q_{i} N_{a, y} \exp \left(\left(-F_{a, y}-M_{a, y}\right) t_{i}\right)\right)^{2} / \sigma^{2}
$$

with the gamma function:

$$
\Gamma(\alpha)=\int_{0}^{\infty} \exp (-u) u^{\alpha-1} d u
$$

A simple moment-based variance estimation procedure was used, although alternatives were suggested.

$$
\sigma^{2}=\frac{1}{n} \sum_{i, a, y}\left[U_{i, a, y}-Q_{i} N_{a, y} \exp \left(\left(-F_{a, y}-M_{a, y}\right) t_{i}\right)\right]^{2}
$$

### 3.5.5 Parameters

Two possible parameterisations were initially considered, and are referred to here as the 'short' and the 'long' parameterisations. In the 'long' parameterisation, year classes are estimated separately using survey data independently by year class. This is similar to the previous stock assessment procedure, but a simpler alternative was proposed (the 'short' parameterisation) in which a flat exploitation pattern from ages 6 to 13 (in 1996) was assumed, with the exploitation at age 5 estimated separately. Younger year classes could then be treated as recruitments in a separate calculation. The 'short' parameterisation is similar to that used for the Icelandic summer spawning Herring. In the 'long' parameterisation, a maximum in the log-likelihood function was located by searching on the following parameters:

> Population abundance N at each of ages $3-9$ and age 14 at 1 January 1997 , Catchabilities $\mathrm{Q}_{\mathrm{i}}$ for each of the three surveys on the adult stock, Catchabilities $\mathrm{Q}_{\mathrm{i}}$ for ages 1 and 2 in the juvenile survey in the Barents Sea,
> Tagging survival $S$ (from the time of tagging to the end of the tagging year).

Population abundance at age 2 in 1997 was estimated conditionally on the fitted catchability, as:

$$
N_{2,1997}=U_{\text {Barensseaca, } 1,1996} / Q_{\text {Barensisca, }, 1} \exp \left(-M_{1,1996} \frac{7}{12}\right)
$$

Population abundances at ages 10-13 in 1997 were estimated by assuming that the estimated fishing mortality exerted on fish ages 13 years in 1996 was also exerted on ages 9 to 12 . This is similar to the assumption made in the previous assessment of this stock.

In the 'short' formulation the parameters estimated are:
Population abundance N at age 14 at 1 January 1997, Population abundance $N$ at age 6 at 1 January 1997, Catchabilities $\mathrm{Q}_{\mathrm{i}}$ for each of the three surveys on the adult stock, Tagging survival $S$.
and a constraint is imposed such that $\mathrm{F}_{6-12,1996}=\mathrm{F}_{13,1996}$.

### 3.5.6 Model fitting and testing

A starting point for the model exploration exercise was defined, being a model structure and data set similar to that used by Anon (ICES 1996/Assess:14). Specifically:

## Catch at age data 1950-1996, ages 0 to $16+$

Tagging data as used by Anon (ICES 1996/Assess:14)
Surveys: 1983, 1988, 1989 and 1990 cohorts only
year -range 1988-1996 (February-March), 1992 and 1993 missing
1992-1994 (December)
1991-1996 (January)
Age-range for F on last age: 8 to 13
Errors: lognormal
$\mathrm{M}=0.15$ on ages 3-16
'long' parameterisation
tagging likelihood function included
The 1991 January survey, which was erroneously omitted last year, has been included, and M on ages 3 and older has been changed from 0.13 (with $\mathrm{M}=0.23$ on the year classes 1987 and older in 1991-1994 due to Ichtyophonus).

Results obtained from this fitting procedure are labelled as 'Run 1' in Table 3.5.1. The following incremental changes to this model were then considered:

Run 2: Revised and extended tag release and recapture data for the 1983 year class presented by Hamre (WD, 1997) were used. The change in the estimate of spawning stock size estimates in 1996 was small, from 5.28 million t to 5.20 million t , and it was decided to adopt this change as it was consistent with previous information.

Run 3: The December acoustic surveys for the years 1995 and 1996 were included, except that the high observation at age 4 in 1996 was excluded. This resulted in a change in the spawning stock size estimate from 5.20 Million $t$ to 3.69 Million $t$, concomitant with the estimate from that survey of a reduced stock size for the 1983 and 1988-1990 cohorts. The Working Group decided to adopt this change as being a valid addition of new information.

Run 4: The high outlying value of stock abundance at age 4 in 1996 from the December surveys was included. This resulted in a revision in spawning stock size from 3.69 to 6.56 million $t$. The Working Group did not wish to allow the assessment model estimates to be so highly dependent on a single observation from a partially recruited year class, and preferred instead to exclude this datum. This could be justified on account of a large increase in variance (493 to 3800).

Run 5: Information on juvenile surveys in the Barents Sea was included. These were found to have an extremely high variance, which made it appropriate to estimate a separate variance term for these surveys and to replace the year class estimate with a weighted mean of the historic recruitments ( $50 \%$ weight) and the survey-forecast recruitments ( $25 \%$ for each of age 1 and age 2 ). As a further constraint and to be consistent with the assumption used in previous years that the acoustic survey of these fish could be used as an absolute estimator of year class strength, the constraints $0.5<\mathrm{Q}_{\mathrm{Barents} \text { Sea }}, 1<1.5$ and $0.5<\mathrm{Q}_{\mathrm{Barents} \text { Sea, }}<1.5$ were also imposed on the model.

Even with these additional constraints, the new information resulted in a change in the perception of spawning stock size from 3.69 to 2.32 million tonnes. Again, the Working Group decided not to allow the assessment of recruited year classes to be so strongly influenced by the highly-variable recruitment index and preferred to exclude the Barents Sea surveys from the assessment model.

Run 6: The model structure as in Run 3 was used with a catch at age data set in which the missing observations (previously set to 1000 fish) were replaced with Shepherd and Nicholson (1991) model predictions. The effect on spawning stock size estimates was small, changing from 3.69 to 3.68 million tonnes, although outlying values of fishing mortality in the catch-at-age matrix were removed. The Working Group considered that the improvement was mostly presentational in nature and did not warrant the additional computational burden that future Working Groups would incur if this procedure were to be adopted.

Run 7: The error structure was changed from lognormal to Gamma. This resulted in an increase in spawning stock size from 3.69 million $t$ to 4.40 million $t$ in 1996. This is consistent with the findings by Patterson (WD 1997) that making this change results in an increased stock size but improved consistency of the distribution of residuals with that predicted by the error model. The estimated selection pattern is shown in Figure 3.5.2.

Run 8: Consideration was given to including the very high survey observations made on the 1991 year class in January 1996 and in the February-March survey in 1996. This resulted in a change in perception of overall stock abundance from 4.40 Million $t$ to 12.08 Million $t$. The large increase in variance suggests the inclusion of these values is inappropriate.

Run 9: The Working Group considered the exploitation pattern calculated using the 'long' parameterisation of the model (Run 7) to be highly fluctuating and questionable and explored the consequences of making a simplifying assumption of uniform exploitation at ages 6 and above in 1996 (Figure 3.5.2). Making this change resulted in a change in spawning stock estimate from 4.40 million $t$ to 6.99 million $t$. The variance increases from 496 to 805, the number of fitted parameters decreases from 9 to 6 .

Run 10: The Working Group considered including information from all year classes in the acoustic surveys on the adult stock. This was previously considered implausible as many year classes are of such low abundance they can only be very poorly estimated, and hence only contribute noise and outliers to the analysis. Including this information with Run 9 results in a change in perception of spawning stock size from 6.99 million $t$ to 2.53 million t , but the variance estimate increases from 805 to 3461 and this fit also is unappealing on that ground.

Run 11: A flat exploitation pattern on ages 8 to 13 (in 1996) is assumed, the exploitation at age 5 is estimated separately and the exploitation pattern is assumed to be linear between ages 5 and 8 (Figure 3.5.2). Compared to run 7 , this run gave a change in the spawning stock estimate from 4.40 to 5.48 million tonnes, which is very close to the value of 5.35 million $t$ obtained in last year's assessment. The variance increased from 496 (Run 7) to 703, and the number of parameters estimated decreased from 9 to 7 .

Clearly, the assessment procedure is highly sensitive to details of model structure and to the inclusion or exclusion of outlying data points. This is probably largely because fishing mortality is quite low, hence the VPA calculations are relatively uninformative. As a result, plausible solutions can be obtained in the range 2.3 to 12.1 million t .

### 3.5.7 Stock assessment of the 1991 and older year classes

For reference purposes a necessarily arbitrary choice was made of the most appropriate model. Due to the short time series of survey information, model testing by retrospective analysis is not appropriate in this case. Although other runs give better fit to the data, the Working Group finds the simple selection pattern of Run 11 more appropriate to use in a management context. In addition, the selection pattern is consistent with prior knowledge of fishery operations, and Run 11 gives good consistency with previous assessments. The age structure in the population estimates from the May 1996 survey in the Norwegian Sea (Table 3.3.4) also appears consistent with the results of Run 11.

Detailed input data are given in Tables 3.5.2-3.5.3. Diagnostic plots are given as Figures 3.5.3-3.5.4. The model was fitted using a FORTRAN implementation written for this purpose. For presentational purposes, terminal fishing mortalities so estimated were used to initiate the conventional VPA (see Section 3.5.9).

In previous assessments, the size of the recruiting year classes has been determined by using the most recent acoustic estimates of these year classes as absolute estimates, and predicting the size of those year classes at age 3 using the natural mortalities given by de Barros (1995), i.e. 1.56 at age 1 and 0.54 at age 2 . In some cases, acoustic estimates from several surveys were added together.

This year it was decided to use the RCT3 program for predicting the abundance of the year classes which were not determined by the assessment model given above, i.e. the 1992-1996 year classes.

The following survey estimates were considered for use in the RCT3 program:
Acoustic survey of the spawning stock in February-March, age 4 (Table 3.3.1)
Acoustic survey in the wintering areas in December, age 3 (Table 3.3.2)
Acoustic survey in the wintering areas in January, age 4 (Table 3.3.3)
Acoustic survey in the Barents Sea in May-June, ages 1 and 2 (Table 3.3.5)
(For 1996, the average of the Norwegian and Russian estimate was used)
International 0-group survey in the Barents Sea 1973-1996 (Table 3.3.7)
The default settings in the RCT3 program were used. The input data are given in Table 3.5.4 and the results of the analysis are given in Table 3.5.5. The year class strength of the 1992-1996 year classes at age 3 (billions) is given in the text table below, together with the estimates of those year classes made by last year's Working Group.

| Year class | 1997 WG | 1996 WG |
| :--- | ---: | ---: |
|  |  |  |
| 1992 | 29.473 | 23.961 |
| 1993 | 13.706 | 5.600 |
| 1994 | 0.688 | 0.845 |
| 1995 | 0.667 | 0.005 |
| 1996 | 3.103 | - |

It was also attempted to include the acoustic survey of 0 -group in Norwegian coastal waters in NovemberDecember (Table 3.3.6) in the RCT3 analysis, this increased the size of the 1996 year class at age 3 from 3.103 to 10.689 billion individuals. As the acoustic survey of 0 -group in Norwegian coastal waters covers only a small proportion of the 0 -group fish in the case of good year classes, and some of the fish found in the 0 -group survey in the Barents Sea was found very close to the coastal areas where most of the fish in the survey in coastal waters was found, it was decided to exclude the acoustic survey of 0 -group in Norwegian coastal waters in NovemberDecember from the RCT3 analysis.

### 3.5.9 The final VPA

The catch at age, weight at age in the stock and catch and maturity ogive for the period 1950-1996 is given in Tables 3.5.6-3.5.9. The final VPA was run using the values of $F$ in the last year taken from the assessment method presented above for the 1991 and older year classes. The fishing mortalities for the 1992-1994 year classes were adjusted so that the abundance at age 3 of those year classes are the same as those predicted by RCT3. The fishing mortalities and stock numbers are given in Tables 3.5.10-3.5.11, while the stock biomass at age and spawning stock biomass at age are given in Tables 3.5.12-3.5.13. A summary of landings, fishing mortality, stock biomass, spawning stock biomass and recruitment is given in Tables 3.5.14 and 3.5.15, for recruitment at age 0 and 3 respectively, and Figures 3.5.5A and 3.5.5B. Plots of recruitment at age 0 and age 3 vs. spawning stock biomass are given in Figure 3.5.6.

### 3.5.10 Yield-per-recruit analysis

The yield per recruit analysis using the fishing pattern and stock parameters from 1997 from the management option table gave estimates of $\mathrm{F}_{0.1}=0.22$ and $\mathrm{F}_{\max }=0.98$. Yield per recruit vs. F is plotted in Figure 3.5.5 c.

### 3.6.1 Input data to the short-term prediction

These data are given in Table 3.6.1. The number at age at January 1, 1997, was taken from the final VPA for the year classes 1994 and older. For the 1995 and 1996 year classes, values corresponding to the RCT3 estimate of year class strength at age 3 were used. The weight at age and the maturity ogive in the stock in 1997 was set equal to the weight at age and maturity ogive for the corresponding age groups obtained from biological samples taken during the December 1996 survey. The 1997 values of those parameters were also used for later years. The weight at age in the catch and the fishing pattern in 1997 and later years were set equal to the 1996 values. The natural mortality was set to the same values as used in the assessment, i.e. 0.15 on ages 3 and older. The reason for those status quo choices is that the total stock size is expected to be relatively stable in the near future.

### 3.6.2 Results of the short-term prediction

The expected catch in $1997(1,500,000 \mathrm{t})$ indicates that the fishing mortality ( $\mathrm{F}_{5-13, \mathrm{u}}$ ) will decrease from 0.21 in 1996 to 0.20 in 1997. The effects of different levels of $\mathrm{F}_{5-13, \mathrm{u}}$ on the catch in 1998 and on the stock and SSB in 1999 are presented in Table 3.6.2.

The assessment shows that the spawning stock biomass increased from 5.5 million tonnes in 1996 to 9.1 million tonnes in 1997, and will increase further to 9.6 million tonnes in 1998. From 1998 to 1999, the spawning stock biomass will decrease for fishing mortalities above 0.06 in 1998. The total (3+) stock biomass will remain stable around 10 million tonnes in the period 1997-1999, but with a decreasing trend. With a status quo TAC in 1998, the $\mathrm{F}_{5-13, \mathrm{u}}$ will decrease from 0.20 in 1997 to 0.18 in 1998 , but will remain above 0.15 .

The total stock biomass is close to the values from last year's assessment, while the spawning stock estimates in 1997 and 1998 have been increased due to earlier maturation than expected last year. The fishing mortality in 1997 is calculated to 0.20 , compared to 0.15 in last year's assessment. The change from last year is mostly due to lower weights at age in the catch than in last year's assessment.

### 3.7 Assessment of Uncertainty

### 3.7.1 Method and assumptions

A Bayesian approach to the estimation of uncertainty in some key parameters of management interest was used. This has allowed the Working Group to incorporate opinions held about the stock which are based on biological observations but which are difficult to quantify. It has now been possible to incorporate some such qualitative observations into the assessment procedure in a formal fashion, although a quantification of a large part of the uncertainty, due to choice of survey data and selection pattern model, remains intractable. The methodology used is described briefly below.

Conventional Bayesian analysis relies on an evaluation of the posterior probability $\mathbf{P}(\Theta \mid \mathbf{X})$ of a certain set of assumptions $\Theta$, given prior belief $\mathbf{P}(\Theta)$ about those assumptions, a set of new information $\mathbf{X}$ and a likelihood function allowing the evaluation of $\mathbf{P}(\mathbf{X} \mid \Theta)$. The conditional probability can be expressed as:

## $\mathbf{P}(\Theta \mid \mathbf{X})=\mathbf{P}(\mathbf{X} \mid \Theta) \mathbf{P}(\Theta) / \int \mathbf{P}(\mathbf{X} \mid \Theta) \mathbf{P}(\Theta) \mathbf{d} \Theta$

Conventionally the $\Theta$ is a vector of input parameters to a model $\mathbf{M}$, which is assumed to be correct and upon which the likelihood function is predicated. It is also possible to treat the entire model structure $\mathbf{M}$ as an additional unknown, and to integrate both over uncertainty in model parameters and over uncertainty in the model structure (in this case each $\Theta$ has a meaning which is specific to each $\mathbf{M}$ ). The evaluation of posterior probabilities proceeds analogously:

## $\mathbf{P}(\Theta, \mathbf{M} \mid \mathbf{X})=\mathbf{P}(\mathbf{X} \mid \Theta, \mathbf{M}) \mathbf{P}(\Theta \mid \mathbf{M}) \mathbf{P}(\mathbf{M}) / \int \mathbf{P}(\mathbf{X} \mid \Theta, \mathbf{M}) \mathbf{P}(\Theta, \mathbf{M}) \mathbf{P}(\mathbf{M}) \mathbf{d} \Theta \mathbf{d M}$

This approach allows the evaluation of a posterior probability distribution for any quantity of management interest (e.g. catch forecast, outcome of a harvest control regime, etc.) that can be calculated from any $\Theta$ and $\mathbf{M}$.

Such a distribution can be constructed for any reasonable range of alternative model components in $\mathbf{M}$, so long as for each model component a likelihood term $\mathbf{P}(\mathbf{X} \mid \Theta, \mathbf{M})$ can be calculated.

In the present case, this has allowed the Working Group to make a calculation of uncertainty that includes uncertainty in the choice of appropriate error model and in the choice of appropriate stock-recruitment function. Gamma, lognormal and normal errors were admitted as alternative error models for the acoustic surveys with equal prior probability. With this approach it is not necessary to make a subjective choice of appropriate stock recruitment-function, as alternatives thought to be plausible can be admitted. In this case, the Working Group admitted three recruitment models as acceptable structural models with equal prior probability, being BevertonHolt models (either for all cohorts, or excluding the extremely abundant 1950, 1959 and 1983 year classes), and a Ricker model with all cohorts included. However, the year classes 1991 and later were excluded from the calculation of the stock-recruitment function.

In summary, uncertainty was admitted on the following parameters as below:

## Cohort abundance at age 14 in 1997:

Cohort abundance at age 6 in 1997
Catchabilities Q for each acoustic survey

Additional mortality due to Ichthyophonus

Relative natural mortality on juvenile fish at ages 0-2

Acoustic survey variance $\sigma^{2}$

Initial survival of tagged fish St

Error Models for Surveys

## Recruitment Models

## Uniform prior chosen to be unrestrictive

Uniform prior chosen to be unrestrictive
Prior Probability proportional to $1 / Q$, range chosen to be unrestrictive

Uniform prior 0 to 0.1 consistent with (year classes 1987 and older, during 1991-1994) previous assessment

Uniform prior in range 1-5; see Section 3.5.2.3

Prior probability proportional to $1 / \sigma^{2}$ (see Jeffreys, 1961), range chosen to be unrestrictive

Uniform prior in range $0.2-1.0$, consistent with survival of tagged fish held in capture

Equal prior probability assigned to normal, lognormal and gamma models

Equal prior probability assigned to Beverton-Holt model (all year classes to 1991), Beverton-Holt model excluding 1959, 1950 and 1983 year classes, and Ricker model (all year classes)

## As 'Run 11'

As 'Run 11'

A Markov Chain Monte Carlo approach was used (Gilks et al. 1996) to generate multivariate samples from posterior probability distributions. A hybrid adaptive rejection sampling algorithm similar to that described by Gilks (1996) was used, except that Gilks' secant upper envelope function was replaced with a series of rectangular approximations. Although computationally less efficient, this algorithm was robust to structural bound-constraints (such as the upper bound of $100 \%$ tagging survival that the assessment model requires). Choice of burn-in period and the interval between which samples were assumed to be uncorrelated was set 1000 iterations and 60 iterations respectively, following previous calculations of minimum values of 600 and 76
respectively using the GIBBSIT algorithm of Raftery and Lewis (1996) on a similar assessment model (Patterson, WD 1997). Due to processing time constraints at the meeting a choice of a rather low thinning value of 60 was made, as a more stable posterior distribution could be calculated at some risk of increasing correlation in the sampled parameters. It was not possible to re-estimate serial correlations in the sampled parameters at the Working Group meeting.

Although it was considered desirable to develop a fully internally-consistent model of stock dynamics and forecasting, this goal was not entirely attained due to the perceived need to use the 'RCT3' recruitment prediction procedure for year classes 1992 to 1996 separately from the assessment procedure. The solution used was to fix the recruiting year classes (ages 1 to 5 in 1997) in the stochastic calculations to the same abundance (relative to the abundance at age 6) that they have in the deterministic calculation.

Recruitments of the 1996 and later year classes were predicted using the drawn stock-recruitment model and parameters, and calculating a non-parametric bootstrap. For consistency, a historic VPA calculation was made for each draw from the posterior to re-estimate the residuals conditional on the values of stock-recruit relationship parameters and of natural mortality in each draw.

The choice of selection model and the arbitrary deletion of data perceived as outliers in the Bayesian analysis has been adopted to be consistent with the choices made in the maximum-likelihood assessment. It would arguably have been preferable to base choices in the maximum-likelihood modelling approach on posterior perceptions from the Bayesian assessment rather than the converse, but that more correct approach was not possible due to time constraints and the much greater computational demands of the Bayesian calculations. The calculations of uncertainty made here are therefore underestimates.

### 3.7.2 Uncertainty in stock assessment expressed as posterior distributions

Posterior distributions calculated by the method described above for the parameters estimated directly in the assessment procedure (cohort abundances, natural mortality rates, etc.), for the 'nuisance' parameters (catchability, survey variance) and for estimates of stock size and fishing mortality are given in Figures 3.7.1 and 3.7.2. These indicate likely stock abundances in the range 4 to 8 billions at age 6 in 1997 compared with the maximum-likelihood estimate of 10.4 billions. At age 14, the maximum-likelihood estimate was 2.9 billion compared with a perception from the posterior distribution in the range 0.5 to 2 billion fish. The perception of natural mortality, which was admitted uncertain in the range 0.1 to 0.25 , indicates that lower values are more likely and the probability reaches a maximum on the bound $M=0.1$. Similarly, estimates of the ratio of juvenile to adult mortality show little tendency to depart from unity, and lower values of Ichthyophonus-induced mortality (less than 0.04 ) also appear more likely.

The posterior estimate of appropriate error model differs from the choice made in the conventional procedure, and indicates a normal error distribution may have been a more appropriate choice in this case.

The distribution of spawning biomass estimates for 1997 (assuming F in 1997=F in 1996) spans a range from 2 to 6 million tonnes (calculated with the 1996 maturity ogive and weights at age).

The maximum-likelihood estimate was shown to be highly sensitive to the exclusion of values perceived as outliers. It is not known to what extent the Bayesian analysis is sensitive to such choices. As this uncertainty was not included in the modelling framework the analysis can be considered only approximately Bayesian.

### 3.8 Medium-Term Projections

Two different approaches to medium-term projections were applied. First, a simple model implemented on an Excel spreadsheet was run, similarly to the approach used at last year's meeting of this Working Group. Second, distributions from the Bayesian approach (Section 3.7) were used for projective runs.

### 3.8.1 Simple spreadsheet forecasts

Medium-term projection of stock and catch were carried out using a simple spreadsheet model. Here, the same assumptions were used as in the short-term prediction (Table 3.6.1), with the exception of maturity at age, which was set at 0.1 on age $4,0.45$ on age 5,0 below and 1 above.

At last year's meeting there was considerable uncertainty as to the most appropriate model to use for recruitment, and a special working group was assigned to the task. Based on the work of this group and other material (WDs by G. Hagen, K. Patterson, D. Skagen, and S. Tjelmeland) the Working Group concluded that for the time being the Beverton-Holt model with logarithmic errors was to be preferred.

Future recruitment was generated from a Beverton-Holt model with a CV (or log-scale standard error) of 1.9. The model was parameterised from VPA data with age 3 as the youngest age, and scaled to age 0 using a total mortality of 2.7 . The obtained parameters were 23.9 for the slope at the origin and 1.05 for the spawning stock that yields a slope half of this.

Uncertainty in current stock size was assumed to be adequately reflected by a standard error of 0.3 on log scale for ages 4 and older in 1997, taken from the Bayesian posterior. This value was used also during the simulations to account for future assessment errors. Uncertainty in younger ages was interpolated linearly from 1.8 at age -1 down to 0.3 at age 4 .

The abundance of 4-year old fish and older fish were assumed to be fully correlated and independent of younger ages. It was found that this particular assumption made little difference as compared to an assumption of full independence across all ages from age 4 and older.

The projections started at January 11997 and the allocated catch for 1997 was implemented using an F of 0.19. The F by age applied during the simulations is the F -value in the catch control law multiplied with the exploitation pattern given in Table 3.6.1 and divided by the average over ages $5-10$ of these numbers.

The average yield as a function of harvest control parameters is given in Table 3.8.1. It is seen that when either the catch ceiling or the fishing mortality is low, then that respective parameter becomes binding. Once F is at or over 0.15 and the ceiling is at or over 1 million tonnes, increases in either parameter lead to increasing catches.

| Maximum catch | Ybar(98-03) | Table 3.8.1 Medium-term simulation output. Average catch, 1998-2003, for different parameters in catch control law. <br> F level in control law |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 0.05 | 0.1 | 0.15 | 0.2 | 0.25 |
|  | 0.5 | 0.41 | 0.50 | 0.50 | 0.50 | 0.50 |
|  | 1 | 0.45 | 0.76 | 0.90 | 0.96 | 0.98 |
|  | 1.5 | 0.45 | 0.80 | 1.05 | 1.20 | 1.29 |
|  | 2 | 0.45 | 0.81 | 1.08 | 1.28 | 1.41 |
|  | 2.5 | 0.45 | 0.81 | 1.09 | 1.30 | 1.46 |

Table 3.8.2 provides a description of how the probability of a low spawning stock by 2003 varies with varying parameters in the catch control law. It is seen that for low values of the parameters there is very low probability of the stock reaching low levels. Conversely, at $\mathrm{F}>0.15$ and $\mathrm{Q}_{\max }>1.5$ million tonnes the probability increases quickly.

|  |  | $\begin{aligned} & 2 \text { Medi } \\ & \text { elow } 2 \end{aligned}$ | mulat onnes | $\begin{aligned} & \text { Proba } \\ & \text { or diffe } \end{aligned}$ | awnin neters | $\begin{aligned} & \text { mass } \\ & \text { ontrol } \end{aligned}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | ${ }_{0}^{\text {F }}$ | trol la | 02 | 0.25 |
|  | 2003] |  |  |  |  | 0.25 |
|  | 0.5 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |
| Maximum catch | 1 | 0.00 | 0.00 | 0.02 | 0.04 | 0.06 |
|  | 1.5 | 0.00 | 0.00 | 0.02 | 0.16 | 0.34 |
|  | 2 | 0.00 | 0.00 | 0.02 | 0.21 | 0.50 |
|  | 2.5 | 0.00 | 0.00 | 0.02 | 0.24 | 0.60 |

Similar results for catches in the 10-year period 1998-2007 and SSB through the end of the period are given in Tables 3.8.3 and 3.8.4, respectively.

| Maximum catch | Ybar(98-08) | Table 3.8.3 Medium-term simulation output. Average catch, 1998-2008, for different parameters in catch control law. | arameters in catch control law. <br> F level in control law |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 0.05 | 0.1 | 0.15 | 0.2 | 0.25 |
|  | 0.5 | 0.37 | 0.47 | 0.49 | 0.50 | 0.50 |
|  | 1 | 0.40 | 0.64 | 0.76 | 0.82 | 0.86 |
|  | 1.5 | 0.41 | 0.67 | 0.84 | 0.94 | 1.01 |
|  | 2 | 0.41 | 0.68 | 0.86 | 0.98 | 1.06 |
|  | 2.5 | 0.41 | 0.69 | 0.87 | 1.00 | 1.09 |

In this case it is seen that there is relatively high probability of the stock declining to low levels, even with a very low fishing mortality. On the other hand, it must be borne in mind that these results are based on a very simple model and it is not clear how the inclusion of more complexity will affect these longer-term results.

|  P[SSB<2.5 by 2008] <br>  0.5 <br> Maximum catch  <br>  1 <br>  1.5 <br> 2  <br>  2.5 | Table 3.8.4 Medium-term simulation output. Probability of spawning stock biomass dropping below 2.5 million tonnes by 2008, for different parameters in catch control law. |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | 0.05 | F | trol law | 02 | 0.25 |
|  | 0.03 | 0.14 | 0.18 | 0.20 | 0.22 |
|  | 0.03 | 0.26 | 0.50 | 0.61 | 0.68 |
|  | 0.03 | 0.28 | 0.52 | 0.72 | 0.79 |
|  | 0.03 | 0.29 | 0.55 | 0.75 | 0.87 |
|  | 0.03 | 0.29 | 0.55 | 0.75 | 0.87 |

If the primary objective is to obtain good catches while maintaining the spawning stock at above 2.5 million tonnes during the next 5 years or so, then the fishing mortality and catch ceiling should not exceed 0.15 and 1.5 million tonnes, respectively.

### 3.8.2 Bayesian medium-term projections

Admitting uncertainty in natural mortality requires a redefinition of the measure of exploitation of the stock, as fishing mortality rates are highly dependent on natural mortality. Although other parameterisations could be considered, a simple solution is to redefine exploitation rate as $E=F / Z$. Hence, for comparison with the conventional assessment ( $M$ assumed fixed $=0.15$ ) a calculation based on exploitation rate has been made.

The view of the state of the stock from taken from the Bayes posterior distributions is rather different from that calculated in the conventional assessment. The exploitation rate, as defined above, is considerably higher, and in the range approximately 3 to 4.5 . The comparable value from the maximum-likelihood approach is 1.53 . Concomitant with that difference, perceptions of stock development from this analysis show a faster decline in stock size at present exploitation rates. A medium-term projection calculated for an assumption of constant exploitation rate is given in Figure 3.8.1, and the associated estimates of risk (as probability that the spawning stock will fall below 2.5 million tonnes) in Figure 3.8.2. A calculation of the consequences of applying a harvest control law of $\mathrm{F}=\mathrm{M}$ (equivalent to $\mathrm{F}=0.15$ in the ML assessment) is given in Figure 3.8.3.

Inconsistencies between Bayesian and maximum-likelihood perceptions of stock dynamics have been noted before, especially in cases where information is relatively scarce (e.g. Walters and Ludwig, 1993). Arguments have been made that in such cases the Bayesian approach is more appropriate and provides a more realistic (and appropriately cautious) perception of stock dynamics.

### 3.9 Catch Control Laws

The simulated harvesting strategies have only included two parameters. These reflect the desire to maintain good and sustainable harvests while avoiding excessive variations in stock or yield due to either stock variations or assessment uncertainty. Due to the high level of uncertainty in the assessment, it is important that the harvest control law for this stock should rely also on a low level of fishing mortality in addition to a comparison with reference stock size.

Although the use of a formal catch control law is a major step on the way towards sustainable harvesting, this particular catch control law lacks a formal reflection of the need to maintain the spawning stock biomass above 2.5 million tonnes, below which reduced recruitment has been observed historically (Figure 3.5.6). The Working Group notes that it would be possible to formally take this need into account by adding more parameters to the catch control law. In particular, if the spawning stock biomass decreases towards 2.5 million tonnes in the future, then there will likely be a need for management action in order to try to prevent a further decline. If this action fails to prevent further decline and the spawning stock biomass drops below 2.5 million tonnes, then appropriate management action would be to decrease the fishing mortality (if not a moratorium), which corresponds to a rebuilding strategy.

This procedure as a whole may be reflected in a catch control law by decreasing the fishing mortality as function of the spawning stock biomass linearly from $F=F_{\text {target }}$ when $\mathrm{SSB}=\mathrm{SSB}_{\mathrm{pa}}$ to $\mathrm{F}=0$ at $\mathrm{SSB}=\mathrm{SSB}_{\text {limit }}$, as outlined by the study group on the precautionary approach to fisheries management (ICES CM 1997/Assess:7). At spawning stock biomasses above $\mathrm{SSB}_{\mathrm{pa}}$, the previously described catch control law of a constant fishing mortality bounded by a catch ceiling apply. The fishing mortality and yield as a function of SSB applying this catch control law to a stock with constant recruitment using the stock parameters used in the short-term prediction is given in Figure 3.9.1.

### 3.10 Management Considerations

The immatures and adults of this stock form a central part of the ecosystem in the Barents and Norwegian Seas, respectively (Section 7). The herring has an important role as a transformer of the production of zooplankton biomass and energy to a form which is available to organisms at a higher level of the food chain. A large stock of herring will utilise larger quantities of plankton (and over larger areas) and be able to support larger fish stocks in the higher food chain levels, than a small stock will do.

The stock assessment indicates a large spawning stock in 1997. However, the assessment is imprecise, the assessment procedure is sensitive to details of model structure and to the inclusion or exclusion of outlying data points. Possible estimates of the spawning stock from varying runs can be obtained in the range 2.3 to 12.1 million $t$. The view of the state of stock taken from the Bayesian posterior distribution is more pessimistic than that calculated from the conventional assessment, they show a lower stock and indicate a faster decline in stock size. The Bayesian approach is more consistent in the treatment of uncertainty and in the correlation of parameters than the conventional approach.

The stock has a very dynamic recruitment pattern, and the spawning stock is expected to decrease in the coming years due to poor recruitment, especially from the year classes 1994 and 1995.

An adoption of a cautious harvesting strategy is likely to improve the medium and long-term benefits to be obtained from this fishery. The stock of Norwegian spring spawning herring is exploited by the world's most efficient purse seine and pelagic trawler fleets. The stock has a known vulnerability to collapse at high levels of exploitation. In the mid-1960s the condition of this stock changed very rapidly, from record catches in 19661967 to a depleted stock in late 1969.

According to the UN agreement on "Straddling fish stocks and highly migratory fish stocks" it is of paramount importance that the Management Agencies of this type of stocks agree in advance to a plan for remedial action in case of a development of spawning stock size to low levels. Possible elements of such plans for Norwegian spring spawning herring are indicated in Section 3.9.

### 3.11 Discards (OSPAR Request)

The herring and capelin fisheries dealt with by WGNPBW are single stock purse seine and pelagic trawl fisheries. Mixing of species rarely occur in the catches. Some additional mortality may occur in some fisheries (Section 3.2). An estimate of discards of blue whiting in the southern fisheries (Spain and Portugal) is given in last year's Working Group report (ICES 1996/Assess:14).

### 3.12 Information on New Developments in the Seasonal and Area Distribution of the Total Norwegian Spring-Spawning Stock

A planning group meeting was held in Bergen in February 1997 (ICES CM 1997/H:3) to plan and co-ordinate surveys under the auspices of ICES, on Norwegian spring-spawning herring in spring and summer 1997. An evaluation meeting for these surveys will be held in Reykjavik on 20-22 August 1997 (Chairman: Hjalmar Vilhjalmsson, Iceland).

All new information on the distribution and migration, based on surveys and fisheries, of the Norwegian springspawning herring will be included in the report from the meeting. The report will be presented to the ICES Annual Science Conference in 1997, and will be made available to the ACFM November 1997 meeting.

## 4 BARENTS SEA CAPELIN

### 4.1 Regulation of the Barents Sea Capelin Fishery

Since 1979, the Barents Sea capelin fishery has been regulated by a bilateral fishery management agreement between USSR (now Russia) and Norway. A TAC has been set separately for the winter fishery and for the autumn fishery. The fishery was closed from 1 May to 15 August until 1984. During the period 1984 to 1986, the fishery was closed from 1 May to 1 September. From the autumn of 1986 to the winter of 1991, no fishery took place. The fishery was re-opened in the winter season 1991, on a recovered stock. From the autumn 1993 the fishery was again closed. A minimum landing size of 11 cm has been in force for several years.

### 4.2 Catch Statistics

The international catch by country and season in the years 1965-1996 is given in Table 4.2.1. Following the recommendation from ACFM, there was no fishing for Barents Sea capelin during 1996.

### 4.3 Stock Size Estimates

### 4.3.1 Larval and 0-group estimates

Norwegian larval surveys based on Gulf III plankton samples have been carried out in June each year since 1981. The estimated total number of larvae is shown in Table 4.3.1. These larval abundance estimates do not show a high correlation with year class strength at age one, but are probably reflecting the amount of larvae produced in each year (Gundersen \& Gjøsæter, in press). An exception is the year 1986, when no larvae were found, probably because the spawning took place so late that the eggs hatched after the survey were carried out. Also in later
years some spawning is known to have taken place during the summer, and offspring from this spawning is not reflected in the larval abundance estimates in Table 4.3.1. The estimate at 2.4 thousand billion in 1996 shows that a sufficiently high number of larvae has been produced to give rise to a year class of intermediate strength. During the international 0-group surveys in August an area based index for the amount of 0-group capelin is calculated (Table 4.3.1). Gundersen \& Gjøsæter (in press) found these indices to be well correlated ( $\mathrm{r}^{2}=0.75$ ) with the 1 -group acoustic estimates obtained at the annual acoustic capelin surveys in autumn. Based on the regression they presented, the 0 -group index obtained in 1996 of 291 should correspond to a year class strength of 153 billion one-year-olds in autumn 1997.

### 4.3.2 Acoustic stock size estimates in 1996

The 1996 acoustic survey was carried out jointly by two Russian and two Norwegian vessels in the period 12 September to 2 October. The results from the survey are given in Table 4.3.2, and are compared to previous years results in Table 4.3.3. The stock size was estimated at 500,000 tonnes, and was dominated by the 1995 year class (one-year-olds) which constituted about $85 \%$ by numbers and $47 \%$ by weight. The older age groups are not very numerous, but the individual growth in weight was the highest on record. About half of the stock biomass consists of maturing fish, and the stock is, therefore, well below the limit reference point of 500,000 tonnes.

### 4.3.3 Historical stock development

An overview of the development of the Barents Sea capelin stock in the period 1986-1996 is given in Tables 4.3.4-4.3.13. The methods and assumptions used for constructing the tables were explained in Appendix A to ICES (1995/Assess:9). In that report, the complete time series back to 1973 also can be found. However, this year, some of the methods and assumptions used are slightly changed, and these changes are described in the working document "Updated tables for the historic development of Barents Sea Capelin based on the spreadsheet model "Capstock" by H. Gjøsæter to the present Working Group meeting. These changes for the most part have only small effects on the calculated quantities. It should be noted that several of the assumptions and parameter values used in constructing these tables are provisional and future research may alter some of the tables considerably. For instance, M-values for immature capelin will be calculated using new estimates of the length at maturity and M -values for mature capelin will be calculated taking the predation by cod into account. However, for giving a crude overview of the development of the Barents Sea capelin stock the tables may be adequate.

Estimates of stock in number by age group and total biomass for the period are shown in Table 4.3.4. Catch in number by age group and total landings are shown for the spring season and the autumn season in Tables 4.3.5 and 4.3.6. Fishing mortality coefficients by age group for the autumn season and natural mortality coefficients by age group for immature and mature capelin are shown in Tables 4.3.7 and 4.3.8. Stock size at 1 January in numbers by age group and total biomass and the mean weight by age group at 1 January are shown in Tables 4.3.9 and 4.3.10. Proportion of mature stock by age group at 1 January and spawning stock biomass at 1 April are shown in Tables 4.3.11 and 4.3.12. Table 4.3.13 gives an aggregated summary.

### 4.3.4 Stock-recruitment relationship

Based on the estimated spawning stock size and recruitment (at age one) included in the stock summary table (Table 4.3.13) a stock-recruitment plot was constructed including data from the years 1973 to 1995 (Figure 4.3.1). The SSB at 1 April is forecasted from the acoustic estimate of capelin larger than 14.0 cm length in the previous autumn ( 1 October), subtracting catches of capelin larger than 14 cm from 1 October to 31 December and the total catches 1 January to 1 April, and reducing with estimated natural mortality coefficients for each age group over the period 1 October to 1 April. The Ms are estimated from the reduction in number in age group $i 1$ October in year $j$ to age group $i+1$ at 1 October in year $j+1$ (ref. Table 4.3.8). The number of recruits are the estimated number of one-year-olds at 1 August. These numbers are back-calculated from the acoustic estimate of this age group at 1 October, adding catches (if any) in the period 1 August to 1 October. Before 1980, the onegroup was seriously underestimated during the acoustic survey, due to incomplete coverage of the areas where this age group is normally found. In these years, the number of recruits (one-year-olds at 1 August) were backcalculated from the acoustic estimate of the two-year olds, compensating for catches and natural mortality in the 14 months from 1 August year $i$ to 1 October year $i+1$. The estimated SSBs and Rs are, therefore, affected by the uncertainty in the acoustic estimates of the various age groups, the uncertainty in the number of individuals removed by natural mortality, and the uncertainty in the number of individuals caught. Of these sources of error, the last one is probably insignificant compared to the other two.

A Beverton-Holt model $R=\frac{S \cdot R_{\max }}{S+S_{1 / 2}}$ and a Ricker model $R=\alpha S e^{-\beta S}$ was fitted to the data. The parameters of the Beverton-Holt model were: $\mathrm{R}_{\max }=804$ (billions) and $\mathrm{S}_{1 / 2}=98.7$, while the parameters of the Ricker model were: $\alpha=5.2$ and $\beta=0.0018$. Which model to choose is open for discussion, but the traditional interpretation of the Ricker curve; that a too large spawning stock hampers recruitment because of cannibalism is not feasible for capelin, since the spawning stock is removed by natural mortality irrespective of size before such a mechanism could affect the recruitment. The Beverton-Holt model, where the recruitment rises towards an asymptote for increasing spawning stock size seems more appropriate on theoretical grounds, and seems to fit the present data quite well (Figure 4.3.1).

See Section 7.1.3 for a discussion of the implications of the presence of herring in the Barents Sea for the recruitment of capelin. It is concluded there that a realistic model for the recruitment of capelin has to take account of the presence of herring. When one year old and older herring is present in significant amount in the Barents Sea in June (more than 2-3 hundred thousand tonnes), the capelin recruitment will probably fail completely. The only exception is when there is an insignificant overlap of capelin larvae and herring, e.g. because the herring is concentrated in a small area compared to the capelin larvae.

### 4.4 Sampling

No fishing took place on the Barents Sea capelin in 1996, and consequently no samples from commercial vessels have been obtained. The sampling from scientific surveys is summarised below:

| Investigation | No. of samples | Length measurements | Aged individuals |
| :--- | ---: | ---: | ---: |
| Acoustic survey 1996 <br> (Norway) | 90 | 4967 | 2013 |
| Acoustic survey 1996 <br> (Russia) | 16 | 3389 | 753 |
| Norwegian bottom trawl <br> survey winter 1997 | 162 | 4619 | 889 |
| Russian investigations <br> winter 1997 | 4 | 400 | 400 |

### 4.5 Management Considerations

Since the assessment of the stock is directly based on the acoustic survey conducted annually in SeptemberOctober, and the main fishing season is from January to March, advice for this stock must be given during the autumn ACFM meeting and the TAC set by the Mixed Norwegian-Russian Fishery Commission during its meeting in November-December. As previously decided by the Northern Pelagic and Blue Whiting Fisheries Working Group, the assessment of Barents Sea capelin is left to the parties responsible for the autumn survey, i.e. IMR in Bergen and PINRO in Murmansk, who will report directly to ACFM before its autumn 1997 meeting.

Previously, a harvesting strategy of aiming at a spawning stock size of at least 500,000 tonnes was used for the Barents Sea capelin. The Working Group is of the opinion that this strategy should be considered, to have a firm basis for a TAC advice when the stock rebuilds, probably in the near future. Work will be initiated at the IMR, Bergen, to revise the models previously used, and to establish harvesting control rules based on the precautionary approach. This work will be followed up by correspondence by the Working Group, with aim to have procedures approved by the Working Group before the capelin survey and assessment meeting in September-October.

## 5 CAPELIN IN THE ICELAND-EAST GREENLAND-JAN MAYEN AREA

### 5.1 The Fishery

### 5.1.1 Regulation of the fishery

The fishery depends mostly upon maturing capelin, i.e. that part of each year class which spawns at age 3 as well as those fish at age 4, which did not reach maturity to spawn at age 3 . The abundance of the immature
components is difficult to assess before their recruitment to the adult stock at ages 2 and 3 . This is especially true of the age 3 immatures.

The fishery of the Iceland-East Greenland-Jan Mayen capelin has, therefore, been regulated by precautionary catch quotas set prior to each fishing season (July-March). Predictions of TACs have been computed based on data from surveys of the abundance of immature 1 and 2 year old capelin, carried out in the autumn of the year before. The process includes historical relationships between such data and the backcalculated abundance of the same year classes, an average growth rate and natural mortality and the provision of a remaining spawning stock of $400,000 \mathrm{t}$. Final catch quotas for each season have then been set in accordance with the results of acoustic surveys of the maturing, fishable stock abundance, carried out in autumn (October-November) and/or winter (January/February) in that fishing season. A more detailed description of the method is given in Section 5.5.1. A summary of the results of this catch regulation procedure is given in Table 5.1.1.

Over the years, fishing has not been permitted during April-June and the season opened in July/August or later, depending on the state of the stock. Due to very low stock abundance there was a fishing ban lasting from December 1981 to November 1983. In addition, areas with high abundance of juvenile 1- and 2-group capelin (in the shelf region off NW-, N - and NE-Iceland) have usually been closed to the summer and autumn fishery.

### 5.1.2 The fishery in the $1996 / 1997$ season

In accordance with a previously determined procedure, ACFM recommended a precautionary TAC of $1,100,000$ t which would not exceed $2 / 3$ of the total TAC predicted for the season, i.e. $1,600,000 \mathrm{t}$. This advice was accepted by all parties concerned.

The season opened on 1 July with Icelandic, Norwegian and Faroese vessels taking good catches in the deep water area near the boundary between the EEZ of Iceland, Greenland and Jan Mayen. Catch rates remained high during July and the first half of August but declined after that. In this period most of the catch was taken in the area between $68^{\circ} \mathrm{N}$ and $70^{\circ} \mathrm{N}$ between about $14^{\circ} \mathrm{W}$ and the Greenland shelf.

After about mid-August catch rates declined and remained comparatively low throughout September. On returning to the shelf area north and northeast of Iceland from the summer feeding grounds farther north, the maturing capelin mixed with the immature part of the stock. Furthermore, the adults soon scattered and only occasionally aggregated in fishable concentrations during October-December.

The total catch in the 1996 summer and autumn season amounted to almost $775,000 \mathrm{t}$, of which about $80 \%$ were taken in July and August. There were no problems due to undersized immatures in the 1996 summer fishery in the northern cold water area. However, the situation was reversed in late autumn and winter when parts of the shelf area north of Iceland had to be temporarily closed to the fishery in order to protect the immature stock.

The capelin remained in scattered concentrations east of Iceland for the most part of January 1997. The monthly catch amounted to about $60,000 \mathrm{t}$, almost half of which were taken by a few boats operating with pelagic trawls.

An intense fishery began in the first days of February in shallow waters off the eastern south coast of Iceland. In spite of stormy periods, catch rates remained high throughout the month and a record catch of just over $460,000 \mathrm{t}$ was taken by the Icelandic fleet. Bad weather also disrupted fishing in March, the Icelandic catch during this last month of the season amounting to $255,000 \mathrm{t}$.

Thus, in spite of the scattered condition of the fishable stock in January and the weather constraints during March, a record catch of just under $775,000 \mathrm{t}$ was taken by Icelandic vessels during the 1997 winter season. In addition, some 22,000 t were taken by vessels from the Faroes and Greenland, mainly in February and March.

### 5.2 Catch Statistics

The total annual catch of capelin in the Iceland-East Greenland-Jan Mayen area since 1964 is given by weight, season and fleet in Table 5.2.1.

The total catch in numbers during the summer/autumn 1978-1996 and winter 1979-1997 seasons is given by age and years in Tables 5.2.2 and 5.2.3 respectively.

The distribution of the catch during the summer-autumn 1996 and winter 1997 seasons is given by size groups at age in Tables 5.2.4 and 5.2.5.

### 5.3 Surveys of Stock Abundance

### 5.3.1 0-group surveys

The distribution and abundance of 0-group capelin in the Iceland-Greenland-Jan Mayen area has been recorded during surveys carried out in August since 1970. The resulting abundance indices, divided according to areas, are given in Table 5.3.1.

An acoustic estimate of the abundance of age 1 capelin has also been obtained during the August 0 -group surveys. Their abundance by number, mean length and weight are given for the period 1982-1996 in Table 5.3.2.

### 5.3.2 Stock abundance in autumn 1996

An acoustic survey was carried out in the period 27 October-12 November 1996 (Working Document by Hjalmar Vilhjalmsson). The distribution of the stock was wide and continuous, reaching from $27^{\circ} \mathrm{W}$, northwest of the NW-peninsula of Iceland, across the outer part of the northern shelf to $10^{\circ} 30^{\prime} \mathrm{W}$ off the northern and central east coast. The largest and most dense capelin concentrations were recorded near the shelf edge off the western and central north coast and northeast of Iceland.

In practical terms, the October/November 1996 survey was not constrained by drift ice and weather conditions were unusually good. There was little interference by aeration or sea swell in any part of the survey area and necessary adjustments for reductions of echo intensity for these reasons were minimal. However, in most areas the recordings consisted of a mixture of mature and immature fish, the ratio of which it was often difficult to determine. Furthermore, the coverage of the shelf area east of Iceland was probably inadequate with respect to the immature part of the stock.

According to the autumn 1996 survey the immature stock component amounted to 111.2 and $16.9 * 10^{9}$ fish, belonging to age groups 1 and 2 respectively. The estimated fishable/spawning stock abundance was $86.4 * 10^{9}$ fish in mid-November 1996. The observed mean weight in the fishable stock was 16.6 g and the fishable/spawning stock biomass, therefore, about $1,435,000 \mathrm{t}$.

Details of this stock estimate are given in Table 5.3.3.

### 5.4 Historical Stock Abundance

The historical estimates of stock abundance are based on the "best" acoustic estimates of the abundance of maturing capelin in autumn and/or winter surveys, the "best" in each case being defined as that estimate on which the final decision on TAC was based. Taking account of the catch in number and a monthly natural mortality rate of $M=0.035$ (ICES 1991/Assess:17) the abundance estimates of each age group are then projected to the appropriate point in time. Since natural mortality rates of juvenile capelin are not known, their abundance by number has been projected using the same natural mortality rate.

The annual abundance by number and weight at age for mature and immature capelin in the Iceland-East Greenland-Jan Mayen area has been calculated with reference to 1 August (before the fishing season) and 1 January of the following year for the 1978/79-1996/97 seasons. The results are given in Tables 5.4.1 and 5.4.2 (1 August and 1 January, respectively). Table 5.4.2 also gives the remaining spawning stock by number and biomass in March/April 1979-1997.

The observed annual mean weight at age was used to calculate the stock biomass on 1 January. With the exception of juvenile capelin, which are surveyed in summer, the historical average growth pattern was used to estimate stock biomass of the maturing components on 1 August from mean weights observed in the autumn of the same year or in January of the following year. The remaining spawning stock biomass is calculated from mean weights in January of the same year. Because there is a small weight increase among mature capelin in February and March, the remaining spawning stock biomass is slightly underestimated.

### 5.5.1 Methods

The precautionary TAC should be set at such a level as to open the fishery before the October/November survey, yet keep it closed when it is likely that fishing will reduce the residual spawning stock below 400,000 tonnes. Thus the prognosis procedure needs to predict the fishable stock in the beginning of the season in order to predict the effects of fishing. To account for the highly variable year class strength and maturing ratio, the procedure needs to predict separately the two major components of the mature stock (age groups 2 and 3). These predictions need to be done in spring.

Available data include acoustic survey estimates of the different age groups in August, October and January. However, the August survey results, used for a number of years in order to predict age 2 recruits by number, have proven unreliable. This has become apparent by comparing these predictions to later assessments of the same stock components. On the other hand, it has been found that autumn (October/November) acoustic estimates of the abundance of age groups 1 and 2 are more reliable predictors of fishable stock abundance about 8 months prior to the fishery.

The maturing part of age group 2 in summer $\left(\mathrm{N}_{2 \mathrm{mat}}\right)$ is a part of the survivors of the 1 -group of the previous autumn $\left(N_{1}\right)$, which is measured in October. A prediction model was developed (ICES 1993/Assess:6), based on a linear relationship between the historic back-calculated abundance of maturing capelin at age group $2\left(\mathrm{~N}_{2 \text { mat }}\right)$ and the autumn acoustic estimates of the same year classes at age $1\left(\mathrm{~N}_{1}\right)$. This relationship was then used to predict the adult 2-group abundance at the beginning of the fishing season some 8 months later.

The maturing part of the 3-group in summer corresponds to the surviving part of the year class which did not mature and spawn in the year before. Unfortunately, the surveys of the immature capelin of age $2\left(\mathrm{~N}_{2 \mathrm{imm}}\right)$ in the year before have usually been gross underestimates and, therefore, have not been used. Similarly, the January survey of this year class only estimates the part which will spawn and thus is no indication of what will appear in summer of next year.

In general terms, however, maturity at age 2 is inversely related to year class size $\left(\mathrm{N}_{2 \text { tot }}\right)$ i.e. the maturing ratio is a function of year class abundance. Therefore, the total abundance of age group 2 in autumn should be an indication of what will appear as 3-group in the following season. Since 1993, a regression relating the backcalculated total abundance of year classes at age 2 to their abundance at age 3 year ( $\mathrm{N}_{2 \text { tot }}$ and $\mathrm{N}_{3 \text { tot }}$, respectively) has been used for predicting the abundance of age 3 capelin.

The data sets comprising all comparisons of numbers by age and maturity, relevant to this prediction model, are given in Table 5.5.1. The mean weight of maturing 2- and 3-group capelin in autumn 1981-1996 (year classes 1978-1994) is given in Table 5.5.2. The above regressions have been updated as new data became available. A comparison of the predicted TAC updated with data from the autumn surveys is given in Table 5.5.3.

### 5.5.2 Stock prognosis and TAC in the 1996/1997 season

The 1993 model for predicting the number of maturing capelin of age 2 from the autumn 1995 acoustic assessment of the 1994 year class gave an estimate of 122.4 billion maturing 2-group fish on 1 August 1996. This is about $30 \%$ higher than the highest recruitment of mature 2-group capelin in the 1979-1995 series.

In view of this and the probable lower maturation rate for large year classes, a curved relationship might be expected to provide a better estimate of recruitment for large year classes. However, the data series are as yet inadequate for determining the exact shape of such a curve. Therefore, the Working Group recommended the continued use of the relationship established in 1993, but with an upper limit near the highest recruitment actually observed. The observed largest numbers of maturing 2-group recruits are 86.9 and 95.7 billion fish, belonging to the 1991 and 1993 year classes respectively. Therefore, the Working Group agreed to set the predictive figure at 90 billion individuals.

The unusually high abundance of immature 2-group capelin (1993 year class), recorded during the autumn 1995 acoustic survey would, when added to the maturing part of that year class, also have resulted in a predicted abundance of maturing 3-group capelin far outside the range previously observed. However, since it was quite obvious from the autumn 1995 acoustic estimate that there will be a fairly large contribution by the 1993 year
class to the fishable/spawning stock of 1996/97, the Working Group agreed that in such cases the most reasonable procedure would be a projection of the autumn acoustic estimate of the age 2 immature component by number to 1 August of the following year. A projection of the estimated abundance of immature capelin of the 1993 year class (Table 5.5 .3 ) yielded 35.0 billion maturing capelin of the 1993 year class when projected to 1 August 1996, assuming a monthly $\mathrm{M}=0.035$.

The fishable stock biomass, obtained by multiplying the stock in number thus predicted by the average mean weight of maturing capelin in autumn, was then projected forward to spawning time in March 1997 with the assumption of a monthly mortality rate of $\mathrm{M}=0.035$ and the constraint of a remaining spawning stock of 400,000 tonnes. This gave a predicted TAC of $1,635,000$ tonnes if spread evenly over the time August 1996-March 1997 (Table 5.5.3). Using the same approach as in previous years, i.e. that the precautionary TAC be set at approximately $2 / 3$ of the predicted total for the season, the Working Group recommended that a preliminary TAC for the 1996/97 capelin fishery be set at $1,100,000 \mathrm{t}$.

According to the autumn 1996 survey the estimated fishable/spawning stock was $86.5 * 10^{9}$ fish in midNovember 1996. At that time the observed mean weight in the fishable stock was 16.6 g and the stock biomass therefore about $1,435,000 \mathrm{t}$. With the usual prerequisite of a monthly natural mortality rate of 0.035 , a remaining spawning stock of $400,000 \mathrm{t}$ and an estimated weight increase of 2.6 g the above abundance estimate indicated a TAC of $1,010,000 \mathrm{t}$ in the period mid-November 1996-March 1997 if the catch were spread evenly over the period. Counting the catch taken in July-October 1996, this corresponded to a total TAC of some 1,700,000 t for all of the 1996/97 season. However, due to the uncertainty of the estimate, described in section 5.3.2, and the large catch still to be taken it was decided to set the TAC at $1,600,000 \mathrm{t}$, i.e. at the level originally predicted.

### 5.5.3 Stock prognosis and assessment for the 1997/1998 season

Calculations of expected TAC for the 1997/1998 season, based on the method described in Section 5.5.1 and data from Table 5.5.1, were used for predicting the abundance by number of maturing capelin of ages 2 and 3 on 1 August 1997. An updated linear regression of the measured abundance of 1-group capelin $\left(\mathrm{N}_{1}\right)$ on the backcalculated abundance of mature 2-group fish $\left(N_{2 \text { mat }}\right)$ gives $y=0.58 x+19.1 ; R^{2}=0.81, p<0.05$. Similarly for the older stock component, where $\mathrm{N}_{2 \text { tot }}$ is regressed on $\mathrm{N}_{3 \text { mat }}$, gives $\mathrm{y}=0.34 \mathrm{x}-9.4 ; \mathrm{R}^{2}=0.63, \mathrm{p}<0.05$. The values used to predict the abundance of the 1995 and 1994 year classes are given in Table 5.5.1. This gave an estimate of 83.8 and 30.9 billion mature fish, belonging to the 1995 and 1994 year classes respectively.

Since 1989 there has been a general downward trend in weight at age of adult capelin, apparently inversely related to adult stock abundance in number (Figure 5.5.1). Plotting these pairs of data as simple linear regressions results in $\mathrm{R}^{2}=0.72$ and 0.83 for age groups 2 and 3 respectively. Applying the appropriate regression equations, $y=-0.027 x+18.8$ for the younger component and $y=-0.059 x+28.4$ for the older one and using the predicted abundance of age groups 2 and 3 on 1 August 1997 combined, i.e. $114.7 * 10^{9}$ fish, resulted in estimated mean weights of 15.7 and 21.6 g for age groups 2 and 3 respectively.

Using the predicted mean weight of maturing capelin in autumn instead of the average mean weight, results in a predicted TAC of $1,265,000 \mathrm{t}$ if spread evenly over the period July 1997-March 1998. This corresponds to a precautionary TAC of about $850,000 \mathrm{t}$. As in previous years, decisions on the final TAC for the 1997/98 season should be based on surveys carried out in October/November 1997 and/or January/February 1998.

### 5.5.4 Management of capelin in the Iceland-Greenland-Jan Mayen area

The fishable stock consists of only 2 age groups ( 2 and 3 year olds, spawning at ages 3 and 4). The fishing season usually begins in July and ends in March of the following year when the remainder of the fishable stock spawns and dies. The fishable stock (= spawning stock) is thus renewed annually and its exploitation must of necessity be cautious. Due to the short life span and high spawning mortality, stock abundance can only be assessed by acoustics.

Since 1992, the key elements in the management of capelin in the Iceland-Greenland-Jan Mayen area have been as follows:

Acoustic survey estimates of juvenile capelin abundance have been used to predict fishable stock abundance by number in the following year (fishing season). Historical average mean weight at age, growth rates and natural mortality have been used for calculations and projections of spawning and fishable stock biomass.

Based on the data described above, a prediction of TAC is made in spring of the year in which the season begins, allowing for $400,000 \mathrm{t}$ remaining to spawn at the end of the season. For precautionary purposes, a preliminary TAC, corresponding to approximately $2 / 3$ of the predicted total TAC for the season, has then been allocated to the period July-December. With regard to a precautionary approach, the working group stresses the importance of setting a preliminary TAC for the first half of the season.

The preliminary TAC is near the lower $95 \%$ confidence limit of the TAC prediction for the whole season (JulyMarch). The final decisions on TACs for each fishing season have been based on the results of acoustic stock abundance surveys in late autumn or in January of the following year during that season.

The procedure just described has worked well in the past for "normal" ranges of stock abundance. However, it is clear that an extra care should be taken when dealing with stock abundance below or above the norm, corresponding to TACs $<500,000$ or $>1,500,000$ tonnes.

### 5.6 Special Comments

As in previous years, the Working Group recommends that measures be taken to prevent the fishing on concentrations of juvenile capelin which have only in part used their natural growth potential.

An overview of stock developments during 1978-1996 is given in Table 5.6.1.

### 5.7 Sampling

| Investigation | No. of <br> samples | Length meas. <br> individuals | Aged <br> individuals |
| :--- | ---: | ---: | ---: |
| Fishery 1996 | 111 | 13043 | 3636 |
| Survey 1996 | 127 | 11450 | 11419 |
| Fishery 1997 | 46 | 4550 | 4523 |
| Survey 1997 | 24 | 2400 | 2385 |

## 6 BLUE WHITING

### 6.1 Stock Identity and Stock Separation

This topic has been dealt with in previous Working Group reports, and in 1994 the two stocks, i.e. the northern one and the southern one, have been treated as one for the assessment purpose (ICES 1996/Assess:14). In 1995 it was stated that several populations of blue whiting could appear in the spawning area, but preliminary analysis did not show any genetic substructure among the blue whiting from west of the British Isles to Gibraltar. The study has continued in an EU-project and further analysis indicated two main components in the spawning area. The location of a separation line has, however, not been defined, but the genetic analysis on samples from the spawning area will be intensified in the coming years (J. Mork, pers. comm.).

In a paper by Skogen et al. (in press) the existence of a possible separation line between a northern and a southern stock is tested by use of a Lagrangian water transport model in connection with a hydrodynamic circulation model. The hypothesis is that the separation could be explained from drift patterns of the larvae in such a way that the northern stock larvae tend to drift northwards and the southern ones southwards. After running the models for 20 years (1976-1995) with the particles assumed to be blue whiting larvae, the result of the modelled drift found a separation line north of the Porcupine Bank. However, the line shows a large interannual variability indicating a mix between the two stocks.

### 6.2 Fisheries in 1996

Estimates of the total landings of blue whiting in 1996 from various fisheries by countries are given in Tables $6.2 .2-5$ and are summarised in Table 6.2.1. The total landings from all blue whiting fisheries in 1996 were 637,825 tonnes, which is $10 \%$ more than in 1995.

The majority of the blue whiting catches was taken in the spawning area and consisted of about 470,000 tonnes. The landings in 1996 from the directed fisheries increased by $9 \%$ from 1995 and the landings from the mixed
industrial fishery, which took place mainly in the Norwegian Trench, increased by $13 \%$. Landings in this area increased by a factor of 4 times between 1994 and 1996. The strong 1995 and 1996 year classes were the basis for this fishery, making up 33 and 53\% in numbers respectively of the landings in 1996.

Landings from the southern fisheries (Spain and Portugal) were 25,099 tonnes which was $10 \%$ less than in 1995.

### 6.3 Biological Characteristics

### 6.3.1 Length composition of catches

Data on length compositions of the 1996 commercial catches of the blue whiting stock by ICES divisions and quarters were presented by Norway, Russia, Spain, Portugal, The Netherlands and Denmark (Tables 6.3.1-6.3.6). The lengths of the blue whiting varied over season and areas.

The majority of the fishes from the directed fishery had the length range from $27-33 \mathrm{~cm}$. Nevertheless the Russian catches consisted mostly of fish with length from $16-22 \mathrm{~cm}$ (due to wintering fishery in the area southeast of Faroes). The modal length of the fish from the mixed industrial fishery was 19 cm .

Spain and Portugal caught blue whiting with modal length at 21 cm .

### 6.3.2 Age composition of catches

For the directed fisheries in the northern area in 1996, age compositions were provided by Norway and Russia, which together accounted for $88 \%$ of the catches. Appropriate Russian age compositions of catches were used for the catches of Estonia, and Norwegian age compositions used to allocate the landings of all the other countries into catch in numbers by age groups. For Denmark and The Netherlands the age-length keys were used on their own length distributions. the age composition in the directed fishery is given in Table 6.3.7.

Age compositions for the mixed industrial fisheries in 1996 were provided by only Norway, which represented $48 \%$ of the catches, and its age compositions were used for allocation of the other nations catches. The by-catch of blue whiting in the Faroes fisheries of Norway pout, was estimated by use of corresponding Norwegian bycatch data (Table 6.3.8).

Spanish age-length keys were used to derive catch-at age data for Portuguese and Spanish landings in the Southern area (Table 6.3.9).

The combined age composition for the directed fishery in the spawning area and in the Norwegian Sea, as well as the total by-catch of blue whiting in the mixed industrial fisheries, and for the landings in the southern area, were assumed to give the overall age composition of the total landings from the blue whiting stock. The number at age group as used in the VPA run are given in Table 6.3.10.

### 6.3.3 Weight at age

Data on mean weight at age were available from Russia, Norway and Spain. Landings from other countries were assumed to have the same mean weight at age as the sampled catches. Table 6.3 .11 shows the mean weight-at-age for the total catch from 1981-1996 as used in the VPA run. The weight in the stock was assumed to be the same as in the catch.

### 6.3.4 Maturity at age

As was the case in the last year, the same maturity at age, given in Table 6.5 .1 for input data for prediction, was used in the VPA run for all years. The values are obtained by combining the maturity ogive from the southern and from the northern areas, weighted by catch in numbers at age (ICES 1995/Assess:7).

### 6.4.1 Acoustic

### 6.4.1.1 Surveys in the spawning season

1996
The results of the sixth joint Norwegian-Russian acoustic surveys carried out in March/April in the spawning area west of the British Isles, were presented in last years report as well as the results of two Norwegian surveys in the Norwegian Sea in March and April 1996 (ICES 1996/Assess:14).

In addition Spain carried out an acoustic survey in the Bay of Biscay in March/April (Carrera and Meixide 1997). The R.V. "Cornide de Saavedra" made two coverages along the shelf edge off northern Spain and south-western of France (Divisions VIIa,b,c), from 21-29 March and 7-13 April respectively, to study the movement of blue whiting in the Bay of Biscay.

The recordings were made by use of a 38 kHz echo sounder. The population structure found in 1996 was different from 1994, and the 1 and 2 year olds represented up to $95 \%$ of the recorded population. The decrease in number of fish from the first to the second coverage was also accompanied with a change in the population structure. The decrease of 2 year olds off France and 1 year olds off Spain from the first to the second coverage without an increase in other surveyed areas, suggests that a postspawning migration is unlikely. It seems that the southwards postspawning migration from the Porcupine Bank area is undertaken by only a few young specimens (mainly 2 and 3 groups) and is moderate compared to the observed northwards postspawning migration (Monstad et al. 1996).

## 1997

Neither Norway nor Russia carried out their traditional acoustic spring surveys in the spawning area west of the British Isles. These have taken place in most years since the beginning of the 1970s, and as formally joint surveys since 1990.

In the Bay of Biscay Spain carried out an acoustic survey in April 1997, but no results were available at the meeting.

### 6.4.1.2 Surveys in the feeding season

Within the Norwegian Sea programme "Mare Cognitum" and during the international surveys for herring investigation in the Norwegian Sea, blue whiting was recorded by several vessels during summer 1996. The recorded concentrations, however, were rather scattered for most of the surveys, and within limited areas.

From the recordings of the Norwegian survey by R.V. "G.O. Sars" from 19 July-15 August, an acoustic assessment of the blue whiting concentrations was made (Monstad 1997). The area from the Norwegian coast westwards to $3^{\circ} \mathrm{W}$ between $62^{\circ}$ and $72^{\circ} \mathrm{N}$ was surveyed (Figure 6.4.1) using the BEI system (Bergen Echo Integrator) connected to a 38 kzH echo sounder.

Scattered recordings of blue whiting were made throughout the area surveyed, and the distribution and relative abundance are given in Figure 6.4.2. The concentrations were highest in the continental shelf area, although the distribution occurred into the Norwegian Sea.

The biomass was estimated at 1.7 mill tonnes, the same as estimated during summer in 1993 and in 1995 within approximately the same area. However, the abundance was much higher this year at $27.9 \times 10^{9}$ compared to 15.6 x $10^{9}$ last year. This was due to the high number of one year olds (1995 year class), and thus confirmed earlier observations that this is a very rich year class.

Age and length distributions are shown in Figures 6.4.3 and 6.4.4 for different sub-area and for the total respectively, clearly demonstrating the young fish being near the Norwegian coast and the bigger and older ones more over deep water areas. The 1995 year class contribution with $84 \%$ in numbers.

During the Russian survey with R.V. "Fridtjof Nansen" from 12 June-11 July, (Figure 6.4.5) the blue whiting recordings were also acoustically assessed (Krysov and Ushakov 1997), using a 38 kHz echo sounder connected to a Sigran G integrator. Blue whiting was found distributed over most of the area surveyed area, with the main concentrations to the south of $65^{\circ} \mathrm{N}$ and eastwards from $6^{\circ} \mathrm{W}$ (Figure 6.4.6). The recordings were mainly as scattered layers in various depths from 150-300m. The 1 year old (1995 year class) dominated in most of the trawl station catches of blue whiting. Older and larger fish was found only in the north-western part of the surveyed area, where 6 and 7 year olds prevailed. The total biomass was estimated at 5.6 mill. tonnes or 48.8 x $10^{9}$ individuals.

### 6.4.1.3 Discussion

The biomass estimates of blue whiting in the spawning area since 1983 are given in Table 6.4.1 with the corresponding spawning stock sizes in brackets.

As mentioned in previous reports the differences in the estimates may be caused by differences in acoustic equipment, weather conditions during the surveys, size of the area surveyed and timing of the surveys with respect to spawning progression and hence the congregation of various parts the stock.

In the spawning area the rich 1989 year class was abundant, even as 1 year olds, and contributed significantly to the catches. Up to 1996 the blue whiting fishery was based on this year class to a great extent. In 1996 the rich 1995 year class (ICES 1996/Assess:14) was found to be abundant in the area to the west of the British Isles, especially in the northern and the southern part. This year class recruited significantly as 0 -group to the catches in the mixed industrial fishery, and in spring 1997 also recruited to the fishery in the spawning area. Because the spawning area was not surveyed in 1997, information on this year class at age 2 is available only from the fishery.

The biomass estimate per rectangle is shown in Figure 6.4.7, combined for the Spanish ( 0.4 mill. tonnes) and the Norwegian surveys ( 5.1 mill tonnes) in spring 1996. It demonstrates the blue whiting distribution along the shelf edge area from The Faroes to the northern coast of Spain. The gap in the recordings in the mid area is due to lack of cruise tracks.

As reported to the Working Group last year the 1995 year class was abundant in the Norwegian Sea in March and April 1996. During the summer surveys it was found to dominate in the recorded concentrations, again confirming its high abundance. The Russian acoustic estimate of 5.6 mill tonnes was obtained during an earlier period than the Norwegian estimate of 1.7 mill. tonnes, and also represents a larger distribution area with the highest concentrations found in the eastern part of Faroes waters. However, this is the first time since the early 1980s that blue whiting concentrations have been recorded at the same level in the feeding area during summer as in the spawning area during spring (ICES 1987/Assess:4).

### 6.4.2 Bottom trawl surveys in the southern area

Bottom trawl surveys have been conducted off both the Galician (NW Spain) and Portuguese coast since 1980 and 1979 respectively, following a stratified random sampling design and covering depths down to 500 m . Since 1983, the area covered in the Spanish survey was extended to completely cover the Spanish waters in Division VIIIc. The area covered in the Portuguese survey was also extended in 1989 down to 750 m . depth. Stratified mean catch and standard error in Spanish and Portuguese surveys are shown in Table 6.4.2 and 6.4.3.

### 6.4.3 Catch per unit effort

No CPUE data from the fisheries in the northern area in 1996 were submitted to the Working Group. Figure 6.4.9 in last year's report (ICES 1996/Assess:14) shows the time series of overall aggregated CPUE values across areas in the Norwegian directed blue whiting fishery in the spawning area since 1982, indicating an increase from 1991 to 1993 and then decreasing to 1995 .

Data on CPUE of 1996 from two bottom trawl fleets were submitted by Spain (Galician single and pair trawl) and shown in Figure 6.4.8. The CPUE values have been stable in the 1990s.

### 6.4.4 Virtual population analysis

### 6.4.4.1 Tuning the VPA to survey results

In total the 6 tuning series used by the Working Group to tune the VPA, the same as used in 1995, were two series from the spawning area west of British isles (Norwegian acoustic and Russian acoustic surveys), one series from the acoustic surveys in the Norwegian Sea, two from Spain (bottom trawl survey and CPUE from pair trawlers) and one from the Portuguese survey (bottom trawl). Earlier tests (ICES 1995/Assess:7) had indicated that variations on XSA options did not improve the results. Alternative tuning methods (YC method), and weighted XSA (where the tuning fleets were manually weighted according to the catch proportions in the area were the surveys were conducted) were also done in the past (ICES 1996/Assess:9). All methods gave similar results, showing conflicting trends in some years with the acoustic surveys. Although the inclusion of fleets that covered areas where the juveniles are distributed improved the tuning in the past, and especially the inclusion of the acoustic survey in the Norwegian Sea, this year ages with very high Log catchability residuals were excluded from the analysis. This was the case for ages 0 and for 9 and older in the Norwegian Sea acoustic survey, ages 0 and 1 in the Spanish and Portuguese bottom trawl surveys and in the Spanish Pair trawling fleet. The available tuning data are shown in Table 6.4.4, with the input values framed.

A standard XSA is presented with the tuning diagnostics shown in Table 6.4.5, and the VPA results are given in Tables 6.4.6-6.4.8. The SSB for 1996 came out with 2.2 mill. tonnes compared to 1.6 mill. tonnes from the prediction last year. The rich 1995 year class came out with $25.6 \times 10^{9}$ as 0 group, which is at the same level as the three other rich year classes; 1982, 1983 and 1989.

The Log catchability residuals plots are presented in Figure 6.4.9 a-f, by fleet and by age group. Figure 6.4.10 shows the retrospective analysis of this assessment. In retrospective testing, the analysis appears to perform with reasonable consistency, suggesting that the stock forecast may perform reasonably well. However, as it was noted in last year's report, the apparently high survey variability suggests that the stock assessment may have a low capability to detect changes in stock size or exploitation rates.

### 6.4.4.2 ICA analysis

An ICA-run (Patterson and Melvin 1996) was made (Table 6.4.9) on the input data described in Section 6.4.4.1. The following choices were made during the run:

- Selection on age $10+$ equal to selection on age 5 ;
- All indices of abundance assumed to bear linear relationships to stock size;
- The 0 -group in the catch-at-age data was weighted by 0.1 , the 1 -year-olds by 0.5 , age 2 and older by 1.0 ;
- The index series were evenly weighted;
- No attempt was made to fit a stock-recruitment relationship.

While the rich 1995 year class in the XSA run was estimated at the same level as the rich 1982, 1983 and 1989 year classes (about 25 billions), the 1989 year class in the ICA run was almost double the size of these earlier year classes (about 42 billions). The estimated size of the two latest year classes varies considerably between the two runs. It should be noted that since the 1996 year class is only estimated from the catch-at-age data, and the 1995 year class from catch-at-age and from one index series, these estimates are quite uncertain. The coefficient of variation (CV) of the 1996 year class was $130 \%$ while that of the 1995 year class was $50 \%$.

The spawning stock in 1996 was estimated at 1.6 million tonnes in the ICA-run, compared to 2.2 million tonnes in the XSA-run. The spawning stock estimates show a decreasing trend from 1992 in both runs. Since the Spawning stock estimate is considerably higher in the XSA-run, the estimated average fishing mortality for age three to seven is higher (.46) in the ICA-run compared to the XSA-run (0.31).

### 6.5 Short-Term Prediction

Input data for the prediction are given in Table 6.5.1. The initial stock size at the beginning of 1997 for ages 1 to $10+$ was taken from the VPA results. The recruitment at age 0 in 1997-1999 was set to 14.2 billions, which is the average from 1981-1995. Maturity ogive and natural mortality were the same used in the VPA. Mean weights at age were estimated as the average of the values used in the VPA for the period 1987-1996. The fishing pattern was considered to be the average of the period 1994-1996, rescaled to the level of reference F in 1996.

Usually the basis for prediction has been a TAC constrained based on a projection of the preliminary catch in the first half of the year the prediction starts. Unfortunately, this procedure was not possible this year, due to the early timing of the Working Group meeting. The Norwegian directed fishery up to April this year was notably less compared to same period in 1996. This is due to the fleet being occupied in the herring fishery and to the new system with separate vessel quotas. Norway will probably also take lower catches in the Faroes zone this year. So far this year the Russian fleet has not caught blue whiting in the international zones west of Ireland, as it used to do. On the other hand the rich year classes of 1994-1996 could result in higher total catches as well as promote higher fishing effort from other countries. Due to these considerations the expected catch in 1997 was assumed to be 600,000 tonnes. This is about $6 \%$ lesser than the total catch in 1996, and corresponds approximately to the status quo fishing level in 1996 (F-factor 0.96).

The results of the prediction are shown in Table 6.5.2. The estimated reference fishing mortality in 1997 was 0.31 , at the same level than in 1996. Continuing at this fishing level gives an SSB of 2.4 million tonnes in 1997, 2.7 million tonnes in 1998 and 2.8 million tonnes in 1999.

A suggestion of the MBAL for this stock, taken as the lowest SSB on record ( 1.5 million tonnes) is discussed in Section 6.8.

### 6.6 Medium-Term Projections

Last year's ICA medium-term projection was run, but due to technical problems this could not be done this year. Instead, a deterministic medium-term projection was run (5 years starting in 1997) and with the same input data as in the short-term prediction (Section 6.5) and with a constraint of an annual catch of 650,000 tonnes, as requested by NEAFC. The results are shown in Figure 6.6.1. Both the total stock, the spawning stock and the fishing mortality is seen to be quite stable during the period.

### 6.7 Spatial, Temporal and Zonal Distribution

The available knowledge from various sources on the distribution and the main fishing areas of blue whiting in the northern area have been summarised and presented in previous Working Group Reports (ICES 1985/H:6; 1991/Assess:2; 1995/Assess:7; 1996/Assess:14). During the two acoustic surveys west of the British Isles in spring 1996, blue whiting eggs were extremely numerous in the sampling area to the north of Porcupine Bank (Belikov, pers.comm.) and larvae from this area to the west of St. Kilda (Monstad, 1996). This indicated that the 1996 year class could be a strong one.

During 1995 and 1996 the landings from the mixed industrial fisheries increased significantly, and in 1996 were 4 times larger than in 1994. The total catch in 1996 by numbers and tonnes is shown in Figure 6.7.1. It clearly demonstrates the dominance of the 1995 year class in numbers, while the 1989 year class still dominates the catches in biomass.

In 1996 recordings of blue whiting were at the same level of abundance in the Norwegian Sea during summer (Faroes, Norwegian and international zones) as in the spawning area west of the British Isles during spring (EU zone).

The total international catch of blue whiting from 1978-1996 divided into areas within and beyond national fisheries jurisdiction of NEAFC are presented in Table 6.7.1, as provided by the Working Group members. Due to the increased catches in the mixed industrial fisheries of 1995 and 1996 in the area of the Norwegian Trench, the percentage in this area has increased significantly for the period. Catches of nations not giving zonal information about the fisheries, have been subjectively allocated to the probable appropriate zones.

Assembling of historical (1979-1995) blue whiting data from 7 countries' trawl catches in the area from Gibraltar to The Faroes has been done within the EU AIR Sefos-project (Monstad et al. 1996b). Length data from France, Spain, The Netherlands, Portugal, Scotland, Norway and Germany were mapped by age groups, using Norwegian keys for the northern area and Spanish keys for the southern area. Most of the data came from bottom trawl stations and hence represent the on-shelf part of the stock, i.e. mainly younger age groups, while the data from west of the British Isles during spring are from pelagic trawl stations and represent the oceanic part of the stock which are both young and older age groups. In Figures 6.7.2-6.7.4 the 1995 results are presented as an example, showing the appearance of blue whiting along the shelf edge from South-Portugal to the Norwegian Sea and in the North Sea.

The number of stations is highest in the south, and hence blue whiting seem to be more frequent there. However, when blue whiting are caught in the north, especially in the 1st half of each year, the numbers are in most cases significantly higher than in the south.

The migratory behaviour causes the appearance of blue whiting in the northern area, i.e. west of the British Isles, during spring when the mature part congregates there to spawn. In the 2 nd half of each year the stock has returned to the feeding grounds, either northwards or southwards, and the majority of the larvae and later the 0groups have likewise drifted northwards or southwards.

The area from the Channel to Gibraltar is a nursery area containing the majority of the southwards drifting larvae. The northwards drifting larvae occupy areas where the survey frequency is much lower, i.e. mainly in Faroese waters, in the Norwegian Trench and further north along the Norwegian coast, and hence the catch frequency of blue whiting is much lower than in the south.

It is not possible to get a complete picture of the distribution from the trawl station results alone, as the number of stations and their distribution are mostly in discordance with the blue whiting's abundance and availability. The maps merely show the geographical distribution of blue whiting within the shelf edge area from Gibraltar to the Norwegian Sea, and its level of occurrence in the survey trawl catches.

The Norwegian surveys to the west of the British Isles since 1979 were all acoustic assessment surveys with blue whiting as the main target. The trawl stations may represent an indication of abundance in the concentrations recorded, but will never give the precise picture. Annual plots for age groups 1,2 and $3+$ are presented in absolute numbers in Figure 6.7.5. Age 1 is more common in the northern and in the southern parts, and less so in the middle of the survey areas. To a lesser extent this tendency also exists for age 2 . Ages $3+$ are more evenly distributed over the whole area and exhibit a shift to the South from the mid-80s onwards.

### 6.8 Management Considerations

In last year's report it was suggested that the lowest SSB observed could be considered as MBAL (ICES 1996/Assess:14). In this year's assessment the lowest observed value was 1.5 mill. tonnes, and the spawning stock biomass in 1997 seems to be well above this level. According to a medium-term projection the stock will remain at that level with a catch constraint of 650,000 tonnes per year.

The stock seems to be increasing due to recruiting strong year class. Thus for the time the Working Group did not perform further analyses into other reference points than the traditional recommended ones.

The $F_{\text {med }}$ and $F_{\text {high }}$ are shown in Figure 6.8.1. A yield-per-recruit analysis was run to estimate the $F_{0.1}$ and $F_{\text {max }}$ and the stock summary results are shown in Figures 6.8.2 a-d. The references values are given in the text table below:

| $\mathrm{F}_{96}$ | $: 0.321$ |  |
| :--- | :--- | :--- |
| $\mathrm{~F}_{0.1}$ | $: 0.154$ |  |
| $\mathrm{~F}_{\text {max }}$ | $:$ | 0.500 |
| $\mathrm{~F}_{\text {high }}$ | $:$ | 0.780 |
| $\mathrm{~F}_{\text {med }}$ | $:$ | 0.321 |

Although some of these values could be considered as limit points in a precautionary advice, the Working Group considered that further analysis is needed to make decisions, taking into account the uncertainties in the assessment and the instability of the VPA when strong year classes enter the fisheries.

### 6.9 Special Comments

1. The Working Group stresses the importance of annual investigations of the blue whiting stock. It is recommended that surveys aimed at assessing the blue whiting stock biomass in the spawning area during spring should be continued.
2. Due to recruitment of the strong year classes of 1995 and 1996 to the fisheries, the mixed industrial fisheries especially will tend to target the high abundance of this resource, and hence a rather high number of small individuals will be caught. To avoid serious biases in the data set for stock analysis, it is strongly
recommended that the countries participating in this fishery continue to sample the catches frequently and bring both biological data and catch data to the Working Group.

### 6.10 Sampling

| Investigation | Number of samples | Length measurements | Aged individuals |
| :--- | :---: | :---: | :---: |
| Fishery 1996 | 542 | 35705 | 4723 |
| Survey British Isles | 52 | 5566 | 4558 |
| Survey Norwegian Sea | 101 | 5571 | 2429 |
| Southern Fishery | 437 | 47025 | 1223 |
| Southern Survey | 213 | 13982 | 2176 |

## 7 ECOLOGICAL CONSIDERATIONS

### 7.1 Barents Sea

### 7.1.1 Climate

During the period 1989-1995 the temperature in the Barents Sea has been higher than the long-term mean (Figure 7.1.1). After a short reduction in temperature in 1994 the temperature increased in 1995, followed by a new reduction in 1996. This trend has continued up to now. At present most of the Barents Sea has temperatures below the long-term mean. This is most pronounced in the eastern part with temperatures well below the mean and lots of ice, while the temperatures are closer to normal in the west.

Figure 1.4 in Sætre (1997) shows the horizontal temperature distribution in August-September 1996 compared to a warm year 1992, and it is easily seen that a much larger area is open for biological production in a warm year compared to a cold year.

### 7.1.2 Zooplankton

The standing stock of zooplankton has been investigated in August-September since 1986. Calanus finmarchicus is the dominant species in the zooplankton community, especially in the Atlantic water masses, while Calanus hyperboreus and Calanus glacialis are more important in the arctic water masses. In addition to these copepod species, krill and amphipods are important as food organisms for planktivores like herring and capelin. The amount of zooplankton present in the area is very much dependent on the abundance of zooplankton in the water masses entering the area above the sill between Fugløya and Bear Island. In winter the zooplankton in the Norwegian Sea is in the deeper water masses and thus water masses entering the Barents Sea in winter will be poor in zooplankton while these water masses will carry a significant amount of zooplankton in summer.

Figure 7.1.2 shows the biomass of two size groups of zooplankton ( $180-1000 \mu \mathrm{~m}$ and $>1000 \mu \mathrm{~m}$ ) in different areas of the Barents Sea during the last years. This time series shows a significant increase in zooplankton during the period 1991-1994, with a maximum in 1994. After 1994 there has been a marked reduction in all size groups, especially in 1996. The reason for this reduction is a reduced inflow of Atlantic water and thus a lower production of zooplankton or increased feeding pressure from plankton feeders in the area. In 1994 the mean biomass of zooplankton was $12.8 \mathrm{gm}^{-2}$, in $199510.0 \mathrm{gm}^{-2}$ while the mean biomass in 1996 was reduced to half of what was found in 1994. This investigation carried out with dip-nets and a small Mocness trawl, indicates as already mentioned a reduction in all size groups of zooplankton. In contrast, the "Multispecies Group" reported large concentrations of megazooplankton (krill) in the western parts of the Barents Sea during fall 1996. This may be because the latter investigation was carried out with larger pelagic trawls which are much more suitable for krill sampling.

Conclusions:

- The eastern part of the Barents Sea is cold.
- Zooplankton stocks decreasing in the Barents Sea (uncertainty about megazooplankton).

### 7.1.3 Cod consumption

Bogstad and Mehl (1996) calculated the consumption of various prey species by cod using stomach content data from the joint IMR-PINRO stomach content data base, a model for the gastric evacuation rate of cod and data on sea temperature and the abundance and geographical distribution of cod. The consumption is calculated for three main areas in the Barents Sea and for the first and second half of the year, for age groups $1-11+$ separately. On average 6,000 stomachs have been sampled annually since 1984. The calculated consumption from 1984 onwards is given in Table 7.1.1. The consumption estimates in Table 7.1.1 do not include the consumption by mature cod in the period when it is outside the Barents Sea (assumed to be 3 months during the first half of the year). During this period it may consume significant amounts of adult herring (Bogstad and Mehl 1996).

### 7.1.4 Consumption by minke whales and harp seals

Nilssen et al. (1997) and Folkow et al. (1997) calculated the consumption by harp seals and minke whales in the Barents Sea using data on energy intake, diet composition, energy density of prey and stock size. For harp seals, the data on diet composition were collected in the period 1990-1996. The food consumption by the 700,000 harp seals (including 100,000 pups) was calculated both for periods with a high and low capelin stock. In the calculations of the annual consumption by 85,000 minke whales in the Barents Sea and in Norwegian coastal waters, data from 1992-1995 were used, but data from 1992 in areas with much capelin were excluded in order to get an estimate for a period with a low capelin stock. Table 7.1 .2 compares the consumption by minke whale, harp seal and cod in the Barents Sea for a situation with a high and a low capelin stock.

### 7.1.5 Herring influence on recruitment of Barents Sea capelin

Based on the estimated spawning stock size and recruitment (at age one) included in the Barents Sea capelin stock summary table (Table 4.3.13) a stock-recruitment plot was constructed including data from the years 1973 to 1995 (Figure 4.3.1). The SSBs and the number of recruits were calculated by the spreadsheet model "Capstock" (ICES 1995/Assess:9, Appendix A). See Section 4.3 .4 for details.

Young herring in the Barents Sea is believed to hamper capelin recruitment (Huse and Toresen 1995). To illustrate years with significant amounts of herring (one year old and older) in the Barents Sea (1984, 1985, 1991, 1992, 1993, 1994, 1995 (Table 3.3.5)) these are plotted as filled circles in Figure 4.3.1 and labelled with year, while points for the remaining years are marked with open circles. The years with herring present show a significantly lower R/SSB ratio than the years without herring, apart from the years 1991 and 1995. In 1991, the spawning stock was very large, and the recruitment was not much lower than average. In 1995, the spawning stock was low (about $50,000 \mathrm{t}$ ). The recruitment was also low (about 100 bill. 1 -year-olds), but the R/SSB ratio was higher than in some of the years without herring present. The amount of herring was not high either in 1991 or 1995 compared to the period 1992-1994, but was at the same level as in 1984-1985 (Table 3.3.5), when the capelin experienced a total recruitment failure.

From the maps showing the herring distribution during the young herring surveys in the Barents Sea (June) and the distribution of capelin larvae during the larval survey in June (Figures 1-9 in Working Document by Bogstad and Gjøsæter), it is evident that the distribution areas of herring and capelin larvae most years show a considerable overlap.

In 1991, however, the distribution area of herring was smaller than in the rest of the period with herring present and covered only a small proportion of the distribution of the capelin larvae. One can only speculate if a lesser degree of spatial overlap between capelin larvae and herring in this year can explain why the capelin recruitment was seemingly better than in other "herring years".

In 1995, very few capelin larvae were detected in June (Figure 8 in Working Document by Bogstad and Gjøsæter), and the larval index was set at 0.0 (Table 4.3.1). The herring distribution area was small, but overlapped completely with the observed capelin larvae. Seemingly, the larvae that gave rise to the year class measured as one-year-olds in 1996 were not detected during the larval survey in 1995, even though that survey
did cover the normal distribution area for spring spawned capelin larvae. One possible explanation is that much of the spawning in 1995 took place late in the season and possibly further to the east, and consequently the larvae that emerged from that spawning were not preyed upon by herring to any noticeable degree, and had a high survival rate.

The stock recruitment relationship for capelin based on data from the period 1973-1995 reveals that the relationship seems to be curvilinear in periods without herring present in the Barents Sea (Figure 4.3.1). See Section 4.3.4 for details. In years with more than 2-3 hundred thousand tonnes of herring present, the recruitment fails completely. Observations from two years, 1991 and 1995, seem to contradict this pattern. In both these years there are reasons to believe that the spatial overlap between young herring and capelin larvae was insignificant, and that the effect on the capelin recruitment caused by predation by herring was low.

The following conclusions may be drawn:

- In years without significant amounts of herring in the Barents Sea, a stock-recruitment relationship for Barents Sea capelin may be constructed based on these years, and modelled by a curvilinear $\mathrm{S} / \mathrm{R}$ model, e.g. the Beverton-Holt or the Ricker model.
- In years with more than 2-3 hundred thousand tonnes of herring in the Barents Sea, either the recruitment fails completely, (if there is a significant overlap in time and space of herring and capelin) or the recruitment follows the general relationship or is only slightly reduced (if there is no or an insignificant overlap in time and/or space between capelin and herring).

### 7.2 Norwegian Sea

### 7.2.1 Climate

The variation in inflow of warm Atlantic water masses is of great importance for the climate and thus production of zooplankton and fish in the Norwegian Sea. Figure 7.2 .1 shows how the temperature in the core of the Atlantic inflow has varied during the last years. The measurements are taken at the Svinøy section, the Gimsøy section and the Sørkapp section, representative for the southern, central and northern part of the Norwegian Sea. This Figure shows a warm period from 1989-1995, followed by a cooling again since 1995. This cooling was caused by the strongest outbreak of Arctic waters since 1952. In 1996 there was a tendency of a short period of warming, and Atlantic v/ater masses again reached the coastal banks of Northern Iceland.

At present this warming is reversed and the prognosis for 1997 says that the western part of the Norivegian Sea and the waters north of the Faroes will continue to be characterised by a strong influence of relative cold, low salinity Arctic water, while the temperature will be closer to the normal in the eastern part of the area.

### 7.2.2 Zooplankton

Zooplankton sampling in the Norwegian Sea has taken place the last years, in connection with the Norwegian Sea program. In 1950s and 1960s the zooplankton was investigated in connection with the herring investigations, and Russian investigations have taken place during most of the period. Here only some results from the two last years coverage are presented. The mean abundance of zooplankton along the Svinøy section is presented in Figure 7.2.2. The average plankton biomass was the same the two years, but the plankton bloom started somewhat earlier in 1996 compared to 1995. The horizontal distribution of zooplankton were investigated in May 1996 (not shown here). An increased biomass of zooplankton was found in the western, northern and north-eastern part of the central Norwegian Sea. The lowest biomass, however, was observed in the southern and middle part of the area, i.e. the Atlantic water where the herring had apparently migrated across or was encountered in greatest densities. These investigations will be continued (ICES CM 1997/H:3), and these time series together with historical data sets will give us more information about the zooplankton community in the Norwegian Sea.

Conclusion:

- Western part of Norwegian Sea is cold.

### 7.3.1 Climate

In 1996 a decrease in water temperature was noted, especially to the north and east of Iceland. An Icelandic survey in February 1997 confirms this trend: while the water temperature south and west of Iceland was normal, the areas north and east of Iceland were somewhat colder than the long-term mean.

## 8 RECOMMENDATIONS

### 8.1 Capelin Symposium

One of the most important levels in the marine food chain is that of pelagic fish. They transfer energy from zooplankton to predators such as other fish, marine mammals and seabirds, some of which are commercially important. Pelagic fish are easily caught and commercially important, thereby filling a dual and often conflicting role as forage and commercial species.

The balance of the food chain is delicate but is maintained in a dynamic equilibrium through natural biological and physical events. However, the equilibrium at all levels, including pelagic fish, can often be shifted in a dramatic and disastrous fashion through human intervention.

In northern marine ecosystems, capelin occupy the dual role of a forage and commercial species. Although the capelin ecosystems differ in many respects, each has undergone profound changes in recent years. For example, in the Barents Sea, capelin have exhibited wide fluctuations in abundance and have recently been at very low levels. At the same time, the cod stock, as well as the Norwegian spring spawning herring, which spend their first years of life in the Barents Sea, have increased. At Iceland, capelin abundance has also fluctuated while that of at least three key predator species. i.e. cod, Greenland halibut and saithe, has declined. In the Newfoundland area, the most important predator, the cod, has declined to historically low levels while seals, another important predator, have increased in abundance.

While the changes just described are simple and selected examples, occurring in complex ecosystems, they serve to illustrate the recent dramatic changes that have occurred within these ecosystems. The reason for these and other variations continue to be investigated and, in many cases, have been the subject of speciai research projects and symposia. In contrast, while capelin continue to be monitored and studied, it is ironic that as the key element in many northern ecosystems, they have not been the focus of any multinational symposia.

Given the key position of capelin as a cornerstone species, and the fact that there is now considerable historical information available on capelin biology, capelin fisheries, their management and interactions with other predators and competitors, the Working Group recommends that a symposium be organised by ICES to deal with these topics. Participation of scientists involved in the investigations of capelin stocks and their role in the ecosystems on both sides of the Atlantic, as well as in the northern Pacific, should be encouraged. The Working Group suggests that the symposium be titled Capelin - What Are They Good For? Biology, Management and the Ecological Role of Capelin and be held at Iceland in year 2000 with Hjalmar Vilhjalmsson as convener.

### 8.2 Blue Whiting Special Meeting

Prior to the late 1960s, there was limited scientific and commercial interest in the blue whiting. With the collapse of the Norwegian spring-spawning herring, attention was diverted to the blue whiting and in 1978, ICES convened the first meeting of a Blue Whiting Study Group. During the 1970s to the present, blue whiting has become the focus of both an important international fishery and increased scientific interest. Many countries collect annual abundance and biological data in support of stock assessment.

Blue whiting is a key research subject in a project of the Norwegian Sea Programme "Mare Cognitum". This project deals with the coexistence and space and food competition between herring, mackerel and blue whiting and their relationships to other species along the continental slope. Stock structure is also being investigated through genetic analyses. The reappearance and increase of the Norwegian spring spawning herring to historical levels, the expansion of mackerel into the Norwegian Sea and the prospects of good recruitment in the blue
whiting population in the last two years, offer the opportunity to address the issue of competition among several pelagic stocks in the Norwegian Sea. Blue whiting is also highly migratory and a straddling stock, thereby presenting problems in its management.

As a result of the above considerations, the Working Group recommends that ICES and NEAFC sponsor a special meeting titled Blue Whiting - What Now? This meeting would address the biological aspects of blue whiting but would also use blue whiting as the key subject in addressing the problems of managing highly migratory and straddling stocks. It is proposed that this meeting would be held in 1999, hosted by the Nordic House in Torshavn, with co-conveners H. í Jakupsstovu, Dr V.K. Zilanov, Dr R. Bailey, and T. Monstad.

$\mathrm{A}=$ catches of adult herring in winter
$B=$ mixed herring fishery in remaining part of the year
$\mathrm{C}=$ by-catches of 0 - and 1-group herring in the sprat fishery
D = USSR-Norway by-catch in the capelin fishery (2-group)
Includes also by-catches of adult herring in other fisheries
In 1972, there was also a directed herring 0-group fishery
${ }^{3}$ Includes 26,000 t of immature herring (1983 year-class) fished by USSR in the Barents Sea
4 Preliminary, as provided by Working Group members

Table 3.2.2 Total catch of Norwegian spring spawning herring (tonnes) since 1972.
Data provided by Working Group members.

Table 6.4.4 Available tuning data. Input values used in the Extended Survivors Analysis are framed.

Lowestoft VPA Version 3.1
2/05/1997 17:54
Extended Survivors Analysis
blue whiting, 1997 Wg, ANON, COMBSEX, PLUSGROUP
CPUE data from file bw-tun2. dat
Catch data for 16 years. 1981 to 1996. Ages 0 to 10.

Time series weights :
Tapered time weighting applied
Power = 3 over 20 years

Catchability analysis :
Catchability dependent on stock size for ages < 2

```
Regression type = C
Minimum of 5 points used for regression
Survivor estimates shrunk to the population mean for ages < 2
```

Catchability independent of age for ages >= 6

Terminal population estimation :
Survivor estimates shrunk towards the mean $F$
of the final 5 years or the 5 oldest ages.
S.E. of the mean to which the estimates are shrunk = .500

Minimum standard error for population
estimates derived from each fleet $=.300$
Prior weighting not applied

Tuning converged after 30 iterations

Figure 3.3.1 Distribution of herring larvae found along the Norwegian shelf 2-22 April 1997.

Figure 3.5.1 Residual plots for including acoustic surveys in the model fit with assumptions of either normal, lognormal or gamma error distributions. The tagging model component is included in all three fits.

Figure 3.5.2 Comparison of selection patterns from two of the model formulations tested. Run 7, the 'long' parameterisation with younger age-classes estimated individually. Run 9, the 'short' parameterisation with a forced flat-topped exploitation pattern. Run 10, 'short' parameterisation but including all acoustic survey data (ages 5+ in January and February-March surveys and 4+ in December surveys). Run 11, 'medium' parameterisation (estimating age 5 and 13, flat pattern on ages 9-13, linear increase from age 5-9)

Figure 3.5.3 Observed and expected values for fishery-independent information from the Working Group's stock assessment model. Only values used in the assessment are plotted.

Figure 3.5.4 Norwegian Spring-Spawning Herring. Residual plots for the fishery-independent information used in the Working Group's stock assessment model. Upper panel, Percentiles of the Gamma distribution for the acoustic surveys. Centre panel, conventional residuals for acoustic surveys. Lower panel, percentiles of the Poisson distribution for the observed taa returns.

Figure 3.5.6

Figure 3.7.1 Estimated Bayes posterior probability distributions for some key parameters in the stock assessment: cohort abundances in 1997, natural mortality, disease-induced mortality, and survival of fish from the tagging experiment. Y-axis divisions indicate the \% probability for each of 15 intervals between the range of values from 950 samples.

Figure 3.7.2 Estimated Bayes posterior probability distributions for some further parameters in the stock assessment: appropriate error model, survey error variance, and catchabilities for each of three acoustic surveys. Distributions of spawning stock size and fishing mortality are calculated from posterior distributions of parameters in the assesment model. Note the fishing mortality is not comparable to F in the maximum-likelihood assessment. Y -axis divisions indicate the \% probability for each of 15 intervals between the range of values from 950 samples (except for error model plot)

Figure 3.8.1. Norwegian Spring-Spawning Herring. Bayesian Medium-term projection for exploitation rate $E$ in 1997-2002 $=E$ in 1996. Upper left panel, total annual yield from the stock. Upper right panel, exploitation rate ( $\mathrm{F} / \mathrm{M}$ ). Lower left panel, recruitment. Lower right panel, spawning stock size at spawning time. Full line, 50th percentile. Dashed line, 25 th and 75 th percentiles. Dotted lines, 5 th and 95 th percentiles.

Figure 3.8.2. Norwegian Spring-Spawning Herring. Bayesian Medium-term projection for exploitation rate E in 1997-2002 $=\mathrm{E}$ in 1996. Upper panel, spawning stock size at spawning time. Full line, 50th percentile. Dashed line, 25th and 75th percentiles. Dotted lines, 5th and 95th percentiles. Lower panel, estimated probability that the stock will be less that 2.5 Million tonnes at spawning time each year.

Figure 3.8.3. Norwegian Spring-Spawning Herring. Calculation of Bayes posterior perceptions of stock size and catch after application of a harvest control law limiting catch to the lower value of 1.5 Million tonnes and the catch calculated for $\mathrm{F}=\mathrm{M}$, from 1997 onwards. Exploitation pattern estimated for 1996 assumed to hold for the period 1997-2002. Upper left panel, total annual yield from the stock. Upper right panel, exploitation rate ( $\mathrm{F} / \mathrm{M}$ ). Lower left panel, recruitment. Lower right panel, spawning stock size at spawning time. Full line, 50th percentile. Dashed line, 25th and 75th percentiles. Dotted lines, 5th and 95 th percentiles.

Spawning stock biomass

Figure 3.9.1. Schematic presentation of a possible catch control law for Norwegian spring-spawning herring. Fishing mortality ( F ) and catch as a function of spawning stock biomass (SSB).

## Barents Sea capelin

Figure 4.3.1 Stock-recruitment plot for Barents Sea capelin (1973-1995 year class). Open circles are years without herring in the Barents Sea. Filled circles are years with young herring present. The solid line is a Beverton-Holt recruitment model and the dotted line is a Ricker model, both models are based on the years without herring present.

Figure 5.5.1 Trends in average weights of mature age 2 (upper graph) and age 3 (lower graph) capelin and total adult stock in number.

Figure 7.1.1 Mean temperature between 50 and 200 meters in August/September in the section FugløyaBjørnøya, Vardø-North and Sem Islands-North, 1964-95.

Figure 7.1.2 Mean values of size separated zooplankton biomass, $g m^{-2}$ (ash free dry weight 198690, dry weight 1991-96), from bottom -0 m in the «multispecies» regions II-VIII. Ash free dry weight is about $80 \%$ of dry weight. $\square 180-1000 \mu \mathrm{~g}$, $>1000 \mu \mathrm{~g}$

Figure 7.2.1 Temperature observed in July/August, in the core of Atlantic water in the sections Svinøy-NW, Gimsøy-NW and Sørkapp-W, averaged between 50 and 200 meters depth.

Figure 7.2.2 Plankton biomass ( $\mathrm{g} / \mathrm{m}^{2}$, average for all stations) at the Svinøy transect in 1995 and 1996.
