REPORT OF THE

Northwestern Working Group

ICES Headquarters 29 April–8 May 2002

This report is not to be quoted without prior consultation with the General Secretary. The document is a report of an expert group under the auspices of the International Council for the Exploration of the Sea and does not necessarily represent the views of the Council.

TECHNICAL MINUTES

North-Western Working Group (NWWG)

ACFM Meeting May 2002

Sub-group Chair: Dankert Skagen Working Group Chair : Einar Hjörleifsson Rapporteur/reviewer : Stuart Reeves Reviewer : André Forest Jesper Boje, Jakup Reinert Vladimir Shibanov and Willy Vanhee

The WG chair introduced the report, noting that in retrospect it was sometimes quite hard to find-out what had been done and what had been changed in some assessments. There is an intention to improve on this next year by e.g. tabulating candidate values for recruitment estimation, and changes in assessment settings.

The chair followed with some comments about assessment approaches, and in particular the desirability of integrating the catch-at-age analysis, recruitment estimation, and short and medium term forecasts all into one step and thus removing the inconsistencies and potential for error that arises when these are all separate steps. This approach also allows for stochastic forecasts and much more explicit statements about the uncertainty associated with a particular assessment.

The WG has used a wide range of assessment approaches, but in some cases where e.g. an assessment is based on a statistical catch-at-age analysis it has still been necessary to use the terminal Fs to run a VPA to get the output which ICES requires. This is clearly undesirable.

When raised in plenary it was noted that as a minimum, and software developed for use in stock assessment should produce the required standard output tables. The Secretariat will prepare some text on this.

The Sub-group supported the idea that an assessment should be more than following a standard template and pushing all the right buttons, but rather that an assessment should actually involve finding-out what the data tell you. The ICES approach can limit the extent to which this is possible, a point which will be raised in plenary.

General comments

The sub-group appreciated the fact that the WG use a broad range of assessment models. However, use of more flexible models, e.g. BORMICON, AMCI, ADCAM etc. requires that much more detail needs to be provided in terms of model specification and diagnostics than for a 'standard XSA'. This is often not the case for the models used here, making it very difficult to review some of the assessments.

The WG should mention whether there is any information about the extent of discarding for all stocks. Even a statement like "Little discarding is thought to occur in this fishery" are better than nothing.

The WG should provide detailed output from catch forecasts, e.g. in the form of the pie charts used for Icelandic Saithe. This is essential for interpreting what is happening in a catch forecast.

In cases where alternative assessments have been attempted, the WG should consider carefully whether they should be included in the Report. If the assessment has not been used then it can be confusing to include the output. It also increases the size of the report.

Fs for short-term forecasts : The recent mean exploitation pattern should only be scaled to the point estimate in the most recent year in cases where there is a clear indication of a trend. Otherwise use the unscaled value, particularly in assessments which are uncertain or have retrospective problems. The WG have introduced the SPALY¹ approach which the SG considered a useful formulation.

¹ Same Procedure As Last Year

The wg should next year look into the use of status quo constraint in the forecasts, for all stocks.

Faroese Stocks

Both the Haddock and cod assessments discarded all commercial CPUE series and place considerable reliance on a single short time series of survey indices. This could potentially lead to unstable assessments, particularly at the very low level of shrinkage used in the XSA runs for these stocks. The WG should reconsider this approach.

Faroe Plateau cod

The plot of the catch-at-age data on log scale plot useful – In this case it highlights a problem with one recent small year class

The WG discarded all commercial CPUE data for this stock and just used one short survey series. The WG are uneasy about the way XSA weights different surveys & there is a recent history of poor estimation of recruitment for this stock hence choice of only survey series. There is an increasing scepticism about use of commercial CPUE series, however the Faroe series are standardised, so hopefully technology creep should be less of a problem.

WG encouraged to maintain commercial CPUE series even if not used, and look carefully at excluding commercial series.

Very weak shrinkage used (2.0) – not investigated but SPALY. The WG defended this as a way of placing more trust in one short survey when there is an anomaly in the catch at age data. The WG should consider the choice of shrinkage – weak shrinkage as used may contribute to instability & the problems experience when changing the plus group age. Also the WG are encouraged to investigate statistical catch at age models – e.g. ICA, AMCI – time permitting – as these may be more appropriate if the catch at age data aren't trusted.

The XSA output of stock numbers at age had been edited to show the overwritten values. This should NOT be done as it makes it very hard to check values etc. Any overwritten recruitments should be edited only in the summary table, but indicated by e.g. '*'

There is a contradiction in the use of survey as only fleet, but then throwing out XSA est. of 1999 year class

The forecast used an exploitation pattern scaled to 2001 point estimate of F- when in this case terminal F is likely to be poorly estimated, so unscaled F should have been used. WG Chair asked to prepare forecast with unscaled F as comparison.

This stock highlighted a general point about the provision of detailed forecast output and pie charts – these were not provided, when they are extremely useful for interpreting the results of catch forecasts..

Faroe bank cod

No comments (no assessment !)

Faroe Haddock

It was noted that time series plots are not the best way to present exploratory runs when the terminal estimates are the point of concern. In this case it led to the wrong conclusion that all approaches produce similar results, when in fact terminal F varied between 0.3 and 0.5. – The WG are encouraged to provide scatter plots of terminal SSB vs. mean F to summarise different exploratory runs.

Estimate of SSB & F highly uncertain – conflicting evidence in various sources of information. WG has selected what it considers to be the most reliable source of info, but other sources of information would have given a different picture.

The comments on fleet use for cod also apply here, i.e. placing all trust in one short survey which is potentially misleading. The survey is considered reliable to age 5-6, but it is also used to tune at older ages - up to age 10 hence there are potential problems there.

In general a rather uncertain assessment . This was supported by the probability profile from exploratory statistical catch at age model.

The comment about use of scaled F as for cod, also applies here, but there is not much difference in this case, so no rerun was requested.

Faroe Saithe

There was some confusion about maturities, apparently raw data are smoothed using a GLM which incorporates a yearclass strength effect – it is unclear how this can be estimated before there is an assessment ! The approach is probably OK but the explanation could be clearer.

The assumption of q dependent on population size for ages 3-4 is not supported by XSA diagnostics.

The WG could look at the internal consistency of tuning series by looking at correlation within cohorts in successive years & also between series.

The assessment is a shaky, but WG has done a good job with limited data.

There was much discussion about population inputs for the short-term forecast. This was eventually rerun with 1998 year-class estimated using long-term GM, and XSA estimate accepted for 1996 year-class. (It was considered that there was no real evidence that the 1998 year-class is as strong as was assumed and the XSA estimate of 1996 year-class not too bad.). The revised forecast also used an unscaled F in view of retrospective problem.

Well done for being the only stock to incorporate pie charts for the forecast results ! These are very useful and should be provided for all forecasts.

Reference points were discussed as there is some need for revision but no firm proposals were made in view of the need to also revise those of cod & haddock.

Icelandic Stocks

In plenary it was noted that the catch forecasts run for the Icelandic stocks routinely assumed a TAC constraint for the intermediate year. This sometimes implied a substantial reduction in F during that year. The WG is asked to evaluate whether these reductions in F have been achieved by TAC regulation in the past, and thus to review whether this practice is appropriate for future forecasts.

Icelandic Saithe

There is a real problem with lack of documentation of the method used, in terms of what was done and what the parameter values mean. Without this documentation, it is very difficult to review the assessment. This is not satisfactory. The comment does not refer to the method itself, but only to (the lack of) information provided about the assessment. The text for this assessment approach was contradictory in that it is first noted that including the survey data in the TSA produced very little differences in the results, abut lower down in the same section it is noted that adding the survey data to the TSA was a significant improvement. No comparison was provided so it was impossible for the reviewers to judge the relative merits of the two approaches. This is a very serious point as the assessment led to a substantial change in the perception of the stock, and it is not clear how much of this is due to the data and how much to the change of method.

The use of a recruitment estimate from another method (ADAPT here) to that used for the catch at age analysis (TSA) needs to have a very clear justification if it is to be acceptable. In this case, it makes little difference so it was not considered necessary to rerun the assessment.

Icelandic Cod

The WG have investigated a wide range of different methods for this stock. While the sub-group encourages this, they felt that such comparisons, shouldn't just involve looking at the interest parameters, but should also investigate why and how the results differ (if they do). This was lacking from these investigations.

Exploration of a range of models is good, but adequate testing and documentation is essential if such models are to be used as the basis of advice.

Comments about lack of documentation for TSA as for saithe.

The final method was selected after visual inspection of the retrospective performance of each. One reviewer noted that comparison of retrospectives is easier using Mohn's 'rho' statistic (as used by Bob, not as described in his 1999 (ICES JMS, **56**, 773-788) paper where the equations are wrong !) than by visual inspection.

The subgroup considered this assessment to represent the 'state of the art' to a certain extent, particularly in respect of the review process, and the extent to which the problems have been investigated and understood. The approach is also well explained in the WG report.

The short-term forecast for this stock assumes TAC constraint for 2002 which leads to a large reduction in F. The WG should review this assumption – see above.

Icelandic Haddock

Note that residual plot is provided for ADCAM fit (which was not used) but not for the XSA fit that was used. However, the SG noted that bubble plot used is a good way of summarising the residuals. Some indications of year effects 1999-2000 are apparent, but these do not appear to cause any severe retrospective problems – perhaps the assessment achieved the right balance between surveys & shrinkage.

ADCAM appears to be useful, but good documentation and testing is essential.

The reviewers appreciated the presentation of the combined assessment & projections including the confidence intervals

Redfish

It took a bloody long time for the SG to go through the *S. mentella* stuff. The WG are encouraged to provide a clearer and more concise summary next year.

Pelagic S. mentella

The WG should be careful with comparing an 'absolute' estimate from acoustic surveys with an absolute catch. A small change in the assumed target strength could give a completely different picture. However, there is a clear indication of a reduction in what is being measured, even if the reasons for this are not clear.

The WG encouraged to continue work on combined Acoustic/trawl index

Deep Sea S. mentella

Please not that if e.g. ASPIC runs are made which are exploratory, then the WG should make it clear that this is exploratory.

Given the possible problems with estimation of r, it maybe possible to estimate r externally for use in the model.

Catch projections : After some discussion the approach used to forecast catch as a basis for advice was changed to :

Catch(2003) = mean CPUE(1999-2001) * mean Effort (1999-2001)

This leads to a catch of 25526t. i.e. 25,500 + 4000t (Faroes) => 30,000t.

This approach picks up some of the recent reduction in effort.

Sebastes marinus

The SG accepted the BORMICON as exploratory, and this work is appreciated. However, Absolutely no information was provided by which the assessment could be evaluated.

The WG should consider Biological reference points based directly on the analytic assessment, but the existing values were retained at present.

In plenary, it was decided to recommend a 25% reduction in effort. Accordingly, the 2001 effort was used as a reference, and applied to the 1999-2001 CPUE.

1.2 Terms of Reference

The Northwestern Working Group [NWWG] (Chair: E. Hjorleifsson, Iceland) will meet at ICES Headquarters from 29 April to 8 May 2002 to:

- a) assess the status of and provide catch options for 2003 for the stocks of redfish in Subareas V, XII, and XIV, Greenland halibut in Subareas V and XIV; cod in Subarea XIV, NAFO Subarea 1, and Division Va, saithe in Division Va, and haddock in Division Va;
- b) for cod, haddock, and saithe in Division Vb that are under effort control, assess the status of and provide effort options and expected corresponding catches for 2003;
- c) update survey and fishery information on the stocks of redfish in Subareas V, VI, XII, and XIV. In particular, update information on the development of the pelagic fishery for redfish with respect to seasonal and area distribution to allow NEAFC to further consider the appropriateness of area and seasonal closures;
- d) consider further possibilities for the incorporation of biological interactions into the assessments of capelin, herring, and cod stocks in Division Va;
- e) update information on the stock composition, distribution, and migration of the redfish stocks in Subareas V and XIV, and comment on the possible relationship between pelagic "deep sea" *Sebastes mentella* and the *Sebastes mentella* fished in demersal fisheries on the continental shelf and slope;
- f) provide information on the horizontal and vertical distribution of pelagic redfish stock components in the Irminger Sea as well as seasonal and interannual changes in distribution;
- g) provide specific information on possible deficiencies in the assessments, including at least: Major inadequacies in the data on catches, effort or discards; major inadequacies, if any, in research vessel surveys data, and major difficulties, if any, in model formulation; including inadequacies in available software. The Group should clarify the consequences from these deficiencies for a) assessment of the status of the stocks and b) for the projection;
- h) for stocks for which a full analytical assessment is presented, comment on this meeting's assessments compared to the last assessment of the same stock;
- i) consider the results presented in the reports of the WGMG and the SGPA with a view to applying these in the assessments;
- j) review the draft Quality Handbook.

NWWG will report by 9 May 2002 for the attention of ACFM.

Request from NEAFC to ICES for scientific advice for 2002 and 2003

In addition to the ToR from ICES the NWWG addressed the NEAFC requests to ICES on the following issue:

1. Regarding redfish stocks:

- a) Review the stock situation and its advice for pelagic redfish in the Irminger Sea for 2002 at the May 2002 ACFM meeting;
- b) submit new information on stock identity of the components of redfish such as "pelagic deep-sea" *Sebastes mentella*, "oceanic" *Sebastes mentella* fished in the pelagic fisheries, and the "deep-sea" *Sebastes mentella* fished in demersal fisheries on the continental shelf and slope;
- c) provide information on the horizontal and vertical distribution of pelagic redfish stock components and fisheries in the Irminger Sea and adjacent waters as well as seasonal and interannual changes in distribution. Information on the vertical distribution should allow NEAFC to further consider the appropriateness of separate management measures for different geographical areas/seasons.

1.3 General comments

The format of the report is similar to the last two years, with Tables and Figures located after all text for each stock. In the 1999 report some information not used directly in the assessment was omitted in order to make it more digestible for clients. Attempts to reduce the amount of documentation have not been made in the last three years reports, as clients of the report as well as ACFM have requested that it should contain sufficient data and diagnostics from analyses.

1.4 Stocks assessed by NWWG

The stocks dealt with by NWWG can be divided into two classes: those for which data are sufficient to allow an agebased analytical assessment, and those for which either the data amount is limited or for which the quality of the data is questionable, impeding analytical assessments. All gadoid stocks are in the first class except for Faroe Bank cod, where a short time-series and incomplete biological sampling of the landings inhibit analytical assessment, and cod in Greenland, where a ceased fishery prevents a VPA. In the second class are most of the redfish stocks, for which difficulties in age determination have prevented calculations of catch-at-age and, therefore, age-based analytical assessment. The Greenland halibut stock in Greenland, Iceland, and the Faroes shifted to this category last year, mainly due to unreliable determinations of age and maturity. One redfish stock, *S.marinus*, sits in the middle of these two extremes, being assessed by a length-based model (Bormicon).

1.5 Choices of stock size indices to be used in calibrations

Consistency between successive assessments of stock size is perceived as a virtue by most ICES assessment working groups. Over years, this has led to the adoption of standard XSA configurations that should be used as default with minimum changes from one year to the next. Given the workload of WG and ACFM, WGs have tended to tamper as little as possible with the settings and the series that are used in the assessment as frequent changes in these appear to be made on an *ad hoc* basis.

The recent assessments of North Sea and Icelandic cod point to the importance of periodically examining critically what indices should be used in the assessment. The main result of the in-depth examination for these two stocks had led to the exclusion of all five commercial fleets in the Icelandic cod assessment, and four of the five commercial fleets in the North Sea cod assessment, due to demonstrated or suspected increases in the commercial fleets' catchability coefficients and/or data errors as well as inability of assessment models to properly use indices from many fleets, giving surveys too little weight as they do not correlate as well with catch in numbers as the indices from the commercial fleets do. The omission of commercial CPUE series has resulted in considerably lower estimated stock sizes, consistent with perceived effects of unmodelled increase in catchability coefficient of the commercial fleets.

Given the rejections of commercial CPUE indices in the North Sea and Icelandic cod assessments and the expected increase in efficiency of commercial fleets, it would be tempting to systematically exclude **ALL** commercial CPUE indices from **ALL** ICES stock assessments, but this would be an unwise over-reaction. What is needed is a careful indepth examination of ALL stock size indices used in each and every assessment to ensure that the indices do provide consistent measurements.

Although it is expected that fishing efficiency of commercial fleets will increase over time, the imposition of technical conservation measures has the contrary effect and it is not always clear what the net outcome will be. The commercial

CPUEs used in the Faroe saithe assessments have been carefully selected from a subset of vessels whose configurations have remained relatively unchanged over the years and have consistently provided reliable logbook information. The CPUE used for Greenland halibut has been modelled to take into account year, area, seasonal, and vessel characteristics, and even though the area fished has increased over the years, eliminating part of suspected changes in catchability. For the redfish stocks included in the mandate of the NWWG the commercial fleets' CPUE is a major source of information on changes in stock size. Regarding the stocks for which analytical assessment or long survey series are not available, trends in catchability coefficients are impossible to detect and results from "better known" species might have to be utilized (WP31).

1.6 Choices of stock assessment methods and/or software

For most of the stocks for which age based analytical assessments were carried out, the terminal fishing mortality was estimated by tuning aged catch data with selected fleet age disaggregated CPUE indices (commercial or survey indices) using two different methods. The adopted assessments of the Faroe cod and Faroe haddock were based on the conventional XSA methods. Terminal fishing mortality of Icelandic cod and Icelandic saithe have been modelled by a Time-series Analysis (TSA), this method having a relatively long history of usage in this Working Group. Terminal fishing mortality of Icelandic haddock was on the other hand not based on any special model but a number of models were run and results somewhere in the middle of the possible results were selected!!

The reader of the report will find that various other types of models were fitted to the Icelandic stocks, including forward-based catch-at-age analysis (Coleraine (WD29), ADCAM (WD33), STAM (WD22)) and the well established backward-based ADAPT - method. The principle of the latter model is the same as that of the conventional XSA, i.e. catch-at-age data are assumed to be without error. The principle of the former group of models is that catch-at-age and survey-indices are predicted from the model and "the best fit" is obtained by minimising the observed vs. the predicted values. This is the same procedure as that of AMCI (now used in WGNPBW) and the forward part of ICA. The advantage of using a forward calculation is that both short-term and medium-term projections are a natural extention of the assessment of the historical data series. One can thus bypass the tedious and often error prone procedure of going through 4 software packages (historical assessment, recruitment estimates, short-term prediction, and medium-term prediction), as is now the norm. Although members of the Working Group concluded that the results from any of these approaches and/or software packages could be used as the basis of the adoption of a final run, they were not used because of unfamiliarity of these methods/software packages to the ICES body at large. The results from two of the models where however used as a basis for short-term forward projection in the Icelandic haddock and saithe.

1.7 Comments on the WGMG and the quality handbook

The NWWG considered the report of the Methods Working Group (WGMG) (ToR i). Views varied on the proposed process for the certification of software (Section 7), particularly as it links with the quality of ACFM advice (Section 2.2). The first creation of the Methods Working Group in the early 1980s aimed at identifying which of the assessment methods available could be useful, standardising the assessment approaches, and providing guidelines on the use of existing software.

The overall philosophy could be described as the provision of assessment software that would be robust to both the data and the user. The current report of the WGMG suggests that this has not been an overwhelming success since for the 67 assessments for six stocks examined, 20 were in error by a factor of 2 or more. We agree with the MGMG (page 2) that "the prevailing inclination [...] to seek solutions through a sophistication of models and methods" is unlikely to be successful and that the data needs to be improved. Unfortunately, under most existing fishery management systems, this may prove either very difficult or very expensive.

The software certification proposal of the current WGMG is in line with the overall philosophy described above. Although there is no disagreement that software should be certified, we consider it equally important to certify the assessor. It is more important to train assessors directly in analysing and interpreting the data available to them rather than teach them how to use a particular piece of software.

The software certification procedures and the quality handbook may make participation in ICES stock assessment working groups unattractive for highly qualified and innovative analysts who could make important contributions to the progress of ICES' work. Those highly qualified and innovative analysts that do come to assessment working groups cannot work as efficiently because of the software certification procedures and quality handbook.

Quality management procedures such as those proposed in the quality handbook manual seem appropriate for organisations that produce high volumes of standard items in a more or less automated way. The production of assessments and formulation of management advice may not be at the stage where it is possible to automate the process.

It relies more on the skills and dedication of the "artisan" involved in the work than on the procedures involved. This may require a different approach to quality management.

An important and often overlooked step is that output from stock assessment model should be easy to read by any statistical program or spreadsheet or even relational databases, while the output from many of the assessment programs used now is totally unacceptable in this context. Similar considerations apply to the input which is decades behind regarding sensitivity to extra spaces, tabs, or commas in input files.

The WG reports are consistently getting bigger and bigger. Reducing the font and going to A6 paper size is not an option because the eyesight of the average user is not improving. An alternative to the current approach of producing large WG reports would be to raise the status of individual working documents and publish them in a formal series as the technical documentation of the advice. Those documents would be authored by the relevant scientists and could count in the scientific production when assessing performance.

1.8 Precautionary reference points

No major evaluation of reference points has been made since 1999. The Working Group recognised that some existing reference points may in some cases be inappropriate (e.g. in Faroe saithe and Icelandic saithe). Given the management regime in effect in the Faroese demersal fisheries, the reference points for the three main species, cod, haddock, and saithe, should be re-evaluated at the same time. The catch rule for Icelandic cod is now under revision and it was considered that revision or establishment of reference points for Icelandic haddock and Icelandic saithe should await the result from that analysis. Until more appropriate reference points are identified and adopted, the existing ones could continue to be used, albeit with some flexibility in the formulation of management advice.

2 DEMERSAL STOCKS IN THE FAROE AREA (DIVISION VB AND SUB-DIVISION IIA4)

2.1 General Trends in Demersal Fisheries in the Faroe Area

The fishery at the Faroes is a multi-fleet and multi-species fishery. Figure 2.1.1 gives a summary of the 2002 assessments of the stocks of Faroe Plateau cod, Faroe haddock and Faroe saithe and Figure 2.1.2 shows the total yield of these stocks.

Fishing mortality on Faroe Plateau cod, Faroe haddock and Faroe Saithe has followed different trends for the three species since the early 1960s (Figure 2.1.1). Fishing mortality for cod and haddock declined steadily from 1961 to the early 1970s, but thereafter evolved differently. For cod, fishing mortality increased and has oscillated around a mean of about F = 0.50 since 1974, with a substantial decrease in the early 1990s when productivity was lower. For haddock F remained relatively low (F = 0.27) until the late 1990s when it appears to have increased to pre – 1973 values. For saithe, F increased regularly from 1961 to the late 1980s, reaching peak values in the early 1990s, but it appears to have decreased since. Over the whole time series, F for haddock is negatively correlated with time (r = 0.70), and, as could be expected, the F for the two species are negatively correlated (r = 0.70). When combined in an overall index of exploitation (yield over SSB), the ratio is remarkably stable around 0.30 from 1961 to 1981 (Figure 2.1.2), but since then it has shown larger fluctuations, exceeding 0.55 in 1991. This index of overall exploitation has steadily increased in recent years from slightly less than in 1997 to about 0.42 in 2001.

The SSB for cod shows four cycles (Figure 2.1.3), the SSB for saithe two and half, and the SSB for haddock, three. The haddock SSB appears to lag that of cod by 2 years (r = 0.88). No such lags are clearly evident for saithe. When added together (Figure 2.1.4), the total SSB increases from 1961 to 1977, then it declined almost steadily until 1992, except for a brief increasing period from 1983 to 1985. SSB has shown an increasing trend since then.

Haddock shows the largest recruitment variability (Figure 2.1.5). There is a more than 50 fold difference between the smallest year class (1.8 million) and the largest one (95.6 millions). Cod shows the next largest variability with a 15 fold difference between the smallest year class (3.6 millions) and the largest one (54 millions). Saithe shows only a 7 fold difference between the smallest year class (8.4 millions) and the largest one (62 millions). The recruitment of cod does not show any particular feature other than the string of small year classes during most of the 1980s. Haddock shows sustained recruitment for the 1959 to 1976 year classes, but from 1977 to 1992, only the 1983-1985 year classes were of average size. All the other were much smaller than average. The 1993, 1994 and 1999 year classes are strong. Saithe recruitment increases regularly from the 1958 year class to the 1966 year class and then decreases similarly regularly until the 1975 year class. Recruitment patterns since then are not been so clearly cyclical.

During the 1980s the Faroese authorities have attempted to regulate the fishery and the investment in fishing vessels. In 1987 a system of fishing licenses was introduced. The fishery also has been regulated by technical means such as legislation on the mesh size, permanent and temporarily area closures, import ban on fishing vessels and a programme of buying back fishing licenses. Mesh size regulations and closed areas are still enforced.

In March 1994 the Faroese Parliament passed a law on the regulation of fisheries within the EEZ. This law introduced quotas for 5 demersal stocks including the Faroe Plateau and the Faroe Bank Cod, Faroe Haddock, Faroe Saithe and redfish. The quotas were allocated to each fleet category by percentage of the total quota and then equally divided between all vessels in each category.

The fishing year starts 1 September and ends 31 August the following year.

2.2 Faroe Plateau Cod

2.2.1 Trends in landings

The nominal landings of cod (1986-2001) from the Faroe Plateau by nations as officially reported to ICES, are given in Table 2.2.1.1. The relatively high recruitment in 1980-1983 allowed a good fishery for cod in the period 1983 to 1986 when landings some years reached almost 40 000 t. Landings decreased afterwards to only 6 000 tonnes in 1993, the lowest on record. In 1995 the officially reported landings increased to slightly above 19 000 t. Information from the fishing industry indicated misreporting in the order of 3 330 t (3 000t. gutted weight) for 1995 which were added to the officially reported landings in Table 2.2.1.2. Misreporting is not suspected to have been a problem afterwards. Landings increased spectacularly in 1996, to above 40 000 t, the highest value during the 1961 to 2000 time period. This increase is believed to be due to a combination of increased stock size, increased availability, and increased effective fishing effort as a result of the new management system introduced June 1, 1996. The catches remained high in 1997 (34 000 t),

but decreased to 24 000 t in 1998 and 20 000 t in 1999. Catches increased slightly in 2000 (22 000 t), and reached 29 000 t in 2001.

In recent years, statistics for the Faroese fishery in that part of Subdivision IIa (Figure 2.2) which is within the Faroese EEZ, have become available. It is expected that these are taken from the Faroe Plateau area so they are included in the total used in the assessment in Table 2.2.1.2 under the row labelled "Used in the assessment". No information on the Faroese landings from IIa were available for 1993-1996, however. The French landings of Faroe Plateau cod in 1989 and 1990 as reported to the Faroese authorities are also included. Scottish catches 1991-1999 reported from the Faroe Bank (Vb2) were in the 2001 assessment moved to the Faroe Plateau (Vb1), by advice from the Faroese Coastal Guard (Table 2.2.1.2).

Since the introduction of the EEZ, the Faroe Plateau cod has almost entirely been exploited by the Faroese fishing fleets. Table 2.2.1.3 and Figure 2.2.1.1 show the landings for the most important fleet categories. In recent years, the longliners and the pair trawlers have usually taken most of the catches. Since autumn 1999, however, single trawlers > 400 HP have increased their share of the total catches considerably as a result of a special quota (in tonnes, not fishing days) allocated to them in shallow water (< 200 m) on a half year basis (September 1 and March 1).

2.2.2 Catch-at-age

Landings-at-age were updated to account for a change in the nominal landings for 1999-2000. Landings-at-age for 2001 are provided for the Faroese fishery in Table 2.2.2.1. Faroese landings from most of the fleet categories were sampled (see text table below). Landings-at-age for the fleets covered by the sampling scheme were calculated from the age composition in each fleet category and raised by their respective landings. The age composition of the corresponding Faroese landings was used to raise the foreign landings prior to 1998 when, the age composition of the corresponding Faroese fleets were used. Landings-at-age from 1961 to 2001 are shown in Table 2.2.2.2. Catch curves are shown in Fig. 2.2.1. They show atypical patterns in 1996 and to some extent in 2001 when there appears to be an increase over the previous year for ages where a decrease would normally have been expected. This could be due to catchability for longliners depending on fish growth (Fig. 2.2.6.1.5), causing atypical catch curves for longliners (Figure 2.2.6.1.4).

Fleet	Size	Samples	Length	Otoliths	Weights
Open boats		13	2,074	540	300
Longliners	<100 GRT	83	16,589	1,745	359
Longliners	>100 GRT	70	13,466	1,919	600
Jiggers		13	2,177	419	300
Sing. trawlers	<400 HP	16	3,107	360	240
Sing. trawlers	400-1000 HP	30	6,348	301	120
Sing. trawlers	>1000 HP	9	1,693	298	240
Pair trawlers	<1000 HP	19	3,974	480	420
Pair trawlers	>1000 HP	46	9,437	894	835
Total		286	56,791	6,416	3,114

Samples from commercial fleets in 2001.

2.2.3 Mean weight-at-age

Mean weight-at-age data for 1961-2001 are provided for the Faroese fishery in Table 2.2.3.1. These were calculated using the length/weight relationship based on individual length/weight measurements of samples from the landings. The sum-of-products-check for 2001 showed a discrepancy of less than 1 %.

Figure 2.2.3.1 shows the mean weight-at-age for 1961 to 2001. From 1991 to 1995 weights at age increased, they remained stable in 1996 and decreased during 1997-1998. Since 1998 they have increased again.

2.2.4 Maturity-at-age

The proportion of mature cod by age during the Faroese groundfish surveys carried out during the spawning period (March) are given in Table 2.2.4.1 (1961 - 2001) and shown in Figure 2.2.4.1 (1983 - 2002). The average maturity at age for 1983 to 1996 were used in years prior to 1983. Full maturity is generally reached at age 5 or 6, but considerable changes have been observed in the proportion mature for younger ages between years. In the 2001 assessment, the maturity of the youngest ages was revised (see ICES 2001). No revision was done this year.

2.2.5 Groundfish surveys

The spring groundfish surveys in Faroese waters with the research vessel *Magnus Heinason* were initiated in 1983. Up to 1991 three cruises per year were conducted between February and the end of March, with 50 stations per cruise selected each year based on random stratified sampling (by depth) and on general knowledge of the distribution of fish in the area. In 1992 the period was shortened by dropping the first cruise and one third of the 1991-stations were used as fixed stations. Since 1993 all stations are fixed stations. The standard abundance estimates is the stratified mean catch per hour in numbers at age calculated using smoothed age/length keys.

The overall mean catch (kg) of cod per unit effort (trawl hour) 1983-2002 is given in Figure 2.2.5.1. The CPUE increased substantially in 1995 and remained high up to 1998. The CPUE decreased in 1999 and 2000, but increased again in 2001 and 2002. Normally the stratified mean catch per trawl hour increases for the first 4-5 years of life of a year class, and decreases afterwards. From 1994 to 1995, however, there was an increase for all year classes, possibly because of increased availability. A more normal pattern was observed from 1996-2000. Due to serious uncertainties as to the integrity of the data in the data base, only total kg/hour and information from aged fish were available in the current assessment. The database is being re-constructed, but the work was not completed to the current assessment.

In 1996, a new summer (august-september) groundfish survey was initiated, having 200 fixed stations distributed within the 500 m contour of the Faroe Plateau. Half of the stations were the same as in the spring survey. This series was ready to use in the current assessement, as it got the highest priority in the reconstruction of the database. The overall mean catch (kg) of cod per unit effort (trawl hour) 1996-2001 is shown in Figure 2.2.5.1, and catch curves in Figure 2.2.5.2. The catch curves show that the fish are fully recruited to the survey gear at an age of 3 or 4.

The abundance index was calculated as the stratified mean number of cod at age. The age length key was based on otolith samples pooled for all stations since there seemed to be a homogenious size at age by strata and depth. Due to incomplete otolith samples for the younges age groups, all cod less than 15 cm were considered being 0 years and between 15-34 cm 1 year. Since the age lengt key was the same for all strata, a mean length distribution was calculated by stratum and the overall length distribution was calculated as the mean length distribution for all strata weighted by stratum area. Having this length distribution and the age length key, the number of fish at age per station was calculated, and scaled up to 200 stations.

2.2.6 Stock assessment

2.2.6.1 Tuning and estimates of fishing mortality

The two tuning series used in NWWG 1998, the single trawlers 400-1000 HP and longliners > 100 GRT both with fishing effort measured in days were replaced in NWWG 1999 by two tuning series based on logbook data for five longliners > 100 GRT and eight pair trawlers > 1000 HP. In these series, effort was measured in 1000 hooks for the longliners and trawl hours for the pair trawlers. Both tuning series are shown in Table 2.2.6.1.1 (age disaggregated) and Figure 2.2.6.1.1 (kg/1000 hooks and kg/hour). The two series show very similar trends for most of the years. Effort standardized catch curves are shown in Figure 2.2.6.1.3 (Cuba trawlers) and Figure 2.2.6.1.4 (longliners).

In the longliner series, fishing sets with information on cod catch, effort and fishing location and with catches of tusk and ling together less than 20% of the total catch were selected. In this way only the fishery directed towards cod (and haddock) was used. The longliner series was further scrutinised in NWWG 1999 by looking at the individual CPUEs for each ship. All outliers were caused by either small catch or small effort data. Given that the index is based on the sum of all records, this meant that the outliers had little influence on the overall results and therefore all ships could be used.

In the Cuba trawler series, fishing sets with information on cod catch, effort, and fishing location east of 7 degrees W on the Faroe Plateau were used (in order to standardise). In addition only "saithe hauls" were used, i.e. the catch of saithe was more than 70 %, and the sum of cod- and haddock-catch was less than 30 %. Thus the Cuba series is a bycatch

series. The Cuba series was in NWWG 1999 further scrutinised by looking at the individual CPUE for each ship. As for the longliners all ships could be used.

In the current assessment, four XSA runs were considered, 1) same settings as last year, 2) Cuba trawlers only, 3) longliners only, 4) survey only (Fig. 2.2.6.1.9). The diagnostics for the commercial tuning series were poorer than the survey (Figure 2.2.6.1.7). Looking at the results, the longliner tuning series seemed to have an important deficiency, since the catchability was dependent on growth rate of cod (Figure 2.2.6.1.5). This suggests that cod preference for longline bait depends on natural food availability. When choosing between the Cuba trawlers and the survey, the working group had more confidence in the survey even if the time span of the survey (1996-2001) is short. In addition, the indices of the youngest age are thought to be more reliable in the survey than in the commercial fleet. Thus the WG adopted the survey tuning series as the basis for short term predictions. The survey is conducted in a much more systematic way than the Cuba trawler series and is not affected by commercial interests or changes in gear technology or gear operation. In addition the diagnostics for the survey was better compared to the Cuba trawlers. It should be noted that all four XSA runs essentially indicated the same development of the stock.

The results from the retrospective analysis of the XSA (Figure 2.2.6.1.8) show that there is a tendency to overestimate fishing mortality.

The estimated fishing mortalities are shown in Tables 2.2.6.1.3 and 2.2.6.1.5 and Figures 2.2.6.1.10 and 2.2.6.1.11. The average F for age groups 3 to 7 in 2001 is estimated at 0.71, considerably higher than $\mathbf{F}_{max} = 0.48$. Figure 2.2.6.1.10 shows, that fishing mortalities were underestimated most years in last years assessment.

2.2.6.2 Stock estimates and recruitment

The stock size in numbers is given in Tables 2.2.6.1.4. A summary of the VPA, with recruitment, biomass and fishing mortality estimates is given in Table 2.2.6.1.5 and in Figure 2.2.6.1.11. A comparison between the survey CPUE and biomass of ages 3+ (Figure 2.2.6.2.1) suggests that the spring survey is a reasonable index of 3+ biomass. The stock-recruitment relationship is presented in Figure 2.2.6.2.2.

The assessment shows the poor recruitment for the 1984 to 1991 year classes, and the strong 1992 and 1993 year classes. Due to the continuous poor recruitment from 1984 to 1991 and the high fishing mortalities, the spawning stock biomass declined steadily from 1983 to 1992 when it was the lowest on record at 20 200 t. It increased sharply to almost 90 000 t in 1996 and 1997 before declining to a level of about 40 000 t in 2000. The 1997 year class was in last years assessment considered to be above average strength, but in the current assessment, it is below average. The 1998 year class seems to be slightly above average strength and the 1999 year class is in the current assessment estimated to be as strong as the highest observed (1982 year class: 47 millions). In fact the RCT3 program (Table 2.2.6.1.6-7) estimated the 1999 year class to be even stronger as did the initial XSA run. The recruits from the 1999 year class were set to 47 millions and thus the fishing mortality of that year class was recalculated as was the stock numbers and biomass at age, spawning numbers and biomass at age, total biomass and spawning biomass, and the yield/SSB ratio.

ACFM recommended last year, that the plus group should be set at 8+ instead of 10+. This was tried but gave much higher estimates of stock size and lower fishing mortalities. The working group was unable to explain these differences but decided that age 9 should be used as the oldest age, and that the plus group should be omitted. Output from the ASPIC model (Table 2.2.6.1.9 and Fig. 2.2.6.1.12-13) give lower estimates of total biomass and fishing mortalities than the current assessment and suggests that the use of the 8+ may not give correct stock estimates.

2.2.7 Predictions of catch and biomass

2.2.7.1 Short-term prediction

In order to estimate the strength of the year classes 1999-2001, the RCT3 program was used. Table 2.2.6.1.6 shows the input values. The catch curve of the 1997 year class is atypical and shows that high numbers were caught at age 1, but much lower than expected at age 2 or 3. Thus, the ages 1 and 2 of this year class were not used in the prediction of the 1999-2001 year classes. The long time span (1963-2001) was used in order to reduce the influence of the poor recruitment in the period 1987-1991 on the VPA mean.

The input data for the short term prediction are given in Table 2.2.7.1.1. The estimate of year classes 2000-2001 was taken from the RCT3 run. The 2002 year class was estimated as the geometric mean for the period 1961-2001. The estimate of the 1999 year class in 2002 (age 3) was obtained by adjusting the number of 2 year old in 2000 for mortality in 2001 (Table 2.2.7.1.1). Estimates of stock size (ages 4+) were taken directly from the VPA stock numbers. The

exploitation pattern was estimated as the average fishing mortality for 1999-2001 rescaled to 2001 values. The rescaling was based on the ages 3-7. The weight at age for 2002-2004 was set to the average of the 1999-2001 values. This implies a reduction in the weights compared to 2001. The proportion mature in 2002 was set to the 2002 values from the groundfish survey, and for 2003-2004 to the average values for 2000-2002.

Table 2.2.7.1.2 shows that the landings in 2002 are expected to be 42 000 tonnes if the fishing mortality stays the same as in 2001. The spawning stock biomass is expected increase considerably (from 52 000 t in 2001 to 64 000 t in 2004). The VPA suggest that the 1999 year class is very strong, which also is supported by the age distribution (Figure 2.2.7.1.1) and the increase in survey CPUE (kg/hour) in 2002 (Figure 2.2.6.2.1). The stock size could be even larger if the individual weights remain as high as those observed in 2000-2001. There is, however, the possibility, that longliners could have concentrated the effort on this strong year class, giving too optimistic prediction.

2.2.7.2 Biological reference points

In 1998, ACFM set \mathbf{B}_{lim} equal to the lowest observed SSB, about 21 000 t and proposed that \mathbf{B}_{pa} be set at 40 000 t based on \mathbf{B}_{pa} =Blime1^{.645 \sigma}, assuming a σ of about 0.40 to account for the relatively large uncertainties in the assessment. ACFM further proposed that \mathbf{F}_{pa} be set at 0.35, more than twice $\mathbf{F}_{0.1}$, about equal to \mathbf{F}_{max} and \mathbf{F}_{med} and at the low end of the range of previously estimated \mathbf{F}_{MSY} , from 0.33 (Stefansson and Bell, WD prepared for the SGPAFM) to 0.56 (NWWG, 1997). In previous years, MBAL was considered to be 52 000 t. Over the period covered by the assessment, fishing mortality has been equal to or less than this proposed \mathbf{F}_{pa} in only 6 of 40 years of available data. This suggest that $\mathbf{F}_{\text{pa}} = 0.35$ may be overly conservative. The updated assessment indicates an $\mathbf{F}_{\text{med}} = 0.41$, $\mathbf{F}_{0.1} = 0.27$ and $\mathbf{F}_{\text{max}} =$ 0.48. \mathbf{F}_{pa} could therefore be set in the order of $\mathbf{F}_{\text{med}} = 0.41$.

Following the logic used to set \mathbf{B}_{pa} , \mathbf{F}_{lim} was set at \mathbf{F}_{lim} =Fpae1^{.645 σ}, that is, \mathbf{F}_{lim} =0.68. Should the \mathbf{F}_{pa} be reviewed, \mathbf{F}_{lim} could be adjusted accordingly.

The stock trajectory with respect to existing reference points is illustrated in Figure 2.2.7.2.1.

2.2.7.3 Medium-term prediction

Medium term 20 years prediction were done in the 2001 assessment (ICES 2001). It was not repeated this year.

2.2.7.4 Long-term prediction

The input data for the yield-per-recruit calculations (long-term predictions) are given in Table 2.2.7.4.1. The exploitation pattern (rescaled to 2001 values) and weight at age were set to the average values for 1961-2001. The proportion mature was set to the average for 1983-2002.

The output from the yield-per-recruit calculations is shown in Table 2.2.7.4.2. and in Figure 2.2.7.4.1. $\mathbf{F}_{0.1}$ was calculated as 0.27 and \mathbf{F}_{max} as 0.48. The present average fishing mortality in 2001 of 0.71 is substantially above \mathbf{F}_{max} and $\mathbf{F}_{med} = 0.41$ (Figure 2.2.7.2.1).

2.2.8 Management considerations

The management system with individual transferable days introduced in 1996 had as an objective to decrease fishing mortality. The current assessment shows that instead, fishing mortality increased from 0.3 in 1995 to 0.7 in 1996. The WG report for 2000 describes the scope for changes in catchability and how they could account for such increases in fishing mortality and it also reports on an external review of the scientific basis for the initial allocation of fishing days and of the method to calculate probability profiles for expected fishing mortalities given the possible utilisation of the allocated fishing days (Pope 2000).

Given the recent history, however, fishing mortality in future years is expected to be above the proposed \mathbf{F}_{pa} of F = 0.35 unless the number of days are reduced substantially.

For reference purpose, the day allocations are summarised in the text table below.

The number of days allocated to each fleet category are given in the table below:

Gear	Allocation	Optional change
LL<110	8861	There are 8861 days to be shared/chosen to be fished either by longlining (<100), jigging or trawling (<400hp)
ST<400	0	There are 8861 days to be shared/chosen to be fished either by longlining (<100), jigging or trawling (<400hp)
ST400-1000	0	No effort limitation, assumed to catch less than 4 % cod.
ST>1000	0	No effort limitation, assumed to catch less than 4 % cod.
PT>400	6839	
LL>110	2527	
OPEN	22444	
JIGGERS		There are 8861 days to be shared/chosen to be fished either by longlining (<100) , jigging or trawling $(<400$ hp)

In addition to the effort control, the fleets are supposed to be constrained to a pre-agreed species composition in the catch as indicated in the table below:

Groups of fleets	Fleet	Cod	Haddock	Saithe	Redfish
		%	%	%	%
Group 1	Single trawlers	4.0	1.75	13.0	90.5
Group 2	Pair trawlers	21.0	10.25	69.0	8.5
Group 3	Longliners > 100 GRT	23.0	28.0		
Group 4	Longliners and jiggers > 15 GRT	31.0	34.5	11.5	0.5
Group 5	Longliners and jiggers < 15 GRT	20.0	23.5	6.0	
Group 6	Others	1.0	2.0	0.5	0.5
		100	100	100	100

These restrictions do not take into account that several of these fleets are in fact involved in a multispecies fishery and that the actual species composition in the water is unlikely to be exactly the same as in catches under the regulation. The percentages are guidelines only and it is not expected they will result in discarding and misreporting. They are therefore unlikely to jeopardise one of the eventual potential benefits of an effort management system, an improvement in the quality of the information collected from the fisheries.

Management systems based on effort controls are expected to lead to overcapitalisation in the fishing fleets because vessel owners will want to maximise the catch they can harvest with the fishing effort allocation they have received. In the medium to long term, this process will lead to increased fishing efficiency of the fleets and it will be necessary to decrease the total number of fishing days available to be allocated in order not to exert excessive fishing mortality. In extreme cases, effort controls can lead to the fishery being open only for a few days per year as was the case for the Pacific halibut fishery a few years ago, and remains the case for some Pacific herring fisheries off the Coast of British Columbia.

In order to constrain fishing mortality within reasonable limits, it will therefore be necessary to adjust the number of days periodically. For this purpose, there is a need for a mechanism to monitor changes in efficiency, and detailed information on the activities of the fleets, on the physical characteristics of the boats and their equipment should therefore be collected. In the case of Faroe Plateau cod, the results of medium term simulations presented in ICES 2001 suggest that fishing mortality should be decreased by 25%.

If the intent of fishery management is to control fishing mortality within some limits, it is important that control be exerted on all fleet components generating fishing mortality. In the Faroes, the main tool to control fishing mortality on cod, haddock and saithe is the effort management system and area closures. Single trawlers larger than 400 HP are limited by fishing area and any possible reduction of fishing days would not affect them. As long as they catch less than

4% cod (as is assumed), the mortality they generate may not be problematic. However, since 1999 they have been allocated cod and haddock quotas, and in theory the additional fishing pressure they generate should be compensated by a reduction in the total number of days allocated to other fleets. Although discarding is not believed to be a serious problem in the Faroes, management by catch quotas provides for incentives for such behavior.

There are clear indications that environmental conditions (food availability) are determining cod production (Steingrund and Gaard, in prep.). When productivity is high, as has been the case in 2000 and 2001, high fishing mortalities may not a problem, but when productivity is low, fishing mortalities may have to be reduced in order to avoid potential stock collapse. Having a lower fishing mortality should not decrease yield over the long run, but the size of the fish had been larger, thus giving possibility to get higher export value for the fish products.

2.2.9 Comment on the assessment

New or changed things compared to last years report: The two tuning series used last year (Cuba trawlers and longliners) were not used in this assessment, but only the groundfish summer survey. The face value of the recruitment of the 1999 year class from the initial XSA run, or the RCT3 estimate, was not used, but the highest observed (1982 year class). Thus corresponding fishing mortality was recalculated as well as the stock numbers and biomass at age, spawning stock numbers and biomass at age, total stock biomass and spawning stock biomass, and the yield/SSB ratio.

The short term prediction (Table 2.2.7.1.2) is very dependent on poorly estimated or assumed year classes. The majority of the predicted biomass in 2003 would come from the 1999-2001 year classes, which are either poorly estimated (1999 year class) or assumed to be of average strength (1999 and 2000 year classes). This is a general problem with predictions where no, or very limited information of year class strength is available.

The most important change compared to last years assessment is the perception of recruitment. In last years assessment the recruitment of the 1997, 1998, and 1999 year classes was estimated at 20, 30, and 15 millions, respectively. In the current assessment the figures are changed to 12, 21 and 47 millions, respectively. These revised figures have changed the short time prediction considerably. Although the SSB trend from this year's assessment is very close to that from last year's assessment, the perception of the fishing mortalities in the period 1996-2000 is different because the selection pattern obtained by using the survey in calibration is different from that obtained when using the CPUE series for the Cuba trawlers and the longliners.

Given the high fishing mortality, the perception of recruitment determines the perception of the stock size and future predictions. There are clear indications that environmental factors (food availability) determine cod production and recruitment in the Faroese area (Steingrund and Gaard, in prep.). The 1999 year class, that in current assessment is estimated the highest observed, requires favorable environmental conditions in order to dominate the fishery in the near future. If the environmental conditions should be poor in the coming years, the stock size and catches could be lower than predicted in this report.

2.3 Faroe Bank Cod

2.3.1 Trends in landings and effort

Total nominal landings of the Faroe Bank cod from 1986 to 2001 as officially reported to ICES are given in Table 2.3.1.1 and since 1965 in Figure 2.3.1.1. Landings have been highly irregular from 1965 to the mid 1980s, reflecting the opportunistic nature of the fishery on the Bank, with peak landings exceeding slightly 5 000 t in 1973. The evolution of landings has been smoother since 1987, declining from about 3 500 t in 1987 to only 330 t in 1992 before increasing to 3 600 t in 1997. In 2001, 1 800t were reported from the Faroe Bank. Most of the Faroese catch has been taken by pair trawlers and longliners (Table 2.3.1.2).

The decreasing trend in the cod landings from Faroe Bank lead ACFM in 1990 to advise the Faroese authorities to close the Bank to all fishing. This advice was followed for depths shallower than 200 meters. In 1992 and 1993 longliners and jiggers were allowed to participate in an experimental fishery inside the 200 meter depth contour. For the quota year 1 September 1995 to 31 August 1996 a fixed quota of 1 050 t was set. The new management regime with fishing days was introduced on 1 June 1996 allowing longliners and jiggers to fish inside the 200 m contour. The trawlers are allowed to fish outside the 200 contour.

2.3.2 Stock assessment

Biological samples have been taken from commercial landings since 1974 (the 2001 sampling intensity is shown in the text table below) and from the groundfish survey since 1983. In 2000, an attempt was made to assess the stock using XSA with catch at age for 1992-1999, using the spring groundfish survey as a tuning series (1995-1999) but the WG and ACFM concluded that it could only be taken as indicative due to scarce catch-at-age data. No attempt was made to update the XSA in 2001 nor this year given the poor sampling for age composition particularly for trawl landings. The Working Group considered it unwise to calculate an indicative XSA that could be misleading given the poor sampling of an important gear sector.

Sampling from commercial fleets in 2001 is as follows :

	Samples of length	s, otoliths, and indi	vidual weights of	of Faroe Bank c	od in 2001.
Fleet	Size	Samples	Length	Otoliths	Weights
Longliners	<100 GRT	2	405	60	0
Longliners	>100 GRT	20	3,891	58	59
Jiggers		2	347	120	120
Sing. trawlers	<400 HP	0	0	0	0
Sing. trawlers	400-1000 HP	0	0	0	0
Sing. trawlers	>1000 HP	0	0	0	0
Pair trawlers	<1000 HP	1	251	0	0
hr (1		25	4.026	220	170
l otal		25	4,836	238	179

The Faroese groundfish surveys cover the Faroe Bank and cod is mainly taken within the 200 m depth contour. The catches of cod per trawl hour in depths shallower than 200 meter are shown in Figure 2.3.2.1. The CPUE was low during 1988 to 1995, varying between 246 and 637 kg/tow since 1996. The 2002 value (443.9) is slightly lower than the 2001 one (537.3)

The length distributions in the 1983-2002 surveys illustrated in Figure 2.3.2.2 show substantially higher numbers in 1996-2002 compared to previous years. They also show, that the 1996 year class is extremely weak, since no fish in the size range 40-65 cm in 1998 (2 years old) are observed. In 1999 and especially in 2001 the proportion of small fish is large compared to other years, indicating good recruitment.

Figure 2.3.2.3 shows a positive correlation between the survey index and the landings in the same year. The relatively high survey index in the spring of 2002 suggests that landings in 2002 could be in the order of 2000 tons or more. The ratio of landings to the survey cpue index provides an exploitation ratio (Figure 2.3.2.4), which can be used as a proxy to relative changes in fishing mortality. The results suggest that fishing mortality has decreased over time and is now close to the lowest observed.

A stock-production model was fitted to landings and the cpue from the survey using ASPIC. The software requires starting guesses for r, the intrinsic rate of increase, MSY, B1/ \mathbf{B}_{MSY} ratio and q, catchability coefficients. There was insufficient time to verify the stability of ASPIC to different starting guesses of these parameters, but a retrospective analysis, using progressively shorter time series of data suggest that the results are reasonably stable. The parameter estimates from ASPIC were: MSY = 2672t, \mathbf{B}_{MSY} = 6843t, \mathbf{F}_{MSY} = 0.3905. The 2002 biomass is estimated to be almost twice \mathbf{B}_{MSY} (1.944). However, the resulting estimated fishing mortality rate since 1996 is unrealistically low, and therefore it casts doubts on the other results of ASPIC suggesting that the biomass may be overestimated. The results are presented in table 2.3.2.5 and figures 2.3.2.6, 2.3.2.7 for information.

2.3.2.1 **Comment on the assessment**

An XSA was attempted in the 2000 assessment but not in the current one. The NWWG concludes that the poor sampling for age composition, particularly for the trawler landings whose catch is not separated into Faroe Bank or Faroe Plateau during the same trips. Therefore, XSA is not considered useful until reliable coverage of the total catch at age can be obtained. Similar to 2001, XSA was not attempted in 2002. The ASPIC general production model shows some promise, but further work is needed before it can be used to provide advice.

2.3.3 Reference points

There are no analytical basis to suggest reference points based on XSA or an accepted general production analysis.

2.3.4 Management considerations

The landing estimates are uncertain because since 1996 vessels are allowed to fish both on the Plateau and on Faroe Bank during the same trip, rendering landings from both areas uncertain. Given the relative size of the two fisheries, this is a bigger problem for Faroe Bank cod than for Faroe Plateau cod, but the magnitude remains unquantified for both. The ability to provide advice depends on the reliability of input data. If the cod landings from Faroe Bank are not known, it is difficult to provide advice on landings. If the fishery management agency intends to manage the two fisheries to protect the productive capacity of each individual unit, then it is necessary to regulate the catch removed from each stock. Simple measures should make it possible to identify if the catch is originating from the Bank or from the Plateau e.g. by storing in different section of the hold.

2.4 Faroe Haddock

2.4.1 Landings and trends in the fishery

Nominal landings of haddock from the Faroe Plateau increased from a low of 10,000 t in 1982 to 14,000 t in 1987, but later decreased drastically to the lowest recorded at about 4,000 t in 1993; a slight increase to about 4,600 t was noted for 1995 but in 1996 and 1997 catches almost doubled each year to about 9,200 t and 16,700 t, respectively. In 1998 landings increased further to more than 19,000 t but decreased again in 1999-2001 to about 14,500 t (Table 2.4.1). Nominal landings for 1982–1992 from the Faroe Bank have varied between 500 and 1,600 t (on average 1,000 t), but dropped in 1993–1996 to 300-500 t. The closure of the fishery on the shallower parts of the Bank in 1990 and the introduction of a controlled fishery there since 1993, as described in Section 2.1, reduced the Faroese landings (Table 2.4.2) whereas Scottish landings remained relatively high in 1990-92. However, in the assessment only the fraction of the Scottish catches which have been reported to the Faroese authorities are included. In 1997 and 1998, landings on the bank increased abruptly to 1,300 and 3,000 t, but declined again to about 1,700 tin 2001 and 2002. In some years, minor Faroese catches of haddock are taken in ICES Division IIa close to the boundary with Sub-Division Vb1 (labelled IIa4 in Figure 2.1.15 in ICES C.M., 1997). These catches are believed to be from the Faroe haddock stock and are consequently used in the assessment (Table 2.4.1).

Faroese vessels have taken almost the entire catch in recent years (Figure 2.4.1). Table 2.4.3 shows the Faroese landings since 1985 and the proportion taken by each fleet category. Pair trawlers and longliners took most of the catches in these years and within these two groups the relative importance of the larger vessels has increased. Due to poor catches and poor economic conditions, the effort of most fleets decreased in the early 1990s but from 1995 it has increased again (Table 2.1.4). In addition, the fishing ban on the cod spawning grounds before and during the spawning period of cod since 1992 (Section 2.1) has had a restrictive impact on the haddock fishery as well. The catch rates for most fleets declined drastically after the late 1980s, but from 1995 the CPUE for most fleets has increased considerably with some conflicting signals in recent years (Figure 2.4.9).

The 2001 monthly Faroese landings of haddock by fleet category from Subdivisions Vb1 and Vb2, are shown on Figure 2.4.2. The landings from the Plateau are high from late summer to the end of the spawning time in April and stay low during the summer time. On the Faroe Bank the monthly landings show a similar pattern although the landings in mid winter are small. In 2001, pair trawlers took the majority of the catch on the Faroe Bank followed by the longliners larger than 100 GRT on second place. On the Faroe Plateau the longliner landings are substantial; during the summer months most of the larger longliners fish in deeper waters and/or outside the Faroese EEZ but at this time the proportion taken by the smaller longliners is considerable. From the late 1980s haddock must be characterized as a by-catch only but this has changed for the major fleets since the middle of the 1990s, due to the recruitment of several large year classes.

2.4.2 Catch at age

For the Faroese landings, catch-at-age data were provided for fish taken from the Faroe Plateau and the Faroe Bank. Data from the two areas are combined, as the fish are believed to belong to the same stock. The sampling intensity in 2001 is shown in the text table below. Compared to 2000, number of samples and of individual weightings was higher in 2000 whereas the number of age readings and of length measurements was somewhat lower.

No. of samples:	411
No. of length measurements:	61690
No. of individual weight measurements:	3538
No. of aged fish:	6182

Samples from each fleet category were disaggregated by season and then raised by the catch proportions to give the 2000 catch at age in numbers for each fleet (Table 2.4.4). Catches of some minor fleets have been included under the others heading. No catch-at-age data were available from other nations fishing in Faroese waters. Therefore, catches by UK and France trawlers were assumed to have the same age composition as Faroese otter board trawlers larger than 1,000 HP. The Norwegian longliners were assumed to have the same age distribution as the Faroese longliners greater than 100 GRT. The most recent data were revised according to the final catch figures. The resulting total catch at age in numbers is given in Tables 2. 4.4 and 2.4.5 and in Figure 2.4.3 the LN (catch at age in numbers) is shown for the whole period of analytical assessments.

The standard procedure for this stock to include all fish age 10 and older into a plus group was questioned last year by ACFM and the WG. The catch at age was inspected this year in a Separable VPA and although in some years there are some large residuals for the youngest and oldest age groups it was concluded that there were no obvious reason to change the default age range. Moreover, these age groups should be better estimated this year due to a larger age range in the tuning series used in the XSA.

In general the catch at age matrix in recent years appears consistent except for the year class from 1996. The number at age 3 in 1999 is relatively high but at age 4 and older this year class turns out to be small. It was not possible to solve this out except for the fact that most of the catch in 1999 was taken by the smaller longliner fleet below 100 GRT in the last 4 months of the year indicating a possible depletion of local aggregations of 3 years old haddock. This is not the whole explanation since also the mean weight at age for this year class is developing atypical for age 2 and 3; in the summer groundfish survey used for tuning age 3 in 1999 also is unbelievable high. There could therefore be some problems in the age readings and/or calculation of catch at age for this year class possible due to poor sampling and an erroneous smoothing of the ALK. This will be further investigated before the next meeting of the WG but since the year class is a small one this problem will most likely only affect the final assessment to a small degree.

2.4.3 Weight at age

Mean weight-at-age data are provided for the Faroese fishery (Table 2.4.6). Figure 2.4.4 shows the mean weights-at-age in the landings for age groups 2-7 since 1976. After a decrease from a high level in the middle of the 1990s for all age groups in the most recent years, the weights have increased again for all ages except for the youngest ages.

2.4.4 Maturity at age

Maturity-at-age data were available from the Faroese Spring Groundfish Surveys 1982–2002. The surveys are carried out in February-March, so the maturity at age is determined just prior to the spawning of haddock in Faroese waters and the determinations of the different maturity stages should be relatively easy. In order to reduce eventual year-to-year effects due to possible inadequate sampling and at the same time allow for trends in the series, a 3-year running average has been used by the WG in the assessment. For the years prior to 1982, average maturity at age from the surveys 1982–1995 was adopted (Table 2.4.7 and Figure 2.4.5).

2.4.5 Assessment

2.4.5.1 Tuning and estimates of fishing mortality

Although several commercial catch per unit effort series are available, only two commercial series (see below) were used for tuning of the assessments in 2000 and 2001. Two annual groundfish surveys are conducted in Vb1, one carried out in February-March since 1982 (100 stations per year down to 500 m depth), and the other in August-September since 1996 (200 stations per year down to 500 m depth). Due to problems with the database, it has not been possible to update the survey indices (stratified mean number at age) since 1999 and a major revision of the data in the database prior to 1999 is necessary before the existing data can be relied upon. This work is ongoing and has been given a very high priority since the last WG meeting. But since this is a very demanding work only the short summer survey series is available this year (see under section 2.2). However, biomass estimates (kg/hour) are available for both series. It is expected that the spring survey series back to 1994will be available for next years assessment; before 1994 the technical

equipment was very different from now both regarding sampling and recordings of data onboard the research vessel and regarding format of data files and database making the revision of the earliest data difficult. Since lack of reliable survey indices has a major impact on the estimation of recent and future recruiting year classes which again deteriorates the current estimate of stock status and the short term predictions, it is regarded as a major step forward that the summer survey now is available.

In tuning of this stock it has been standard to combine all available series in one tuning files. Recently it has been brought up that this is not a wise thing to do, and in general the use of commercial cpue series has been questioned (see f.ex. Section 2.4.9). Therefore the WG decided to make several runs using different combinations of series and with each series separately. Also different shrinkages were applied. Retrospective runs for many of these exercises are shown in Figure 2.4.6, and ranges of results are given below in the text as well as in Table 2.4.8 and in Figure 2.4.7. Since the main difference the runs is the recruitment estimates, the WG decided to present detailed XSA diagnostics and VPA results from the run with the summer survey only using catchability independent of stock size for all ages (in recent years this has been dependent on stock size for ages younger than 3) and a shrinkage of 2.0 as has been usual for this stock in recent years (except last year when shrinkage was set at0.5) (Table 2.4.10). Figure 2.4.8 shows the log catchability residuals for ages 2-8; age 9 was very noisy and left out. Age 1 was included in the tuning although it is not in the commercial catch at age matrix. The importance of this survey as indicator of stock abundance at age is reflected in Figure 2.4.8B, where the LN (stratified mean catch at age in numbers) for all year classes in the series is shown.

The two commercial series used for tuning of last years VPA (and which have been used this year in evaluations of the performance of the summer survey) consist of a longliner series consisting of the logbook data from 5 selected longliners larger than 100 GRT (directed effort measured as number of hooks) and a trawler series consisting of logbook data (catch at age in numbers and corresponding effort in number of trawl hours) from a homogenous group of pair trawlers larger than 1 000 HP which have been engaged in a mixed saithe, cod and haddock fishery since the middle of the 1980s (Table 2.4.9). Basically the series are the same as used last year (updated), and descriptions and analysis of them have been given in former reports of this WG and will not be repeated here.

Plots of age aggregated cpue's (kg/hour) for the two commercial series and for the two surveys are given in Figures 2.4.9A and 2.4.9B showing some conflicts in recent years. The two survey series are however very consistent.

The fishing mortalities from the final XSA run are given in Table 2.4.11 and in Figure 2.4.10. According to this the fishing mortality has shown an overall decline since the early 1960s and it has been estimated to be below or at the natural mortality of 0.2 in several years from the late 1970s. Since 1993 it has been increasing again and in 1998 and 1999 it was estimated above 0.5, but decreased in 2000 and 2001 to 0.32 and 0.38, respectively. In comparisons all the runs with different fleets and different shrinkages gave fishing mortalities in the range of 0.3 to 0.5 (Table 2.4.8)

2.4.5.2 Stock estimates and recruitment

Compared to recent assessments, last years assessment changed the perception of stock size (and fishing mortality) considerably; this year's assessment is consistent with the view presented in the 2001 assessment. The stock size in numbers is given in Table 2.4.11 and a summary of the "VPA" with the biomass estimates is given in Table 2.4.13 and Figure 2.4.810. According to this assessment, the spawning stock biomass decreased from 66 000 t in 1987 to 22 000 t in 1994, increased to 85 000 t in 1997 but have since decreased to about 53 000 t in 2000. In 2001 it increased again to 58 000 t. The decline in the spawning stock began in the late 1970s due to very poor recruitment in those years. The stabilization at relatively high SSB's in the mid-1980s was due to the relatively good 1982 and 1983 year classes, but the decline since then was partly due to poor year classes since the mid-1980s, as well as the pronounced decline in the mean weights at age in the stock. The main reason for the very abrupt increase in the spawning stock biomass is the recruitment and growth of the outstandingly large 1993 year class and the well above average 1994 year class. The most recent increase in the spawning stock is due to new strong year classes entering the fishery. Last year there were considerable doubts about the sizes of these incoming year classes, especially the 1998 year class, which came out very high from the XSA. Due to the lack of reliable recruitment indices it was decided to replace it with the geometric mean of the 1980-2000 recruitments at age 2. This years XSA shows that this decision was rather conservative but it also gives a very high estimate for the most recent year class at age 2, i.e. the 1999 year class. Since recruitment indices now are available from the summer survey, it was decided to use them in a Rct3-analysis to come up with another estimate of this year class. Although the summer series is very short (6 years), the correlation between it and the converged VPA was high, and it was decided to use the point value from the Rct3 (Table 2.4.11-13) in stead of the XSA value; the number at age 2 in 2001 was therefore reduced from above 90 millions to 44 millions. All other values in this year (Total biomass, Spawning stock biomass, fishing mortality, Y/SSB) were adjusted accordingly (Tables 2.4.11-13). In comparison, all the different runs presented in Table 2.4.8 gives the range 47-120 millions for this year class at age 2. The present approach could therefore seem to be rather conservative but seems more reliable than the one last year.

2.4.6 Prediction of catch and biomass

2.4.6.1 Input data

2.4.6.1.1 Short-term prediction

The input data for the short-term predictions are given in Table 2.4.14-15. The year classes up to 1998 inclusive are from the final VPA, the 1999-2000 year classes at age 2 are estimated using Rct3 and the 2001-2002 year classes are the geometric mean of the 2 year olds in 1980-2002. Age 3 in 2002 is estimated from the Rct3 age 2 value and calculated forward using standard XSA equations. Input to and result of the Rct 3 analysis are given in Tables 2.4.16-17.

The exploitation pattern used in the prediction was derived from averaging the 1999–2001 fishing mortality matrices from the final VPA and then rescaling the averages to 2001. Since the smallest on record year class from 1991 comes out from the VPA with very high fishing mortalities at age 6 and 7 and this will have a large impact on prediction of future biomasses and catches, this year class was omitted from the averaging. The same exploitation pattern was used for all three years.

The mean weight at age for ages 2-10 in 2002 was calculated as the average weight at age in 1999-2001. Inspecting the growth of the different year classes it was decided to replace the value for age 6 in 2002 with the value for age 6 in 2001. The 2002 mean weights at age were also applied for 2002 and 2003. The same weights at age were used for the catch and for the stock as was done in the assessment.

The maturity ogives for 2002-2004 are based on samples from the Faroese Groundfish Spring Surveys and estimated as the average of the smoothed 2000-2002 values.

2.4.6.1.2 Long-term Prediction

The input data for the long-term yield and spawning stock biomass (yield per recruit calculations) are listed in Table 2.4.18. Mean weights-at-age (stock and catch) are averages for the 1977–2001 period. The maturity ogives are averages for the years 1982-2001. The exploitation pattern was derived from the fishing mortality matrix from the final VPA as average F-values for the long time period, rescaled to the 2001 F_{bar} (age3-7).

2.4.6.2 Biological reference points

The yield- and spawning stock biomass per recruit (age 2) based on the long-term data are shown in Table 2.4.18 and Figure 2.4.10. F_{max} and $F_{0.1}$ are indicated here as 0.51 and 0.19, respectively. From Figure 2.4.11, showing the recruit/spawning stock relationship, and from Table 2.4.19, F_{low} , F_{med} and F_{high} were calculated to be 0.05, 0.24 and 0.81, respectively.

In previous assessments of this stock the Minimum Biological Acceptable Limit (MBAL) was set at 40 000 t because the occurrence of good recruitment is considerably higher when the spawning stock biomass is above this value (Figure 2.4.11). Therefore, this is an appropriate value for a limit reference point and thus, B_{lim} is set by ACFM at 40 000 t. In the 1998 assessment, the B_{pa} was calculated as the value lying 2 standard deviations above B_{lim} , that is 65 000 t. By examining among other things the SSB-R plot, ACFM instead proposed $B_{pa} = 55 000$ t. The reference point F_{pa} was proposed by ACFM as the F_{med} value 0.25. The F_{lim} is defined to be two standard deviations above F_{pa} and was set by ACFM at 0.40. By inspecting the VPA results for the whole series, the NWWG felt this proposal to make sense, as the recruitment in the last two decades has been very low with occasional big year classes. However, if recruitment returns to the levels seen in the 1960s and 1970s, when the stock apparently could withstand high fishing mortalities, this proposal might be too conservative, and there are some indications of such a trend.

The history of the haddock fishery in relation to the four reference points can be seen in Figure 2.4.12. In the period 1961-69 the fishing mortality was above F_{lim} and the spawning stock biomass was below B_{pa} . Then the fishing mortality decreased and the stock biomass increased resulting in the stock/fishery was within or close to biological safe limits in most of the 1970s and 1980s. In 1989 the stock went below Bpa and continued to decrease below B_{lim} in 1991. This decrease in SSB continued until the lowest observed SSB was reached in 1994. The biomass has since increased, mainly due to the outstanding high 1993 year class and the well above long term average 1994 year class and has since been above or close to. The fishing mortality has however been above F_{pa} since 1996, was even above F_{lim} in 1998 and 1999 and is now estimated just below Flim.

2.4.6.3 **Projections of catch and biomass**

2.4.6.3.1 Short-term prediction

In the light of the performance of the new management system, it is not unrealistic to assume the same fishing mortalities in 2002 as in 2001 because the fleet is the same and so is the number of fishing days per fleet. The catch in 2002 is then predicted to be about 21 000 t and continuing with this fishing mortality will result in a 2003 catch of 18 000 t. The SSB will in this case decrease from 63 000 t in 2002 to 57 000 t in 2003, and 50 000 t in 2004. The results of the short-term prediction are shown in Table 2.4.20. This prediction should be interpreted cautiously given the apparent poor estimation of recruitment and the changes in estimations of recent terminal fishing mortalities. If stock size and landings in 2000 (and 2001) are compared, the predicted 2002 landings seem too high.

The overall cpue from the survey supports the development of the SSB in recent years (Figure 2.4.9). However, this series is more optimistic regarding the two latest years than the current assessment.

2.4.7 Medium term projections

Medium term projections were made last year and not repeated in this assessment.

2.4.8 Managements considerations

Stock and yield are highly variable due to fluctuations in recruitment, especially when fishing mortality is high. Although the stock with present favorable environmental conditions appears to be able to produce enough recruits to stay above B_{pa} this is not expected to sustain with fishing mortality continuously above the F_{pa} ; from the short term prediction this year the stock is predicted to decrease below B_{pa} in the short term .In order to gain yield in the long term and to stabilize yield, fishing mortality should be lowered from recent high levels to below F_{pa} ; juvenile and young fish area closures should be introduced for all gears capable of catching these fishes.

2.4.9 Comments on the assessment

This year assessment indices from commercial fleets were not used for tuning of the VPA. This decision was based on retrospective patterns statistic diagnostics from the XSA and the fact that these series do not have good information on some ages, especially the youngest. Also the results from the working group on Icelandic cod in autumn 2000 and a recent study by Guðmundsson and Jónsson (Working document no. 31) revealing marked trend in catchability in cpue series from commercial fleets were taking into account. Indices from commercial fleets are still very valuable even if they are not used directly for tuning of the VPA and they are as such an important source of information on the state of the stock. They gave the same main message in the assessment as the survey but in a situation where they would show opposite trends it would demand thorough investigation of both the survey and the cpue indices.

Even if the summer survey series is very short it gives very valuable information on recruitment and those the present assessment is thought to be more reliable than in recent years. However, for comparison many results and retrospective patterns are presented in the report from runs with other fleets and different fleet combinations. The Aspic software was applied on this stock using the yearly kg/tow from both surveys as indices of stock size (Table 2.4.13). The results are comparable to the accepted VPA.

Compared to the predicted values last year regarding recruitment, exploitable biomass (ag2+), spawning stock biomass and fishing mortality for 2001, this years estimate for 2001 of recruitment is 366% higher, exploitable biomass is 162% higher, spawning stock biomass is 142% and fishing mortality 20% lower. The main reason for these discrepancies is the poor estimation of recruitment to this stock. The use of the new summer survey series in the tuning of the VPA and in prediction of future recruitment has – even if it is very short – is believed to make this years assessment and predictions more reliable. When some more years are added to the summer survey series and when the spring survey will be available the consistency of the stock assessments between years is expected to improve considerably.

2.5 Faroe Saithe

2.5.1 Landings and trends in the fishery

Nominal landings of saithe from the Faroese grounds (Division Vb) have been highly variable since 1960 ranging from 10 000 t to 60 000 t over that period. In 1990 record high landings of about 60 000 t were taken. Thereafter landings

declined steadily to 20 000 t in 1996. Since then landings have increased to 39 000 t in 2000 and to 51 800 tonnes in 2001 (Table 2.5.1.1, Figure 2.5.1.1).

With the introduction of the 200 miles EEZ in 1977, saithe has mainly been fished by Faroese vessels. The principal fleet consists of large pair trawlers (>1000 HP), which have a directed fishery for saithe, accounting for about 60% of the reported landings in 1993-2001 (Table 2.5.1.2). The smaller pair trawlers (<1000 HP) have a more mixed fishery and they account for about 20% of the total landings of saithe in 1993-2001. During the last decade the proportion of saithe in the catches has generally increased for larger pair trawlers and larger single trawlers (>1000 HP) but decreased for the smaller pair trawlers and jiggers. Other vessels only have small catches of saithe as by-catch.

The CPUE derived from the Cuba pair trawlers, with effort in hours fished, is not affected by the problem with fishing days because the effort comes from logbooks rather than from the landing slips and also because of direct contact with captains of the boats involved. The effort for Cuba Beta pair trawlers, witch is used as tuning fleet, increased by about 5% in 2001.

Catches used in the assessment are presented in Table 2.5.1.1. These include foreign catches that have been reported to the Faroese Authorities but not officially reported to ICES. Catches in that part of Subdivision IIa which lies immediately north of the Faroes have also been included.

2.5.2 Catch at age

Catch at age is based on length and otolith samples from Faroese landings of jiggers, small and large single and pair trawlers, and landing statistic by fleet provided by the Faroese Authorities. Catch at age was calculated for each fleet by four-month periods, before the numbers were combined. Catch at age was thereafter raised by the foreign catches. The catch-at-age data for previous years were also revised according to the final catch statistics (Tables 2.5.2.1 and 2.5.2.2). The sampling intensity in 2001 was similar to that in 2000:

Fleet	Samples	Lengths	Otoliths	Weights
Jiggers	8	1608	180	180
Single trawlers 1000 – 1499 HP	2	374	60	60
Single trawlers 1500 - 1999 HP	8	1430	300	300
Single trawlers > 2000 HP	10	2134	90	60
Pair trawlers 400 – 699 HP	2	396	60	60
Pair trawlers 700 – 999 HP	21	4737	420	360
Pair trawlers 1000 – 1499 HP	128	27104	3237	3177
Total	179	37783	4347	4197

2.5.3 Weight at age

Mean weights at age have varied by a factor of about 2 during 1961-2001. For example, the mean weights at age 5 varied between about 1.6 kg and 3.3 kg while at age 7 it varied between 2.6 kg and 5.3 kg (Table 2.5.3.1 and Figure 2.5.3.1). Mean weights at age were generally high during 1980-86 and dropped in the period 1987-1991. The mean weights increased again in the period 1992-96 but have shown a general decreased since. The SOP for 2001 was 100%.

2.5.4 Maturity at age

Maturity at age data is available from 1983 onward. Due to poor sampling in 1988 the proportion mature for that year was calculated as the average of the two adjacent years. A model was used, described in the 1993 Working Group report (ICES C.M.1993/Assess:18), for predicting maturity at age in order to alleviate some of the problems involved with the sampling data. The basic model used was a GLM with a Logit link function describing maturity at age as a function of age, year class strength, mean weight at age and a year effect. This model was applied to predict the entire maturity at age for 1983-2001 (Table 2.5.4.1 and Figure 2.5.4.1).

2.5.5 Stock assessment

2.5.5.1 Tuning and estimation of fishing mortality

The results of a summer survey initiated in 1996 were investigated as a possible index of stock size to calibrate XSA. The survey showed relatively good internal consistency up to age 10 vs age 11. Total mortality estimates (5+/6+, 6+/7+, 7+/8+) all showed very low total mortality over the period 1998 to 2001 suggesting that availability to the survey may have increased during that time. Survey population estimates at age 3, 4 and 5 were particularly large.

Various settings were investigated in the XSA, but using the default with ages 3 to 9 was presented for discussion. The standard errors of the log q residuals were high for ages 5 to 9, there was a marked trend in residuals and the Working Group concluded that the survey results used could not be considered a reliable index of stock size at this time. Reliable survey results would be particularly useful to estimate recruitment and the Working Group recommends that the survey data be further investigated, e.g. by excluding particularly large sets from the calculation of population estimates.

One tuning series has been used in the XSA since 2000. The series was introduced in 1998 (ICES C.M. 1998/ACFM:19), and consists of saithe catch at age and effort in hours, referred to as the Cuba Logbook series. The series extends back to 1985 and consists of data from 8 pair trawlers greater than 1000 HP (Cuba trawlers) which specialize in fishing on saithe and account for 5 000-8 000 t of saithe each year. In the Cuba Logbook series, information for each haul was supplied and only those hauls where saithe contributed more than 50% of the total catches of cod, haddock and saithe were used (Table 2.5.5.1).

The final XSA run in the current assessment was made with the same parameters as in 2001. The CPUE series used are shown in table 2.5.5.1. The XSA diagnostics are in Table 2.5.5.2 and the output from the XSA is presented in Tables 2.5.5.3-5. The values of S.E. (log q) are high, but for the principal year classes they appear reasonable. The log catchability residuals from the XSA tuning for age groups 3 and 5-11 (Figure 2.5.5.1) show more negative values in the first eight years than in the last nine years of the 17 years time series.

Retrospective analysis of the average fishing mortality for age groups 4-8 years (Figure 2.5.5.2) shows a tendency to overestimate F. This implies that biomass was correspondingly underestimated (Figure 2.5.5.3).

The fishing mortalities for 1961-2001 are presented in Table 2.5.5.3 and in Figure 2.5.5.4. The average fishing mortality for age groups 4-8 was 0.36 in 2001.

2.5.5.2 Stock estimates and recruitment

Recruitment in the 1980s was above or close to average (28 millions). The strongest year class since 1986 was produced in the 1990s and the average for that decade is about 39 million (Figure 2.5.5.5). Even though recruitment had been above average in the 1960s and 1970s, SSB declined from nearly 112 000 t in 1985 to 71 000 t in 1991 as a result of high fishing mortality yielding the highest (1990) and third highest (1996) landings of the whole 1961-2001 period. The historically low SSB persisted in 1992-1995 (Table 2.5.5.5 and Figure 2.5.5.6). The SSB has increased since 1996 with the maturation of the 1992, 1994 and 1996 year classes. SSB was estimated to be 137 000 t in 2001, which is an increase of 13 000 t compared to 2000, and well above the average SSB (94 000 t) in the 1980s. The relation between stock and recruitment is showed in Figure 2.5.5.7.

2.5.6 Prediction of catch and biomass

2.5.6.1 Input data

Input data for prediction with management options are presented in Table 2.5.6.1 and input data for the yield per recruit calculations are given in Table 2.5.6.2.

The size of the 1996 and 1998 year classes from the calibration were both higher than the highest observed. Both the survey and the commercial cpues indicate that these year classes are very abundant. Their sizes were reset to approximately the highest observed (1983 year class at age 3 in $1986 = 61\ 000$) and the fishing mortality in 2001 on those year classes was adjusted accordingly.

Population numbers for the short term prediction up to the 1998 year class are from the final VPA run whereas values for the 1999-2001 year classes are the geometric mean of the 1977 to 1998 year classes. Mean weights for the stock and

for the catches are the same for 2002-2004, the arithmetic mean for 1999-2001. In the long term prediction (yield per recruit) mean weights for 1961-2001 were used.

In the short term prediction the fitted proportion mature values from the model for 2002 were used for that year and for 2003 and 2004 the average of fitted values for 2000-2002 was used. In the long term prediction the average of fitted values for 1983-2002 was used.

For all three years in the short term prediction the average exploitation pattern in the final VPA for 1999-2001, rescaled to Fbar (ages 4-8) in 2001, was used. In the long term prediction the exploitation pattern was set equal to the average of exploitation patterns for 1961-2001.

2.5.6.2 Biological reference points

Yield per recruit and spawning stock biomass per recruit curves are presented in Figure 2.5.6.1. Compared to the 2001 average fishing mortality of 0.38 in age groups 4-8, \mathbf{F}_{max} is 0.42, $\mathbf{F}_{0.1}$ is 0.16, \mathbf{F}_{med} is 0.35 and \mathbf{F}_{high} is 0.82 (Table 2.5.6.3, Figure 2.5.6.1 and Figure 2.5.6.2).

Yield and spawning biomass per Recruit F-reference points:

	Fish Mort	Yield/R	SSB/R
	Ages 4-8		
Average Current	0.378	1.499	3.439
\mathbf{F}_{\max}	0.422	1.501	3.091
$F_{0.1}$	0.161	1.337	7.106
F _{med}	0.346	1.495	3.739

ACFM set $\mathbf{F}_{lim} = 0.40$ and $\mathbf{F}_{pa} = 0.28$ (May 1998), and $\mathbf{B}_{lim} = 60\,000$ t and $\mathbf{B}_{pa} = 85\,000$ t (May 1999). The current assessment (Table 2.5.5.5 and Figure 2.5.5.4) shows that fishing mortality has averaged 0.32 over the time period, that F has been above \mathbf{F}_{lim} in 12 out of 41 years (29%) and consistently above \mathbf{F}_{pa} since the early 1980s. There does appear, however, to have some relationship between fishing mortality and SSB with lower SSBs associated with higher fishing mortality (Figure 2.5.6.3). When fishing mortality and SSB are plotted versus time (Figure 2.5.5.4 and 2.5.5.6), initially, both F and SSB increase at the same time. SSB peaks in 1972 and subsequently decreases until 1981 while fishing mortality continues to increase. The brief increase in SSB in the early 1980s occurred at F in the order of 0.40. The 1983 to 1985 year classes were all relatively strong. Yet they did not result in substantial increases in SSB, because of high fishing mortality. Medium term simulations done during the 2001 NWWG meeting showed either stable SSB or slightly decreasing SSBs at F status quo (0.41) with a negligible probability that SSB would fall below \mathbf{B}_{lim} . Therefore, fishing mortalities in the order of 0.40 do not appear associated with a high probability of stock collapse. Given the history of the stock and the possible influence of changes in productivity on Faroese stocks, the average fishing mortality over the time period (F = 0.32) could be considered as an appropriate \mathbf{F}_{pa} , with \mathbf{F}_{lim} derived using the usual formula of $\mathbf{F}_{lim} = \text{Fpae1}^{-645xs}$ where s could be 0.30, implying $\mathbf{F}_{lim} = 0.53$.

The stock and recruitment relationship for Faroe saithe (Figure 2.5.5.7) shows a pattern somewhere in-between types 2a and 3a identified by the SGPA, i.e. generally increasing recruitment as SSB decreases with some smaller recruitment at the lowest SSB. Given this pattern, it is not possible to identify with any certainty the SSB below which recruitment becomes impaired. Using the lowest SSB as \mathbf{B}_{lim} would probably be overly conservative while using it as \mathbf{B}_{pa} may be somewhat risky. Given the difficulties in identifying the biomass where recruitment becomes impaired, the equilibrium SSB corresponding to \mathbf{F}_{pa} above could be used as \mathbf{B}_{pa} and \mathbf{B}_{lim} could be calculated using the usual formula $\mathbf{B}_{lim} = Bpae1^{.645xs}$ where s could be 0.30.

Although the WG recognises that the existing biological reference points are not appropriate, there was insufficient time to do the complete set of analyses necessary to make firm proposals for new reference points. In addition, given the management regime in effect in the Faroese demersal fisheries, the reference points for the three main species, cod, haddock and saithe, should be re-evaluated at the same time. Until more appropriate reference points are identified and adopted, the existing ones could continue to be used, albeit with some flexibility in the formulation of management advice.

The history of the stock/fishery in relation to the four reference points can be seen in Figure 2.5.6.3.

2.5.6.3 **Projection of catch and biomass**

Results from predictions with management option are presented in Table 2.5.6.4 and Figure 2.5.6.1. Catches at status quo F would be 54 000 t in 2002 and 57 000 t in 2003. The spawning stock biomass would increase from 141 000 t in 2002 to 144 000 t in 2003, substantially above \mathbf{B}_{pa} in both years.

Results from the yield per recruit estimates are shown in Table 2.5.6.3 and Figure 2.5.6.1.

A projection of catch in number by year classes in 2002 and weight composition in SSB by year classes in 2003 is presented in Figure 2.5.6.4. The catch in 2002 is predicted to rely on the three most recent year classes (76%) that all may be poorly estimated. In 2003 the 1996 and 1997 year classes are expected to contribute almost half the SSB. This may be a reminder that one has to be cautious regarding the reliability of the short term prediction, because of the uncertain estimate of the 1997 and 1998 year classes.

2.5.7 Management considerations

The spawning stock biomass has increased to above \mathbf{B}_{pa} and is expected to remain above \mathbf{B}_{pa} at status quo fishing mortality, due to good recruitment in the short term.

2.5.8 Comments on the assessment

The XSA settings and tuning fleets are the same as last year.

There still is no independent recruitment index to predict recruits in the first year in the short term prediction. Attempts have been made to establish a programme for echo sounding and biological sampling of age group 0-2. However this needs to be developed further and consequently no results are available at this stage. It has been suggested by NWWG that an attempt should be tried to analyse the correlation between survey index and stock in number from VPA, principally ages 2 and 3.

The question of migration has been brought up previously. Although tagging data indicates that saithe migrate between management areas, and some indications are seen in the assessment as well, no attempts have been made to quantify the migration rate of saithe. An analysis of saithe otoliths using otolith elemental fingerprinting (OEF) between management areas in the North Atlantic is initiated by Iceland, which hopefully will add valuables information of saithe stocks in the north Atlantic and migrations between management units.

The 2002 assessment has been calibrated in a way very similar to the 2001 assessment. The results indicate that biomass is higher than was estimated in the 2001 assessment (2001 SSB = 125000t compared with 89000t) and that fishing mortality is lower. In the 2001 assessment, recent year classes were assumed to be equal to a geometric mean of recent year classes. In the 2002 assessment, the estimates from the XSA calibration, adjusted down to the highest previously observed, were used.

1) Including catches from Sub-division Vb2. Quantity unknown 1989-1991, 1993 and 1995-2001.

2) Provisional data

3)From 1983 to 1996 catches included in Sub-division Vb2.

4) Includes catches from Sub-division Vb2 and Division IIa in Faroese waters.

5)Includes French and Greenlandic catches from Division Vb, as reported to the Faroese coastal guard service

6) Reported as Division Vb, to the Faroese coastal guard service.

7) Reported as Division Vb.

8) Includes Faroese landings reported to the NWWG by the Faroese Fisheries Laboratory

Table 2.4.2 Faroe Bank (Sub-division Vb2) HADDOCK. Nominal catches (tonnes) by countries,

1982-2001, as officially reported to ICES, and the total Working Group estimate in Vb2.

¹ Preliminary.

² As from 1991.

³ Quantity unknown 1989-91.

⁴ Includes catches from Sub-division Vb2 and Division IIa in Faroese waters.

⁵ Includes French, Greenlandic, Russian catches from Division Vb, as reported to the Faroese coastal guard service.

⁶ Includes Faroese, French, Greenlandic catches from Division Vb, as reported to the Faroese coastal guard service.

3 DEMERSAL STOCKS AT ICELAND (DIVISION VA)

3.1 Regulation of Demersal Fisheries

With the extension of the fisheries jurisdiction to 200 miles in 1975, Iceland introduced new measures to protect young juvenile fish. The mesh size in trawls was increased from 120 mm to 155 mm in 1977. Mesh size of 135 mm was only allowed in the fisheries for redfish in certain areas. In addition a system was implemented whereby fishing can be forbidden immediately in areas where the number of small fish in the catches exceeds a certain percentage (25% < 55 cm for cod and saithe and 25% < 48 cm for haddock). These areas have usually been closed for two weeks and can be extended in time and space if necessary.

A system of transferable boat quotas was introduced in 1984. The agreed quotas were based on the Marine Research Institute's TAC recommendations, taking some socio-economic effects into account. Until 1990, the quota year corresponded to the calendar year but at present the quota, or fishing year, starts on September 1 and ends on August 31 of the following year. This was done to meet the needs of the fishing industry.

Adoption of a Harvest Control Rule for the Icelandic cod stock in 1995

In May 1995, the Icelandic government adopted a Harvest Control Rule (HCR) for the Icelandic cod fishery, based on work carried out by a government appointed group of fisheries scientists and economists (Anon., 1994; Baldursson *et al.*, 1996; Danielsson *et al.*, 1997). The group investigated the consequences of various long-term harvesting strategies for cod by using risk analysis, taking into account biological and economic interactions between cod and its major prey, capelin and shrimp. The group showed that a harvest rate of 25% of the average fishable (4+) biomass of cod at the start and the end of assessment year with a minimum of 155 thousand tonnes TAC would lead to a low probability of stock collapse, defined as SSB going below 100 thousand tonnes. The government implemented this catch-rule as a Harvest Control Rule in the next five fishing years.

Amendments adopted in June 2000

The assessment of the Icelandic cod stock in the year 2000 showed that the fishable biomass in 2000 had been overestimated by 180 thousand tonnes in the preceding assessment. Based on the 2000 assessment the HCR for the quota year 2000/2001 resulted in a recommended catch of 203 thousand tonnes. This reduction in catch between two consecutive years, which was largely driven by the downward revision in stock estimates, highlighted to the managers the uncertainty in stock assessments and the undesirability of tying a catch rule directly to point estimators in stock assessment. In June 2000 the Icelandic government therefore asked the MRI to explore whether an upper limit of between-year changes in TAC (catch-stabilizer) would jeopardise the original aim of the long-term harvesting strategy imposed by the HCR, with the addition of excluding the 155 thousand tonnes TAC floor.

Under the given time constraint only limited studies were possible. The basic approach taken was the same as that done previously by the working group (Stefánsson *et al.* 1997a; 1997b) and the work was carried out by one of its member. In addition to simulating cod, capelin and shrimp the analysis included two seal species and three species of baleen whales. The same criterion was used for the definition of stock collapse i.e SSB going below 100 thousand tonnes. No density dependent growth in the cod stock was assumed and only limited options of catch developments of whales and seals were explored, but different assumptions will affect the mean catch figures of cod. Fifteen percent CV in stock estimates was assumed. The general conclusion of all base-case trials showed limited sensitivity of introduction of a range of catch-stabilizers (10-60 thous tons). However, when various catch-stabilisers were applied under a regime of drastic reduction in recruitment (half the normal recruitment per SSB), the effects became clear; the lower the stabiliser was fixed, the greater probability of SSB collapse. It appeared that when catch-stabiliser applied was 25 thous tonnes or less, the risk increased significantly, while catch-stabiliser, allowing 30 thous tonnes or higher interannual changes in catches performed far better. In light of these provisional trials, the 30 thous tonnes catch-stabiliser was considered a safe approach.

On the basis of these results the Icelandic government adopted a modification to the HCR by including a 30 thousand tonnes catch-stabiliser and abandoning the minimum catch floor of 155 thousand tonnes. This resulted in a TAC of 220 thousand tonnes for the fishing year 2000/2001 instead of 203 thousand tonnes and 190 thousand tonnes for the fishing year 2001/2002 instead of 155 thousand tonnes if no stabiliser would have been in effect.

At the time of the catch-rule amendment, because of time constrains, detailed alternative simulations were not possible. A working group was set up by the Ministry of Fisheries in 2001 with the objectives to analyse the experience of using the catch rule and try out alternative approaches taking into account obvious shortcomings of the current harvest control

rule and use state of the art knowledge for further development. This working group is supposed to deliver preliminary report before the start of the next fishing year 1 September 2002.

3.2 Saithe in Icelandic waters

3.2.1 Trends in landings

Saithe landings from Icelandic grounds (Division Va) have declined from a peak of 103 Kt in 1991 to close to 30 Kt in the last 4-5 years (Table 3.2.1.1). The Icelandic landings in the quota year September 2000/August 2001 amounted to 31 395 t, or a little more than the national TAC of 30Kt for the same period.

Landings of saithe in the fishing years 2000/2001 and 2001/2002 and in calendar years 2001 and 2002 show that the fishery proceeds at a steady rate, higher catches in the current years than last year are explained by a strike in 2001 (Figure 3.2.1.1).

According to fishermen it has become increasingly difficult to avoid saithe on the fishing grounds when operating in a quota system. At the end of 2001 the ministry of fisheries raised the saithe TAC for fishing year 2001/2002 from 30Kt to 37Kt.

3.2.2 Fleets and fishing grounds

More than three quarters of the catches in 2001 were taken by bottom trawl, 14% in gillnets, 5% on hooks and 2% in Danish seine (Figure 3.2.2.1). The proportion of the catch taken in gillnets has declined from almost a third of the total in 1994 and 1995, while the bottom trawl share has increased. Landings of hook and Danish seine catches were fairly stable in the period 1993-2001.

The main fishing grounds of the bottom trawl fishery are southwest of Reykjanes and off the south east coast (Figure 3.2.7.3) but the gillnet fishery is concentrated on spawning grounds south and southwest of Iceland.

3.2.3 Catch at age

Compared to last years prognosis considerably higher numbers were caught of age groups 3-5 than expected but for other age groups estimated numbers in \underline{CaA} agree with the prognosis made in last years assessment (Figure 3.2.3.1).

Data from samples from most gear types were used to calculate the catch in numbers at age for the total landings in 2001, with the sampling level indicated in the text table below, and used as input for the assessment (Table 3.2.3.1).

Gear/nation	Landings	No. of otolith	No. of	No. of length	No of length
	(t)	samples	otoliths read	samples	measurements
Gillnets	4 514	25	1 158	27	3 224
Jiggers	1 503	5	204	11	1 230
Danish seine	745	2	100	4	701
Bottom trawl	24 211	98	4 646	156	23 398
Other gear	867	-	-	-	-
Faroese jiggers	125	-	-	-	-
Total	31 965	130	6 108	198	28 553

Gillnet catches were split according to a gear-specific age-length key, the rest of the catches were split according to a key based on all samples from commercial gear except those from gill nets. The length weight relationship used was $W = 0.02498 \cdot L^{2.75674}$ for all fleets. Minor revisions were made to the catch at age matrix to account for slightly adjusted landings in 2000 (Table 3.2.3.1 and Figures 3.2.2.2 and 3.2.2.3).

3.2.4 Mean weight at age

Mean weights at age in the landings are computed on the basis of samples of otoliths and lengths along with length distributions and length-weight relationships. The mean weights at age are computed for the same categories as the catch numbers at age and are then weighted together across the fleets. The 1992 year class has had lower than average mean weight as age group 4-9 (Figure 3.2.4.1 and Table 3.2.4.1). Age groups 3-5 have lower mean weight at age in

2001 than the same age groups the year before, while those for age groups 6 and 7 were higher. Weights at age in landings were also used as weight at age in the stock.

3.2.5 Maturity at age

As has been pointed out in earlier reports of this working group, the maturity at age data for saithe can be misleading due to the nature of the fishery and of the species, and inadequate sampling. A GLM model, described in the 1993

Working Group report (ICES. C.M.1993/Assess:18), has been used to explain maturity at age as a function of age and year class strength. This model was used to predict maturity at age for 1980-2001 (Table 3.2.5.1). The maturity at age prior to 1980 is from ICES C.M. 1979/G:6.

3.2.6 Migration of saithe

According to available data approximately 115 thousand saithe were tagged in the NE-Atlantic last century, most of them in the Barents Sea with total returns just under 20 thousand (S. T. Jonsson 1996). At Iceland 6 000 saithe were tagged in 1964-65, the recapture rate being 50% (Jones and Jonsson, 1971). Based on recaptures by area approximately 1 in 500 of tagged saithe released outside Icelandic waters were recaptured in Icelandic waters and 1 in 300 released in Icelandic waters were recaptured in distant waters (S. T. Jonsson 1996). For comparison, cod long term average rate of emigration from Icelandic waters is 1 in 2000 tagged fish (J. Jonsson 1996), a rate almost an order of maginitude lower. Taken at face value, this leads to the conclusion that there is not a significant difference in the rates of semi-trans-Atlantic migrations of saithe east and west. Since there are more saithe in distant waters than on Icelandic grounds the latter might on average be on the receiving end of a NE-Atlantic saithe migratory budget.

Other evidence of saithe migrations exist, albeit of a more circumstantial nature. Sudden changes in average length or weight at age and reciprocal fluctuation in catch numbers at age in different areas of the NE-Atlantic have been interpreted as signs of migrations between saithe stocks (Reinsch 1976, Jakobsen and Olsen 1987, S.T. Jonsson 1996). Since mean weight at age decrease along an approximately NW-SE-NE gradient, migration of e.g. northeast arctic saithe to Icelandic waters will, theoretically, be detectable as a reduction in size at age (Figure 3.2.4.1). Catch curves from some year classes, from different areas show some reciprocal variations. Inspection of the data based on the above indicate that the most likely years and ages for immigration are as follows: Age 10 in 1986, age 7 in 1991, age 9 in 1993 and the 1992 year class as age 7 saithe in 1999 and 8 in 2000.

A tagging program was started in Icelandic waters in 2000. More than 1 700 mostly juvenile saithe, caught with hooks at the nearshore nursery areas were tagged in 2000. The program continued in 2001 when approx. 3 000 saithe were tagged, at the same localities and some new ones. Recapture rates to date have reached more than 5% for saithe released in 2000 (Figure 3.2.6.1), mostly from saithe of approx. 50 cm or more at tagging. The fish tagged in 2000 were mostly from age groups 2 and 3 and therefore less than 50 cm so they are not expected to enter the fishery until autumn 2001. It is planned to continue these taggings for monitoring saithe migrations.

3.2.7 Stock Assessment

3.2.7.1 Tuning input

3.2.7.1.1 Commercial fleets

CPUE data based on Icelandic trawler log books are available from 1970 and from 1988 for the gillnet fleet. To begin with the logbooks were kept on a voluntary basis by skippers of a few vessels, but since 1991 it has been mandatory to keep logbooks, both for the trawling and the gillnets fleets.

With reduced stock size in the 1990s a continuous shift, from effort directed at saithe towards mixed fisheries, has been observed. Traditional analyses using CPUE data from commercial fleets have been based on the criteria of using tows where more than certain percent (50-70) of the catch was saithe. For saithe, big schools of fish are occasionally encountered but the number of schools might decrease with reduced stocksize. To bypass this problem CPUE from all tows and gillnet settings from the most important fishing areas for saithe was calculated. In the 2000 assessment tuning time series analysis (TSA) was tuned with CPUE from the trawler fleet in the period January – May. As fishermen have complained about the way fleets based on logbook information to tune the assessment are set up, when they claim to be avoiding saithe, other commercial fleet alternatives have been studied.

GLM and RAW fleets were set up for Gudmundssons catchability study prior to NWWG2002 (WD31)

- GLM: a 'glm'-index, or the year effect from a multiplicative/general linear model including also fishing vessel, month and location (as statistical square of 1° longitude by 1/2° latitude) of capture.
- RAW: a 'raw'-index, or the annual mean CPUE of the data used as input for the model for the 'glm'-index.

Data from 1985-2001 were chosen as this is covered by the Icelandic GroundFish Survey (IGFS), logbooks and catches. The fishery is year-round, here separate indices are calculated for the periods January-May and June-December. Only one region is used here although in previous exercises using these data the Icelandic shelf has sometimes been split in north and south regions. All vessels operating with a bottom trawl for groundfish reporting to the MRI logbook database were included, both stern trawlers and smaller boats.

'glm'-indices

The 'glm'-indices used in this study were derived in generally the same way as in Stefánsson (1997, 1988) using the multiplicative modelling approach of Gavaris (1980).

The choice of sets, in which the species studied was more than 50% of the catch, for inclusion in the analysis is admittedly *ad hoc*, but this percentage has been used earlier when indices of this type have been used in Icelandic assessments and experience indicates that the results are not very sensitive to the choice of percentage. However the approach has to be modified if all catches, including zeros, are to be included in the analysis.

'raw'-indices

Annual arithmetic averages of the data used as input to the model above were calculated and are used directly as an index of biomass.

It has also been proposed that a set of vessels be chosen, with the criterion of 'not being restricted by quota' when fishing for saithe. A new fleet was set up with this in mind, where each year, the 10 trawlers, who reported the highest saithe catches for a given year, were chosen. CPUE was found for this fleet and others previously considered by NWWG and is shown for all fleets together (Figure 3.2.7.1) where it is apparent that all trawl fleets indices increase from 2000 to 2001 but the gillnet fleets go down. The fleet of top 10 trawlers was studied with respect to measure of central tendency chosen to calculate the index (WD28) The main fishing areas of trawlers remained more or less unchanged in 1993-2001, although saithe is only caught intermittently by trawlers north of Iceland and the area where trawl hauls where saithe are more than half the catch has increased slightly from a low in 1998 (Figure 3.2.7.2).

The problem with commercial tuning fleets is twofold. Fleets based on commercial CPUE age-disaggregated for tuning XSA or TSA have the serious drawback of being auto-correlated with catch in numbers, since it is not possible to age-disaggregate them independently. Further, under a restrictive quota, as for the saithe in recent years, it is probable that some avoidance effect may make a tuning fleet such as the one used in the 2000 assessment of saithe in Va biassed downwards. Use of a biomass index from commercial fleets is a much more attractive alternative, but for that programs different from XSA have to be used, or the TSA modified. As no commercial index has been agreed upon and because of the dangers of catchability changes (see ICES CM 2001/Assess:20, WD31) the use of commercial fleet tuning data in assessment was put off until further studies have been made.

3.2.7.1.2 Survey

Survey indices for saithe around Iceland are highly variable but have now been studied in more detail to be studied in more detail for the purpose of using them in assessment.

In this assessment indices of stratified mean abundance by age group in the IGFS (Icelandic GroundFish Survey) have been greater consideration than previously (Table 3.2.7.1). Length distributions from the survey show distinct peaks for 2-4 year old saithe that can to some extent be tracked from one year to the next (3.2.7.3). The distribution area of saithe in the survey is similar to the major fishing grounds, even showing a parallel in 1993 between distribution in survey and fleet (Figures 3.2.7.4). Catch curves for saithe in the IGFS show that a Z of 0.6 is possibly not far from the truth (Figure 3.2.7.5) and the Shepherd Nicholson model fitted to the survey gives CV=0.6 for ages 2-9 but 0.32 with ages 4 to 8. Residuals from model are shown in Figure 3.2.7.6.

The stratified indices for saithe could not be used for tuning without some doctoring, i.e. the most extreme outlier has been set at the second highest observation. By using medians of age group numbers and multiplying them with the proportion of positive stations, that nuisance might be avoided. Extreme hauls of saithe on the IGFS are rare and it is disappointing to let that prevent us from using information that could be of help in assessment. Although saithe is

among the species with the highest CV in IGFS (Figure 3.2.7.6.), it should be kept in mind that it is possibly 'better to be vaguely right than definitely wrong'. We now tune three models with a survey fleet, that is independent of the catch at age, although somewhat noisy.

3.2.7.2 Estimates of fishing mortality

As has usually be done prior NWWG-meetings, time series analysis (TSA) (Gudmundsson 1994, WD30-32) and XSA were used in preliminary assessment runs of the stock. This year APAPT(tive framework) was also used prior to the meeting (Gavaris 1988, Rivard and Gavaris 2000). TSA run with the same settings as last year gave estimates of $F_{4.9}$ in 2000 of 0.37 and spawning stock biomass (SSB) of 86 Kt at the start of 2001 as compared to $F_{4.9,2000}$ of 0.36 and SSB of 84 Kt estimated in spring 2001.

XSA runs with survey and commercial fleet all had more or less poor diagnostics and it was decided present only one run for comparison with TSA and ADAPT, with emphasis on ADAPT and XSA performance in predicting recruitment, when the two were tuned with the IGFS saithe indices. In the text table below a the range of XSA results for summary statistics in the terminal year can be observed, for commercial and survey XSA tunings, with different fleets, for different seasons and for different number of tuned age groups, but settings otherwise similar to those in previous XSAs of this stock (starting with 11 'commercial' and ending with 5 different survey tunings):

	R3	F	SB (B4+) F4-9	9
glm	Ę	52	275	0.157
top10u50	4	16	269	0.158
glmjundes	4	17	249	0.167
umean	4	17	243	0.184
glmjanmay	4	15	233	0.200
umeanjundes	4	13	223	0.189
umeanjanmay	4	14	221	0.221
glmjanmay5_10	3	38	190	0.239
umeanjanmay5_10	3	39	187	0.262
top10u50t1	3	36	165	0.300
top10u50t2	3	36	163	0.304
smoothsmb	3	36	139	0.396
smb123	3	33	134	0.349
smb	3	32	134	0.342
smb234	2	29	133	0.348
.smb345	2	27	129	0.353

In the ADAPT and XSA comparison the programs were run with settings as close to identical as they permit. Both were run with zero catches for ages younger than those present in the C@A, age range 2-12 in ADAPT, 1-12 in XSA. No plus group was used. As tuning indices we chose age groups in which no zeros occur in the IGFS index matrix, i.e. ages 2-9, which had to be shifted to the end of the previous year in XSA, but were set at the beginning of the year in ADAPT, in order to tune with the most recent survey. Proportional catchability was assumed for all age groups in both models. In ADAPT population weighted mean F_{8-11} was used for calculating the oldest age group. In XSA, tapering was not applied since the IGFS is a standardized survey, which has changed relatively little since it started in 1985. TSA used IGFS data differently, the average of indices at age 3-5 were used as a 'recruitment index' for a year class at age 4, ages 6-8 were used to calibrate the model with C@A.

Retrospective plots of TSA B4+ and F4-9 are shown in Figure 3.2.7.7 and 3.2.7.8, and of N3 from ADAPT and XSA are shown in Figures 3.2.7.9 and 3.2.7.10. Fishable biomass (4+) for the three survey tunings are shown in Figure 3.2.7.11 and an overview of results final results of the three models and a SPALY TSA run are given in the text table below:

	B _{4+,2002} (Kt)	F _{4-9,2001}	N _{4,2002} (millions)	N _{3,2002} (millions)
TSA (SPALY)	127	0.345	21	N/A
TSA (survey)	143	0.334	15	N/A
ADAPT	155	0.36	17	37 (bootstrap bias corrected)
XSA	158	0.33	17	46

Time series analysis were run by Guðmundur Guðmundsson of MRI and Seðlabanki Íslands, the following is his commentary to the saithe TSA runs this year:

'For saithe the variances from the survey are much higher than for cod and haddock and results from a joint analysis with catch-at-age data tend to differ little from results obtained from analysis of catch-at-age data alone.

The best retrospective analyses are obtained by using a linear trend between constant values in the three first and last years as a recruitment index. This is, however, not a very satisfactory arrangement and liable to produce biased results if the trend comes to a halt or changes course. We have found that a fairly accurate recruitment index (at 4 years) is obtained by the average over 3-5 years indices from respective cohort in the survey. Estimates of catchable biomass in 2001 are about 10,000 tonnes higher with this index than the trend. It is highly significant compared with the trend according to the likelihood function. The retrospective analyses in the last years are satisfactory, but actually worse than with the trend further back.

CPUE indices for saithe from trawlers have much lower transitory variations than the survey, but appear to have changed systematically over the time period included here so that the variations represented by λ and δ_{st} are not negligible. Estimates obtained from trawl indices without these terms produce much higher values of catchable biomass than other estimates' (WD30).

On the basis of the above, i.e. that adding a survey index to TSA was a significant improvement and the relatively slight differences between the three survey runs it was decided to keep TSA as the adopted method for the stock, but tune it with survey in the final run. Contrary to what was stated ICES CM 2001/Assess:20 we have now shown that useful indices of recruitment are available for saithe from the IGFS survey. Therefore TSA calibrated with the IGFS is chosen as the final assessment run (WD30) and first estimate of saithe year class strength year class 1998 are based on ADAPT, which performed better than XSA in retrospective prediction of N3.

Continuing the precedence from last years assessment, saithe migration was estimated. The same migration events as in the 2001 assessment were included and estimated again. The years and ages were selected by studying anomalies in length and weight at age data as well as by comparison of Icelandic catch at age data with C@A for Faroese and Norwegian saithe (see also section 3.2.6). The years and age groups chosen were the ones for which the largest discrepancies in catch at age data had been detected in TSA runs. The strength of the migrations was estimated in TSA. The estimates of migrations were (in units of millions): N_{10,86} = 2.3 , N_{7,91}=7.6, N_{9,93}=4.1, N_{7,99}=2.0, N_{8,00}=1.9

It has been observed that Icelandic saithe shows density dependent growth which causes larger year classes to grow slower. Distinguishing between slower growth and migration can at times be tricky as slower growth delays recruitment to the fishery. Even though slower growth is the cause of anomalies in catch at age data, modelling it as migrations is probably better than ignoring them.

Table 3.2.7.2 shows the estimated stock size and fishing mortalities from the selected TSA run along with estimated standard errors. The estimated standard errors are underestimates of the real standard errors. This applies in particular to results using commercial fleet data as these data are strongly correlated with the catch-at-age data. ADAPT results are given in table 3.2.7.3 for comparison. Fishing mortality and stock in numbers from a VPA accounting for migration are given in Tables 3.2.7.4 and 3.2.7.5.

3.2.7.3 Spawning stock and recruitment

The spawning stock biomass is shown in Figure 3.2.7.12 and given in Table 3.2.7.6. After a decline from 1970-1977, the spawning stock biomass averaged between 160-180 Kt in 1978-1989 and increased to about 190 Kt in 1990. Since 1992 the spawning stock biomass has declined to a minimum in 1999-2000 of slightly above 80Kt, which is the lowest SSB recorded. Spawning stock biomass at the beginning of 2002 is estimated at 106Kt.

Estimates of recruitment at age 3 are plotted in Figure 3.2.7.12. The 1983-1985 year classes are all well above the 1962-1998 long-term average of 41 million 3 year old recruits. The 1984 year class was among the highest on record at 78 million recruits. All year classes after 1985 are below the long term arithmetic average. The average size of the 1986-1995 year classes is estimated at only 20 million recruits, which is below the lower quartile of the historic series of recruitment. Recruitment has improved somewhat recently, year classes 1996-1999 are all estimated above the 20 million 3 year olds used a first estimates of recruitment in the 2000 and 2001 assessments (Figure 3.2.7.12). The scatter of SSB and recruitment is shown in Figure 3.2.7.13.

3.2.8 Prediction of catch and biomass

3.2.8.1 Input data

Predicted catch in 2002 is based the quota for the fishing year 2001/2002 which was changed to 37Kt at the end of the year . As the fishery has not escalated (Figure 3.2.1) no overshoot is added. The input data for the catch projections is shown in Table 3.2.9.

Year classes 1999-2001 were set at 30 million 3 year olds, the median recruitment in the period 1962-2001.

For catch predictions and stock biomass calculations, the mean weight at ages 4-9 were predicted using multiple regression analysis where the mean weight at age was predicted by the mean weight of the year class in the previous year and the year class strength. Since the regression analysis showed significant relationships only for the above age groups, the mean weights at age for other age groups were averaged over the 1999-2001 period.

For the short-term predictions, maturity at age was predicted as described in Section 3.2.5. The selection pattern was based on average fishing mortality for 1999-2001, with F8+ set at the average for age groups 8-14. This average was scaled to the reference F of 2001. Median recruitment for year classes 1959-1998 was used for 3 year olds in 2002-2004. Short term prediction based on these inputs is given in Table 3.2.10

For long-term yield and spawning stock biomass per recruit, the exploitation pattern was taken as the average of the fishing mortalities during 1985-2001 from the TSA survey run. Averages over 1985-2001 for maturity and mean weight at age for all age groups were used, along with a natural mortality of 0.2 (Table 3.2.11).

Standard plots for short and long term predictions are shown in figure 3.2.11.

3.2.8.2 Biological reference points

The ACFM has set \mathbf{B}_{pa} at 150 Kt, \mathbf{B}_{lim} tentatively at 90 Kt, and \mathbf{F}_{pa} at 0.3. \mathbf{F}_{lim} has not been set for this stock. The stock is well below \mathbf{B}_{pa} but more than 15Kt above \mathbf{B}_{lim} to according to this assessment. The \mathbf{B}_{lim} reference point is based on the lowest observed SSB but it seems that these spawners are capable of producing at least more recruits than the lower quartile, or the recent low average. The reference points for this stock might need revision. The standard PA-plot is shown in figure 3.2.8.2.

3.2.8.3 Medium term projections

Medium term projections were made last year by the working group (ICES CM 2001/Assess:20).

3.2.9 Management considerations

A further reduction in fishing mortality, of at least 10% is advisable. Reducing fishing increases the probability of lowering fishing mortality to \mathbf{F}_{pa} , and if improved recruitment is observed for incoming year classes so will the likelihood of the SSB reaching \mathbf{B}_{pa} .

3.2.10 Comments on the assessment

In last year's assessment TSA was run on catch at age only, with linear trend in recruitment estimated. This year information from IGFS survey was added to the TSA.

The assessment is uncertain, but shows positive signs. Data not used in the assessment (Figure 3.2.7.1) suggest that the rate of increase in stock size from 1999-2000 to the present might be an underestimate.

Year classes 1996-1999 were set at 20 million 3 year olds in last years assessment compared to 24, 28 and 22 million in the current assessment. Year class 2000 was set at 30 million 3 year olds, although the ADAPT bootstrap bias corrected estimate is 37 million.

Age group 9 in 2001 belongs to the 1992 year class for which migration was estimated in 2000, 2001 and is estimated again in this assessment. That migration has been split on two years, as 7 year olds in 1999 and 8 year olds in 2000. Catch at age 9 in 2991did not exceed prognosis as catches of this year class did the 2 previous years (Figure 3.2.3.1).

ADAPT and XSA performance in estimating N3 was compared with results from retrospective runs indicating that ADAPT performed slightly better. An ADAPT estimate for year class 1999 was used in this assessment.

Three assessment methods were used this year with similar results. ADAPT might be used in the future for estimating recruitment, and possibly be used as the primary assessment tool.

Length-weight relationships are kept the same for both fleets and from year to year in the interest of consistency, a change in the relationship might occur in conjunction with adding weight information to the assessment.

The stock was overestimated until in the 1997 assessment but has been more stable in more recent assessments. It recovering from the lowest observed level at present. The reference F values have been at or above \mathbf{F}_{med} for the whole time series in the assessment, and were higher than \mathbf{F}_{max} in 1993-1995. Recruitment in recent years (the 1986 and more recent year classes) has been below the long term average but year classes 1996-1999 are all estimated higher than 20 million used in projections 2000 and 2001.

Tag returns and stock assessment data indicate migration between saithe stock units in NE-Atlantic, and indications from catch at age have been described (Reinch 1977, Jakobsen & Olsen 1987). Little is known about their magnitude and frequency. Better understanding of saithe biology, e.g. behaviour, recruitment and migrations, is needed. A few new studies on saithe have recently been initiated. The tagging program mention in section 3.2.6 will continue at least in 2001 and 2002, with the addition of electronic tags in 2002. A nordic project setting out to test a hypothesis of migration of the 1984 and 1992 year classes of saithe from east to west in the NA-Atlantic by analysis of otolith chemistry from four saithe stocks managed by Iceland, Faroe Islands and Norway (and EU and Russia) is under way.

3.3 Icelandic cod (Division Va)

3.3.1 Trends in landing

In the period 1978–1981 landings of cod increased from 320 000 t to 469 000 t due to immigration of the strong 1973 year class from Greenland waters combined with an increase in fishing effort. Catches then declined rapidly to only 280 000 t in 1983. Although cod catches have been regulated by quotas since 1984, catches increased to 392 000 t in 1987 due to the recruitment of the 1983 and 1984 year classes to the fishable stock in those years (Table 3.3.1 and Fig. 3.3.1).

During the period 1988-1996 all year classes entering the fishable stock were well below average, or even poor, resulting in a continuous decline in the landings. The 1995 catch of only 170 000 t is the lowest catch level since 1942. In the years 1993 - 1995 a marked reduction in effort against cod was observed (Table 3.3.2 and Figure 3.3.9.A) with the adoption of the HCR. The largest reduction was by the trawlers who diverted their effort to other species and other areas.

From 1995 catches increased continuously to 1999 when the estimated landings were 260 000 tonnes but decreased to 235 000 tonnes in the year 2000 and 2001.

3.3.1.1 Catch in number at age and sampling intensity

The fleet fishing for cod at Iceland operates throughout the year. The fishing vessels are of different sizes but can however be grouped into three main categories: 1) Multi-gear boats; < 300 GRT, 2) Small boats; < 20 GRT, 3)Trawlers; > 300 GRT.

The trawlers operate throughout the year outside the 12 mile limits. They follow the spawning and feeding migration patterns of cod and fish on spawning grounds off the south west and south-coasts during the spawning season but move to the feeding areas off the northwest coast during the summer time. During the autumn, this fleet is more spread out. The multi-gear boats operate mainly using gillnet during the spawning season in winter and spring along the south-west coasts but in recent years this fleet has also used gillnet in late autumn. In the years 1995 to 1998 this fleet increased the mesh size in their nets from 7 to 9 inches but reduced the mesh size back to 8 inches in 1999 and the use of 7 and 8 inches mesh size has been increasing again in the last 2 years (Figure 3.3.3). Part of this fleet uses longlines during autumn and early winter. During summer some of these boats trawl along the coast out to the 3 mile limit. Others fish with Danish seines close to the shore. Most of the smaller boats operate with handlines, mainly in shallow waters during the summer and autumn period.

The data samples comprising the age-length keys for 2001 are given in the following table: The number of samples in gillnets in January-May can be explained by inclusion of gillnet surveys in the numbers.

			Nos. le	Nos. le.	Nos.	Nos.	Nos. age
Gear	Season	Area	measured	samples	weighted	aged	samples
Bottom trawl	Jan-May	North	62622	267	1096	2789	57
Bottom trawl	Jan-May	South	13909	79	1028	1099	21
Danish Seine	Jan-May	North	42	1	0	0	0
Danish Seine	Jan-May	South	3807	25	250	248	5

Gillnet	Jun-Dec	South	3045	18	298	288	6
Total			259082	1332	8878	13687	277

Catch in number at age is calculated by splitting the landings by 5 fleets("metiers"), 2 areas and 2 seasons. The gears are long lines, bottom trawl, gillnets, hand lines and Danish seine, seasons January-May (spawning season) and June-December and regions North and South. Historically, there have been some changes in fleet definitions and thus there does not currently exist a fully consistent set of catch-at-age data on a per-fleet basis.

The sampling effort in each cell (Gear-Season-Area) in the year 2001 is shown in the table above.

In some cases samples are not available for a cell or are to few to give reliable keys. In those cases otholith samples from "related" cells are used. Notably hand lines are included with long lines in the same area and season.

In recent years emphasis has been put on relating the sampling scheme to the landings database automatically, calling for samples when certain amount has been landed in each cell, calculated daily ("real time proportional sampling scheme").

The total catch-at-age data is given in Table 3.3.3 and Figure 3.3.4. The Shephard Nicholson model gives a CV of 0.2 for age groups 4-10. It should be noted that much higher proportions of the older age groups are taken during the first part of the year and this fishing mortality affects estimation of the spawning stock at spawning time. Since the catch-at-age data have historically only been available for January to May, and not by shorter periods, it is assumed that 60% of the those catches were taken during January to March, i.e., before spawning time (Table 3.3.4). Natural mortality before spawning is assumed to be one fourth of the annual natural mortality.

3.3.2 Mean weight at age

3.3.2.1 Mean weight at age in the landings

Mean weight at age in the landings is calculated with the catch in numbers. Before 1993 weighting of cod was relatively uncommon so length-weight relationships were based on little data. Since 1994 weighting has been much more extensive but currently all fishes sampled for otholith are weighted and length-weight relationships can be calculated from current data. The weights are shown in table 3.3.5 and figure 3.3.7.

Mean weight at age have been shown to correlate well with the size of the capelin stock and capelin stock size has for some time been used as a predictor of weights in the landings. In 1981-1982 weights were low following collapse of the capelin stock and were also relatively low in 1990-1991 when the capelin stock was small. The weights were very high in 1994 to 1998 but have been low in 1999 and 2000, lower than the predicted from the capelin stock size. In 2001 about 15% increase in mean weight at age was observed for age groups 3-5, the weights for age groups 6-10 were about same as in 2000 and about 15% decrease was observed for older fish.

Mean weights at age are not available on an annual basis for catches taken before 1973, and hence the average for the years 1973 - 1991 is used as the constant (in time) mean weight at age for earlier years.

3.3.2.2 Mean weight at age in the stock

Weights at age in the landings have been used without modification to compute stock biomasses, with the exception of the spawning stock biomass (see below).

Data collected in the Icelandic groundfish survey (IGFS) have the potential for providing better estimates of mean weights at age in the stock. As the survey takes place early in the year with small meshes in the trawl codend mean weights in the survey multiplied by number in stock would give a much better measure of "real stock size". A problem with using survey weights for calculation of stock biomass is that they are only available back to 1985 and weighting of mean weight at age from areas with different growth rates is sensitive to catchability and annual differences in spatial distribution.

The calculated annual mean weights at age in the IGFS show similar pattern as the weights in landings although survey weights for ages 3 to 5 are always considerably lower than weights from the catches from the same period.

3.3.2.3 Mean weight at age in the spawning stock

Weight at age data from the commercial catch period January-May have been used for estimation of mean weights at age in the spawning stock. It is assumed that catches in different gears and areas appropriately reflect stock composition with regard to mean weight at age. Weights in the SSB have decreased in 1999 and 2000 after being very high in 1996 to 1998. In 2001 an increase was observed for age groups 3-9 and decrease in older fish. The peak in 1996 to 1998 could be related to selection of the commercial fleets who were using large mesh size in gillnets in this period (Figure 3.3.3). Mean weights in the spawning stock are shown in table 3.3.6 and figure 3.3.8.

3.3.3 Maturity at age

Maturity at age is based on samples from the commercial fleets in January-May (ICES 1992/Assess:14) (Table 3.3.7 and Figure 3.3.6). It has been pointed out that using data collected throughout the year may bias the proportion mature in various ways (Stefánsson, 1992). The approach taken is, therefore, to compute the proportion mature at the time of spawning, by considering only the first part of the year (January-May), but aggregating across gears and regions. Maturity at age increased substantially from 1982-1995 to relatively high values and decreased again in 1996-2000 but a sharp increase was observed for age groups 3-7 in 2001.

Maturity at age data are not available on an annual basis for catches taken prior to 1973 and, hence, the average for the years 1973–1991 is used as a constant (in time) maturity at age for the years prior to 1973.

3.3.4 Stock Assessment

Recent assessment and reviews

The 2000 ICES assessment showed that the stock had been seriously overestimated in recent years. In May-June 2000 the MRI asked a group of external experts to review and reanalyse the assessment. The group was chaired by Prof. John Pope. Various alternative assessment models were used: XSA (John Pope), Coleraine (Árni Magnússon/Ray Hilborn), Cagean like model (Pat Sullivan), TSA (Guðmundur Guðmundsson) as well as some unconventional methods such as Bormicon (Höskuldur Björnsson). The group met twice, first in May/June 2000 and again in late autumn.

At the spring meeting, several different tuning sets and assumptions were explored. The outcome of the final runs of the various assessment models are shown in Figure 3.3.4. The main conclusion was that the ICES assessment (XSA using a number of cpue tuning series from the survey and the commercial fleets) gave a higher estimate of biomass than most of the assessments done by the reviewing body. Variations in catchability and selection patterns in recent years were identified. The reviewing body did however not suggest in their June meeting that the assessment should be rejected and concluded that the MRI/Working group methodology and procedures were sound.

In the autumn 2000 the reviewing group met in Reykjavík to discuss the results of the review with Icelandic scientists. Various aspects of assessments, data sets and assumptions were discussed. The main critique on the ICES assessment was the use of multiple fleets and area split survey indices in XSA, letting XSA select the weights of different fleets. For future assessment it was suggested that a combined survey index should be used and that XSA should be run on only one tuning series at a time. It was also pointed out that XSA is unable to compensate for changes in efficiency of the commercial fleets (except for down weighting) and there is potential danger of overweighing the commercial cpue indices as they are often highly correlated with catch at age data. The reviewing group also recommended the usage of various alternative assessment models.

The 2001 assessment showed that there had been overestimation in biomass in recent years. In 2001 the results from XSA using one survey fleet for calibration was adopted as a final run by ICES. TSA and various other assessment models tried for at MRI gave all very similar results. In spring 2001 the minister of fisheries asked a group of external experts lead by Dr. Andrew Rosenberg to review the recent years assessments with emphasis on uncertainty in assessments. The group has not delivered a final report yet, but in a presentation at a public hearing on the cod assessment held by the Ministry of Fisheries in November 2001, Dr. Rosenberg presented a preliminary results of the group. Those as well as analysis by MRI scientists presented at the meeting showed that the assessment of Icelandic cod in recent years were partly data driven and partly a result of model mispecification. It was concluded that the overestimation in recent years should be taken into account in future management consideration.

Current assessment

In coherence with above and the results of a recent study done Gudmundsson and Jónsson (Working document No. 31), showing substantial linear trend in catchability in cpue form commercial fleets, only survey indices were used for calibration of assessment models in this years assessment. Six different assessment models were run: **XSA** and **TSA** as last year, **AD-CAM**-Statistical Catch at Age model written in AD-Model Builder developed at the MRI (Working Document no. 33), **STAM**-Statistical Catch at Age Model written in Excel developed at the MRI (Working Document no. 22), **Coleraine**-a general statistical catch at age model developed at the University of Washington (Working Document no. 29), **ADAPT**-an adaptive framework developed at Department of Fisheries an Ocean in New Brunswick, Canada.

3.3.4.1 Tuning data

Survey indices

A conventional Cochran type method was used for calculating survey indices. The stratas used follow depth contours. The Cochran indices were calculated separately for two areas: Northern area and Southern area and then combined. For all models used except for the TSA the indices were combined by simple summation (Table 3.3.8 and figure 3.3.11) but for the TSA tuning the two area indices a weighted geometric mean was calculated (Table3.3.9). The total biomass index from the survey is presented in figure 3.3.10. The Shephard Nicholson model gives a CV of 0.24 for age groups 2-9 for the survey indices.

Figure 3.3.13 shows plots of survey index for cod vs. the index of the same year class in the survey one year later. This type of plot should show good relationship if the survey is consistent, except when fishing effort varies much. The best relationship is between ages 3 and 4, age groups that are fully recruited to the survey but age 3 does usually have low fishing mortality.

To use the latest information available for tuning, the 2002 survey indices were moved three months back in time i.e. to end of December 2001 for the age groups 4-9. The same applies to abundance indices for the other survey years. No shift in time needs to be applied to age groups 3 and 2.

3.3.4.2 Estimates of fishing mortality

Six different assessment models were run all using the same datasets, catch in number at age, Table 3.3.3, and survey indices, Table 3.3.8, expect for TSA using weighted geometric mean of North and South areas indices, Table 3.3.9.

XSA tuning

Firstly the default run from last years assessment was run on the updated data sets. The resulting tuning diagnostic and terminal F's are presented in Table 3.3.10, resulting retrospective analysis in Figure 3.3.16 and Figure 3.3.17 and the log catchability residuals in Figure 3.3.8. The estimated terminal reference F (average of age groups 5-10) is **0.81**.

TSA

The results of the TSA run are presented in Table. 3.3.11. The test statistics from standardised residuals of prediction errors of catches and survey indices seem satisfactory. (Table 3.3.11 and Figure 3.3.18). The results from corresponding retrospective analysis are presented in Figures 3.3.16-17. The terminal reference fishing mortality based on this run is **0.81**.

AD-CAM

The input parameters, estimated fishing mortality rates and stock in numbers are presented in Table 3.3.12 along with the resulting residuals. The residuals plot are presented in Figure 3.3.18 a the corresponding retrospective pattern in Figures 3.3.16-17. The terminal reference fishing mortality is estimated **0.82**.

STAM

The estimated parameters and results of the STAM run are presented in Table. 3.3.13 as well as the residuals of prediction errors of catches and survey indices seem satisfactory. (See also Figure 3.3.18 for plot of the residuals). The results from corresponding retrospective analysis are presented in Figures 3.3.16-17. The terminal reference fishing mortality based on this run is **0.83**.

Coleraine

The estimated parameters and results of the Coleraine run are presented in Table. 3.3.14 as well as the residuals of prediction errors of catches and survey indices. (See also Figure 3.3.18 for plot of the residuals). The results from corresponding retrospective analysis are presented in Figures 3.3.16-17. The terminal reference fishing mortality based on this run is **0.67**.

ADAPT

The estimated parameters and results of the ADAPT run are presented in Table 3.3.15 as well as the residuals of prediction errors of catches and survey indices seem satisfactory. (See also Figure 3.3.18 for plot of the residuals). The results from corresponding retrospective analysis are presented in Figures 3.3.16-17. The terminal reference fishing mortality based on this run is **1.0**

The selection of a final run

In Table 3.3.16 and Figures 3.3.19 and Figure 3.3.20 a summary of the resulting terminal fishing mortalities and estimated stock in numbers in 2002 from the six different models are presented. The resulting terminal reference fishing mortalities from the XSA, TSA, AD-CAM and STAM are very similar or in the range of 0.81-0.83. Those four models also show very similar fishing mortality pattern. ADAPT gives the highest value for the reference fishing mortalities, 1.0, and

Coleraine the lowest estimate, 0.67. The relatively low differences between the results of the various models in the estimated stock size in numbers at the beginning of the year 2002 are mainly in the younger age groups. In this assessment these year classes are estimated by the RCT3 recruitment model.

Comparison of the retrospective results from the various models (Figures 3.3.16-17) show that the most consistent patterns are observed using the AD-CAM model looking at both the reference fishing mortalities and the fishable biomass (4+). The retrospective pattern from the TSA runs do show the second best consistency and the other models do show somewhat more inconsistent pattern and the other models. The NWWG concluded that the AD-CAM modelling approach is the most appropriate since it provides stock and recruitment estimates within the same statistical framework including probability profiles. Medium term projection are also a natural extension of this type of model approach. However, as the AD-CAM model has not yet been published or gone through a recognised reviewing process, the group adopted the TSA run as a point estimate for forward projections.

The resulting fishing mortalities from the final TSA run are given in Table 3.3.17 and in Figure 3.3.21. The fishing mortality increased to a peak in 1988, decreased in 1989 but then rose to another peak in 1993. Due to restriction of the cod quota effort dropped markedly in 1994 and 1995. In recent years fishing mortality has again shown an increasing trend.

3.3.4.3 Stock and recruitment estimates

The resulting stock size in numbers and stock in weight from the final VPA are given in Tables 3.3.18 & 3.3.20. In the stock in numbers table, the recruitment in the most recent years (year classes 1997–2001 as 3-year-olds in 2000-2004) was estimated using RCT3 as described in Section 3.3.7.1.

3.3.5 Biological and technical interactions

Several important biological interactions in the ecosystem around Iceland are connected to the cod stock. The single most important interaction is the cod-capelin connection (Pálsson, 1981) and this has been studied in some detail (Magnússon and Pálsson, 1989 and 1991a and Steinarsson and Stefánsson, 1991). Another important interaction is between cod and shrimp. This has been studied by Magnússon and Pálsson (1991b) and Stefánsson *et al.* (1994). The cod-capelin interaction is used in the short-term prediction in Section 3.3.7.1 based on the results in Steinarsson and Stefánsson (1996).

Various factors affect the natural mortality of cod and several of these factors could change in magnitude in the future. The cod is a cannibal and the mortality through cannibalism has been estimated in Björnsson (WD 26,1998). Cannibalism occurs mainly on prerecruits and immature fish. Further, the minke whale, the harbour seal and the grey seal are apex predators, all of which consume cod to varying degrees. Most of these M values will affect cod at an early age, before recruitment to the fishery.

It has been illustrated that not only may cetaceans have a considerable impact on future yields from cod in Division Va (Stefánsson *et al.*, 1995), but seals may have an even greater impact (Stefánsson *et al.*, 1997). These results imply that predictions which do not take into account the possible effects of marine mammals may be too optimistic in terms of long-term yields. It is therefore desirable to include marine mammals as a part of future natural mortality for the cod stock.

A number of fleets operate in Division Va. The primary gears are described in Section 3.3.2. Earlier work by this group included the separation of catches into finer seasonal and areal splits, but this has not been taken further at this meeting.

A numerical description of interactions between fisheries and species requires data on landings as well as catches in numbers at age of each species by gear type, region and season.

3.3.6 Prediction of catch and biomass

3.3.6.1 Input data to the short-term prediction

For short-term predictions, it is essential to take into account potential changes in mean weights at age due to environmental conditions. It has been shown that cod growth is to some extent correlated to size the of the capelin stock. Table 3.3.21 gives the size of the capelin stock biomass since 1979. Regressions based on the capelin stock size are used to predict the mean weights at age for age groups 4-8 in the catches and ages 5-8 in the spawning stock for the year 2002. For the year 2003 onwards, the average capelin stock size over the years 1979–2002 is used for prediction. (Table 3.3.25). In the most recent period maturity at age has been decreasing but a marked increase was observed in 2001. For the short-term predictions the average for the years 1999–2001 has been used for the years 2002-2004. The

exploitation pattern used for the short-term predictions was taken as the average of the years 1999–2001 from the VPA. The combined Cochran survey indices, age groups 1-4 and recruitment estimates from the VPA, for the year classes 1985-1996, were used for recruitment prediction. It was considered more appropriate to use relatively short time span considering the relative low recruitment in recent years compared to the long term average The input for the RCT3 is given in Table 3.3.23. The size of the year classes 1997–2001 has been estimated using RCT3, with the output as given in Table 3.3.24. Th recruitment estimates from the various other models give similar estimates, see Table 3.3.16.

3.3.6.2 Short term prediction results

Input data to the short term prediction and results from projections up to the year 2004 with different management options are presented in Table 3.3.25 and Figure 3.3.23.

Based on the reported landings for the first month of 2001/2002 fishing year and an assumption of the use of amended harvest control rule for the coming fishing year the expected catch in 2002 will be 190,000 t corresponding to F=0.59. The buffer of the amended catch control rule (with an upper limit of between year changes in TACs of 30 thous. tonnes) will not be applied and the resulting TAC in the 2002/2003 fishing year is 183,000 tonnes. The SSB will increase slightly in 2003 and the resulting a reference fishing mortality is about 0.45.

3.3.6.3 Input data to the long-term prediction

For long-term predictions, fluctuating environmental conditions can be ignored, but it is essential to take into account potential changes due to density-dependent growth. These have been investigated for this stock (Steinarsson and Stefánsson, 1991 and ICES 1991/Assess:7) where no signs of density-dependent growth were found. However, the results in Schopka (1994) contain indications of some density dependence of growth and this will affect the long-term results at low fishing mortalities. This is not taken into account in typical yield-per-recruit calculations. Effect of catch on mean weight at age by selection of the largest individuals of incoming year classes is also an important effect not taken into account.

Naturally, any stock-recruitment relationship will affect yield-potential calculations and this is not taken into account in the yield-per-recruit calculations.

Average exploitation pattern, mean weight at age and maturity at age over the years 1982–2001 has been used as input (Table 3.3.26).

3.3.6.4 Long-term prediction results and biological reference points

The biological reference values for \mathbf{F}_{max} and $\mathbf{F}_{0.1}$ are 0.32 and 0.15 respectively. Yield per recruit at the \mathbf{F}_{max} - level is 1.78 kg. (Figure 3.3.25 Table 3.3.27).

A plot of the spawning stock biomass and recruitment is given in Figure 3.3.26. When using the period 1955–1997, the reference points \mathbf{F}_{med} and \mathbf{F}_{high} are about 0.54 and 0.87, respectively.

The inclusion of the stock recruitment relationship has a major effect on long-term predictions. From Figure 3.3.26 it is seen that below-median recruitment occurs more frequently when the SSB is below-median than when the SSB is above the median. The increased probability of poor recruitment at low SSB levels is of major concern.

3.3.7 Medium term simulation

The AD-model builder Catch at age model (ADCAM described in working paper 33) does stock estimation, recruitment estimates and prognosis all at once. The settings used for the cod were .

- Catch in numbers 1955-2001, age 1-14.
- Fishing mortality nonparametric. Estimated for every year and age
- Recruiment was estimated from a Ricker SSB-recruitment model taking age variety in the spawning stock (Shannon index) into accound (Working paper 33). Trend in Rmax was estimated and CV of the residuals was allowed to vary with spawning stock size. The trend is estimated separately for the early and late part of the period and assumed to stop in 1996.
- CV in commercial catch data and survey indices as function of age estimated.

- Fishing mortality of each age group evolve as random walk with standard deviation specified as proportion of the estimated CV in the catch at age data. In the input file the process error (variablility in F) is specified to be larger than the measurement error but for the younger ages but the measurement error is specified to dominate in the older age groups.
- Future simulations were done with the amended harvest control law, assuming lognormally distributed assessment error with autocorrelation of 0.2.

Results of the simulations are shown in Figure 3.3.27. The results indicate low probability that the catchable biomass (age 4+) will remain at the low level observed in the last decade. This is despite median recruitment being modelled as low in coming years. The variability in recruitment is relatively large since the model estimated negative relationship between CV in residuals from the SSB-recruitment relationship and SSB.

Not allowing the trend in Rmax gives a more optimistic picture of recruitment and stock development in coming years. Spawning stock size and Shannon index are highly correlated with time so incorporating time trend in Rmax does not give significant reduction in the negative log-likelihood function but the effects on estimated future recruitment are large as the Shannon index and the spawning stock can improve but time can not be reversed.

3.3.8 Management considerations

Catch quotas for the Icelandic cod stock have since 1994 been based on the 25% catch rule. This catch rule was based on extensive simulations and has been considered precautionary. Until year 2000 the Icelandic government followed the catch rule with minimal deviations although it has turned out that the TAC has exceeded the 25% rule due to overestimation of the stock. In 2000 the Icelandic government, after some limited studies by the MRI, changed the adopted 25% catch rule by limiting the allowed changes in TAC between years to 30 thousand tonnes. For the last 2 fishing years the 30 thousand tonnes catch-stabilizer has been effective resulting in a TAC of 220 thousand tonnes in fishing year 2000/2001 instead of 203 thousand tonnes and a TAC of 190 thousand tonnes in the fishing year 2001/2002 instead of 155 thousand tonnes if no stabilizer would have been in effect. The NWWG observed that 30 thousand tonnes stabilizer, if used from the time that the initial 25% catch rule was adopted in 1994, would not have prevented the overexploitation of the stock in recent years.

Based on the current assessment and harvest control rule the resulting TAC for the next fishing year is 183 thousand tonnes. The 30 thousand tonnes catch-stabilizer will not be effective.

The catch control rule is now in reviewing process by a group scientists appointed by the Ministry of Fisheries. This group is suposed to deliver a preliminar report in June of this year.

The AD-CAM model described in working document no. 33 was used for short term projections using the amended catch control rule. The results are presented in Figure 3.3.24A and B show that the probability that the catchable biomass(4+) stock will be well above present level if the catch control rule will followed next few coming years.

At present fishing mortality is high (F5-10 in the year 2002 about 0.6) and age 5 and younger fish account for more than 70% of the fishable biomass(4+). This will be reflected in the age composition of the catches in 2003, age group 6 and younger will represent about 80% of the landings. The age composition of the spawning stock is highly skewed. Spawners at age 5 and younger will constitute to about 60% of the spawning stock biomass in 2003 and fishes older than ten years old less than 4%. Given the relatively high proportions of younger fish in both the fishable as well as in the spawning stock biomass a lower fishing mortalities than resulting from the catch control rule should be considered.

3.3.9 Comments on the assessment

The current assessment is now more consistent with previous years assessment compared to recent years assessments were substantial overestimation was observed. As in previous year assessment indices from commercial fleets were not used for the calibration of the assessment models used. This decision was based on retrospective patterns, the results from the working group on Icelandic cod in autumn 2000 and a recent study by Guðmundsson and Jónsson (Working document no. 31) revealing marked trend in catchabilty in cpue series from commercial fleets. Indices from commercial fleets are still used even if they are not used directly in tuning and they are as such an important source of information on the state of the stock. They usually give the same main message as the survey and a situation where they would show opposite trends would demand thorough investigation of the survey and the cpue indices.

The fishable biomass 4+ in 2001 was estimated 577 thousand tonnes in last years assessment compared to 640 thousand tonnes in the current assessment. This difference of 63 thousand tonnes, or 11%, is well within the error a limit of last

years point estimate. The observed increase in the mean weight at age for the age groups 4-8, compared to last years prediction, accounts for about 2/3 of the discrepancies and the rest by relatively small difference in the estimated stock in number in 2001. The SSB is now estimated to have been 311 thousand tonnes at spawning season and spawning time in the year 2001. The last years estimate was markedly lower or only 219 thousand tonnes. The sharp increase in observed maturity at age in 2001 for age groups 3-7 does account for the bulk of this increase but some increase in mean weight at age was also observed for age groups less than 10 in the SSB. The year classes 1997-2000 were estimated 185, 170, 185 and 175 receptively in last years assessment compared to 180,165,176, 210 in the current assessment.

The main causes of the overestimation of this stock in the years 1998-2000 is now considered to be the use of combination of commercial cpue and survey indices for calibration of stock assessment models and high availability of cod in the years 1997 and 1998. The causes for the anticipated increase changes in availability in these years are still not quite understood. Many factors have been mentioned such as: hydrographical changes, capelin availability, increased availability with reduced effort (disturbance), increased natural mortality, emigration, increased discards etc. Some of those theories have been analysed but no analytical results are available. As those effects still remain unexplained the point estimate in this years assessment is not corrected for possible changes in parameters of this kind.

3.4 Icelandic haddock

3.4.1 Introductory comment

Haddock (*Melanogrammus aeglefinus*) in Icelandic waters is only connected with other haddock stocks in that 0-group and occasionally young fish found in E-Greenland waters originate from the Icelandic stock. The species is distributed all around the Icelandic coast, principally in the relatively warm waters off the west and south coast, on fairly shallow grounds. It is also found off the North coast and in warm periods a large part of the immature haddock can be found in that area.

Icelandic haddock was assessed at the North-Western Working Group in 1970 and 1976 but otherwise assessments were conducted by the Marine Research Institute in Iceland until in 1999 when it was again assessed by the North-Western Working Group.

3.4.2 Trends in landings and fisheries

During the sixties haddock landings rose to a record level of around 100 000 tonnes for several years (Figure 3.4.2.1) After that, landings have been between 40 000 and 65 000 tonnes. Historically landings by foreign fleets accounted for up to half of the total landed catch. Since 1976 fisheries by foreign nations have been negligible except a small catch by the Faroese. Haddock landings are subject to fluctuations, reflecting variability in stock biomass and recruitment, which is very variable.

The landings in 2001 are estimated as 39600 tonnes decreasing from 42 200 tonnes in 2000 In last year the forecasted landings for the year 2001 were 40000 tonnes, very close to the current estimate.

In 2001, 56% of landings were by demersal trawl, 8% by Danish seine, 31% by long line and 5% by gillnets, similar to 2000. The share of longline in the fishery increased between 1998 and 1999 and has been similar since then. This increase was due to increased longline effort where cod is probably the main target species.

3.4.3 Catch at age

Catch at age for 2001 for the Icelandic fishery is provided in Table 3.4.3.1. Catch at age is calculated by 3 fleets and two time intervals. The time intervals are January-May and June-December and the fleets are gill nets, long line and bottom trawl. Hand lines are included with the long line fleet. Danish seine (as well as minor units such as pelagic trawl and other gears which are dragged or hauled) are included in the trawl feet. The Faroese catch that is caught by long line is included in that category. Numbers sampled in 2001 are given in the table below.

Gear	Total landings	Number length measured	Number aged
Longline	12400	26118	2740
Gillnets	1900	2982	489
Danish Seine	3300	3752	307
Trawl	22100	68145	5121
Total	39700	100997	8657

Figure 3.4.3.1 shows the catch in number plotted on log scale. The curves indicate that total mortality is high or close to 1 for the oldest haddock. The 1976 year class is shown for comparison but the fishing mortality was low around 1980. Figure 3.4.3.1 indicates that CV in these data is low. Shephard Nicholson model gives a CV of 20% for age groups 2-8.

3.4.4 Weight and maturity at age

Mean weight at age in the catch is shown in Table 3.4.4.1

Mean weight at age in the stock for 1981–2001 is given in Table 3.4.4.2. Those data are calculated from the Icelandic groundfish survey. Weights for 1985–1992 were calculated using a length-weight relationship which is the mean from the years 1993–2000. Weights from 1993 onwards are based on weighting of fish in the groundfish survey each year. Stock weights prior to 1985 have been taken to be the mean of 1985-2002 weights.

Both stock and catch weights have been relatively low since 1990 compared to the eighties. Since 1990 the weights have not shown any apparent trend but it seems like the large year classes (1990 and 1995) grow slower.

Maturity at age data are given in Table 3.4.4.3. They show high maturity at age in recent years compared to earlier years. Maturity at age data from 1985 onwards are taken from the groundfish survey but maturity at age in catches January - May is used 1980 to 1984.

3.4.5 Survey and cpue data

Haddock is one of the most abundant fishes in the Icelandic groundfish survey, being caught in large number at age 1 and becoming fully recruited at age 2 or 3. Age disaggregated indices from the survey are given in Table 3.4.5.1.

The index of total biomass from the survey is shown in Figure 3.4.5.1. It was at record low in 2000 but has increased since then due to good recruitment and is in the year 2002 the highest since the series started.

Running the Shephard Nicholson model on the survey gives CV of 25% for ages 1 to 7 but 38% if ages 8 and 9 are included. The consistency of the survey indices can also be seen in Figure 3.4.5.2 where the abundance indices of a year class are plotted against the abundance indices of the same year class one year later showing some outliers in the 2001-2002 comparison. In Figure 3.4.5.3 survey indices are plotted against VPA estimates with regression lines based on all data until 1999 and r^2 in the fit of these lines included. The figure shows that the survey indices are good indices of stock size and the relationship between survey index and number in stock is close to linear for all age groups.

CPUE from the commercial fleet is shown in Figure 3.4.5.4. The figure is calculated from records where more than 50% of the catch is haddock. The CPUE for the trawl fishery increased by 15% between 2000 and 2001 while the CPUE for the other gear types is identical in 2001 to what is was in 2000.

3.4.6 Stock Assessment

3.4.6.1 Tuning input

Last years assessment was based on using the groundfish survey ages 2-9 for tuning. This year the same settings were used. The tuning data for the XSA run are shown in Table 3.4.6.1.

3.4.6.2 Tuning and estimation of fishing mortality

The XSA run used for the assessment uses survey indices from age 1985-2001, ages 2-9 for tuning. Shrinkage was set to 2 years and 2 ages with SE = 0.5. Varying the shrinkage did not affect the results much. Catchability of all age groups was independent of stock size.

Results from the XSA run are given in Table 3.4.6.2 and summary plots in Figure 3.4.6.1. The resulting mean F in 2001 for age groups 4–7 from the final run was 0.75. The plot of yield and fishing mortality (Figure 3.4.6.1) indicates that fishing mortality increased substantially in 1986 before falling slightly the following year and has been stable since but increasing in the recent years. Figure 3.4.8.5 shows the development of biomass 3+.

Retrospective pattern from the final run is shown in Figure 3.4.6.2. The retrospective patterns show good consistency with a slight tendency to underestimate the stock in recent years.

Looking at the composition of the stock in the beginning of 2002 the most important year classes are the recruiting year classes (1998 and younger) but the large 1995 year class is only 5.5% of the catchable biomass(3+).

In addition to the standard XSA runs a number of other models and settings were tested. The results are summarized in the table below.

	F ₄₋₇ – 2001	SSB	Biomass 3+
			2001
Default XSA run. Survey indices 2-9	0.75	53.1	89.0
XSA using survey indices from age 1-9.	0.74	50.3	91.7
XSA using survey indices and glm indices from bottomtrawl in the	0.64	58.3	97.1
2^{nd} half of the year.			
TSA (age 3-9)	0.72		91.4
ADAPT using survey indices from age 1-9	0.81		89.6
ADCAM using survey indices from age 1-9.	0.73		91.0

As may be seen all the models using the survey indices only give similar results while the run incorporating the CPUE from the bottom trawl fleets gives lower fishing mortality as has been the case in recent years.

The AD-model builder Catch at age model (ADCAM described in working paper 33) does stock estimation, recruitment estimates and prognosis all at once. The settings used for the haddock were.

- Fishing mortality was estimated for every year and age.
- Recruitment was assumed to be lognormally distributed around a fixed mean with the CV of the lognormal distribution estimated. Autocorrelation of the residuals (0.15) was included
- CV of commercial catch data and of survey indices as function of age estimated.
- Fishing mortality of each age group was random walk with standard deviation specified as proportion of the estimated CV in the catch at age data. In the input file the process error (variablility in F) is specified to be larger than the measurement error for the younger ages but the measurement error is specified to dominate in the older age groups.

Residuals from the model are plotted in Figure 3.4.6.3 showing mainly positive residuals in 2002 but negative in 2000 and 2001. The usual pattern seems to be that each year the residuals of all agegroups have the same sign and the model estimates correlation of the residuals of adjacent agegroups in the survey to be 0.5. Residuals from XSA (Table 3.4.6.2) show the same pattern.

3.4.7 Recruitment estimates

As stated earlier year classes 1998 - 2000 are very strong and are going to dominate the catches for a number of years. Therefore short term predictions are more driven by recruitment estimates than the XSA results. Recruitment of this stock is highly variable ($\sigma = 0.75$ on log scale) and survey indices reasonable measure of stock size (Figure 3.5.4.3). There seems though to be a marked increase in the catchability of the survey between the years 2000- 2001 and 2002 as demonstrated by the XSA residuals, so the recruitment estimates for year classes 1999 and 2000 from these surveys are unusually contradicting.

RTC3 input and results are shown in Tables 3.4.7.1 and 3.4.7.2. Looking at the 2000 year class the VPA mean is 48 million, 1 year estimate 115 million, 2 year estimate 214 million and weighed estimate 133 million. VPA mean has low weight but has considerable effect on the results due to the geometric mean. A number of other methods and settings were used to estimate recruitment and the results are shown in table below.

Looking at the results in table below the estimates for the 1999 year class range from 106 to 123 million and for the 2000 year class from 133 to 165 million fishes. Looking at the posterior profiles in Figure 3.4.7.1 the range 130 to 165 million for the 2000 year class corresponds to 20 and 60 percentiles and 106 and 130 million for the 1999 year class at age 2 correspond to 25 and 80 percentiles. On basis of this comparison the maximum likelihood values from the

ADCAM model were selected for recruitment estimates noting that they were somewhere in the middle of probable values.

	Rec	ruitment (milli	ion 2 year o	old.)					
Year class	RTC3	RTC3 no	Adapt	Std. XSA	ADCAM	XSA from	Survey	Survey	Used
		shrinkage				age 1	2001	2002	values

2001	35	35	33		27			32	29

3.4.8 Prediction of catch and biomass

3.4.8.1 Input data

The input data for the prediction are shown in Table 3.4.8.1

For the short-term catch prediction and stock biomass calculations, the mean weight at age 3-8 in the catches in 2002 were predicted using regression analysis, where the mean weight at age was predicted by the mean weight of the same year class in the previous year. For the years 2003 to 2005 the mean for the years 1999 - 2001 was used. For age groups 2, the mean of the years 1999-2001 was used.

For the stock weights survey weights for the year 2002 were used for that year but for the year 2003 mean weight at age was predicted by mean weight of the same year class in the survey in 2002. For 2004 and 2005 the mean of the weights in 2000-2002 was used.

The exploitation pattern was taken as the mean exploitation pattern from 1997–2001.

Recruitment for year classes 1999 – 2001 was taken from the ADCAM model (table above). Recruitment for year classes 2002 and 2003 was taken to be the geometric mean of recruitment from 1980–1999.

A TAC constraint of 45 000 tonnes was applied to the prediction for the year 2002 based on the landings in the first 4 months of 2002 and the proportion landed in the first 4 months in the year 2000. (In 2001 there was a strike in April).

In addition to the standard prognosis the ADCAM program was used for prediction using the 45 kT constraint for the year 2002 and the proposed \mathbf{F}_{pa} of 0.47 for the following years. Assessment error was assumed to be lognormal with 10% CV and no autocorrelation. Weights in stock and catch were the mean of last 3 years.

For the long-term yield and spawning stock biomass per recruit, the exploitation pattern was taken as the mean relative fishing mortality from 1980-2001. Mean weight at age in the stock and the maturity ogive are means from 1980-2001. Mean weight at age in the catch is the mean from 1980-2001. Input data for long term yield per recruit are given in Table 3.4.8.2.

3.4.8.2 Biological reference points

The yield per recruit is shown in Table 3.4.8.3. and Figure 3.4.8.1

Compared to the estimated fishing mortality of $F_{4-7} = 0.75$ for 2001, $F_{max} = 0.45$ and $F_{0.1} = 0.18$. These values are lower than last year as yield per recruit was run using plus group this year but not last year.

Yield per recruit at \mathbf{F}_{max} corresponds to 0.88 kg. (Table 3.4.8.3). Mean weights as in the most recent years would give lower yield per recruit.

A plot of spawning stock biomass and recruitment from 1981-2000 is shown in Figure 3.4.8.2 and a plot of recruitment vs. spawning stock in Figure 3.4.8.3.

In the year 2000 the working group proposed provisional \mathbf{F}_{pa} set to the \mathbf{F}_{med} value of 0.47 and since no further work has

been done since then on reference points for this stock that value will be used for \mathbf{F}_{pa} this year. Since 1986 F_{4-7} has exceeded \mathbf{F}_{max} and for only 4 years since 1960 has F_{4-7} been lower than \mathbf{F}_{pa} .

3.4.8.3 **Projection of catch and biomass**

At the beginning of 2002, the biomass of age 3+ is predicted to be 120 000 tonnes with a spawning stock of 69 000 t. (Tables 3.4.8.4 and 3.4.8.5 and Figure 3.4.8.4).

With a catch of 45 000 t in 2002, fishing mortality is estimated to be 0.57, the biomass of age 3+ is predicted to be 168 000 tonnes in the beginning of the year 2003 and the spawning stock biomass 98 000 tonnes.

The short term deterministic predictions indicate that in for wide range of fishing mortalities the biomass of the stock is going to increase in coming years due to good recruitment. In those predictions the catch in the year 2002 is estimated to be 45,000 tonnes. This catch will lead to considerable lowering of fishing mortality compared to 2001. The results from the ADCAM model (Figure 3.4.8.5) confirm that the stock biomass and catch are going to increase in the next years but reduce after 2004 when the small 2001 year class starts entering the catch.

3.4.9 Management considerations

For more than a decade fishing mortality on haddock has been high with F_{4-7} between 0.6 and 0.8 since 1986. The advice in 2001 was based on \mathbf{F}_{med} and if followed would have meant substantial reduction in fishing mortality while the real outcome was that the fishing mortality reduced only a little.

The short term predictions do not show much advantage in reducing fishing mortality. It must though be born in mind that a number of factors, like discard, hidden mortality due to mesh penetration and reduction of mean weight at age by removal of the largest individuals of each age group not included in these predictions.

Discard and hidden mortality due to mesh penetration has been a point of concern in this stock (Pálsson 2002). Some preliminary information on discard are available indicating substantial discard in some years but no direct information on the harm caused by mesh penetration are available. The discards have been estimated by Pálsson (2002) based on comparison of length distributions from sea and harbour sampling. The table below is a summary from Pálsson (2002) indicating a large reduction in discards in recent years from very high levels in 1994 – 1997. This reduction is partly due to bad recruitment from the 1996 and 1997 year classes. Preliminary results for the year show some increase from the year 2000 but the estimate is though much less than for 1994-1997. Most discard is observed when catchable biomass is low and recruiting year classes are large. Possible explanation for relatively little discard in 2001 in spite of good recruitment and small catchable biomass is that large part of the recruiting year classes 1999-2000 is growing up off the north coast, in areas where fishing effort is small.

year	1988	1989	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000
Discard tonnes	1481	1499	364	3349	3858	2414	4236	8397	4577	6160	2501	1349	1930

The short term predictions do not take any of these factors into account nor do they include possible effect of much fishing effort on weight at age in the catches and in the stock. The predictions are therefore not valid when fishing effort differs considerably from recent years, they will most likely underestimate the stock if effort is reduced but overestimate if effort is increased. For similar effort the predictions should be reasonably accurate.

The assessment results show that the 1996 and 1997 year classes are small, specially the 1996 year class. The 1998 to 2000 year classes are on the other hand above average. In the fishing year 2002-2003 most of the catches will be from year classes 1998 to 2000. As the 2000 year class is potentially very large and will mostly be below landing size, limiting fishing effort in the next fishing year is important.

3.4.10 Comments on the assessment

The current assessment was done using only groundfish survey indices for tuning. .

Fishing mortality on haddock increased after 1985 (Figure 3.4.6.2.) The high fishing mortality was at least partly due to an overestimation of the stock biomass through the use of catch weights that are 20-25% higher than survey weights which have been used in the assessment since 1999.

The assessment presented here gives $F_{4-7} = 0.75$ in 2001. As mentioned earlier assessment including commercial CPUE give lower mortality ($F_{4-7} = 0.65$ in 2001). In spite of this high fishing mortality the stock size is going to increase in coming years due to good recruitment.

This year's assessment gives a more optimistic view of the stock than last years assessment. At the beginning of 2002, the biomass of age 3+ is predicted to be 120 000 tonnes with a spawning stock of 69 000 t. (Table 3.4.8.4) while forecast from last year for the year 2002 were 104 000 tonnes for the biomass (3+) and 56 000 tonnes for the spawning stock biomass. Of this discrepancy 2500 tonnes can be explained by less than anticipated catch but the rest by higher estimate of number in stock, mostly of year classes 1998 and 1999. This change in estimate is driven the results from the survey 2002.

In this year's assessment a number of different models were used and the range of results investigated. The point estimates selected for prognosis come from XSA for the older groups and ADCAM for the younger groups. The most important part was though that no special model was used and the selection was based on the results of all the models used.

Extended Survivors Analysis

"ICELANDIC COD (Div. Va); data from 1972-2001"

CPUE data from file codvarnt.dat

Catch data for 31 years. 1971 to 2001. Ages 3 to 14.

Fleet	First	Last	First	Last	Alpha	Beta	
	year	year	age	age			
SMB. Tot	1984	2001		3	8	0.99	1
SMB. Tot	1985	2001		3	3	0.17	0.25
a3 on a3							

Time series weights :

Tapered time weighting not applied

Catchability analysis :

Catchability dependent on stock size for ages < 5

Regression type = C Minimum of 5 points used for regression Survivor estimates shrunk to the population mean for ages < 5

Catchability independent of age for ages >= 11

Terminal population estimation :

Survivor estimates shrunk towards the mean F of the final  $\ 3$  years or the  $\ 4$  oldest ages.

S.E. of the mean to which the estimates are shrunk = .500

Minimum standard error for population estimates derived from each fleet = .300

Prior weighting not applied

Tuning converged after 15 iterations

Regression weights

#### Input data and estimated parameters:

The fitting procedure was based on minimizing

$$SSR_{c} = \sum_{ay} \frac{\left[\ln(C_{ay}) - \ln(\hat{C}_{ay})\right]^{2}}{2\sigma_{a}^{2}}$$
$$SSR_{I} = \sum_{ay} \frac{\left[\ln(I_{ay}) - \ln(\hat{I}_{ay})\right]^{2}}{2\rho_{a}^{2}}$$
$$SSR_{T} = a_{c}SSR_{c} + a_{I}SSR_{I}$$

The weighting factor ( $a_c$  and  $a_l$ ) in each case was set to one. To reflect different accuracy by age in the estimation of catch-at-age and survey-index-at-age the residuals by age in the SSRC and SSRI were weighted according:

Age ->	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Catch (sigma)			0,32	0,22	0,16	0,13	0,12	0,11	0,12	0,14	0,17	0,24	0,36	0,60	0,60
Survey (rho)	0,39	0,30	0,24	0,22	0,20	0,21	0,22	0,26	0,32	0,43					

In order to force the model to fit the observed yield within each year an additional minimization factor (penalty factor) was set in:

$$SSR_{Y} = \sum_{y} \frac{\left[\ln(Y_{y}) - \ln(\hat{Y}_{y})\right]^{2}}{2\sigma_{a}^{2}}$$
$$SSR_{T} = a_{c}SSR_{c} + a_{I}SSR_{I} + a_{Y}SSR_{y}$$

where the ay factor was set to 1000.

The input data were into the model where:

1) catch-in-number matrix was based on ages 3 to 14 for years 1985 to 2001, Ca for ages 1 and 2 were assuemd 0 (thus 204 input values).

2) aged survey indices for ages 1 to 9 for years 1985-2002 (162 input values).

3) auxillary data on the CV by age groups for Cay and Uay - data obtained from <u>hoski@hafro.is</u> (see intext table above).

4) auxillary data such as corresponding weight at age in the catch and in the survey and maturity at age in the catch.

The number of estimated parameters were:

1) 13 estimates of Na85 for a = 2, 3, ..., 14

2) 18 estimates of N1y for y = 1985, 1986, ...., 2002

3) 9 estimates of  $\alpha_a$  for a=1, 2, ..., 9

4) 7 estimates of  $\beta_a$  for a = 1, 2, ..., 7. I.e. power model was used for age groups 1-7, simple linear model for age groups 8 and 9 was used ( $\beta$ =1). The judgement on where to use power model was based on residual plots.

5) 17 estimates of Fy for y = 1985, 1986, ...., 2001

6) estmates of a50 and a95

or a total of 66 parameter estimates.

See WD-22

Iceland Cod: VPA and groundfish survey data,N+S 4 21 2

#### **Table 3.3.24**Cod at Iceland. Division Va. Output from RCT3

Analysis by RCT3 ver3.1 of data from file :

in_2002.dat

Iceland Cod: VPA and groundfish survey data,N+S

Data for 4 surveys over 21 years : 1981 - 2001

Regression type = C Tapered time weighting not applied Survey weighting not applied

Final estimates shrunk towards mean Minimum S.E. for any survey taken as .20 Minimum of 3 points used for regression

Forecast/Hindcast variance correction used.

Yearclass = 1997

#### 4 THE COD STOCK COMPLEX IN GREENLAND (NAFO SUBAREA 1 AND ICES SUBAREA XIV) AND ICELANDIC WATERS (DIVISION Va)

## 4.1 Inter-relationship Between the Cod Stocks in the Greenland-Iceland Area

Tagging experiments carried out at Greenland and Iceland show that mature cod at West Greenland migrate to East Greenland. Tagging experiments at East Greenland also show that mature cod from that area migrate to Iceland (Tåning, 1937; Hansen, 1949; and Anon. 1971). On the other hand, immature cod seem not to emigrate from East Greenland to Iceland, but in some years immature cod migrate from East Greenland to the West Greenland stock (Anon. 1971). Tagging experiments at Iceland show that migration of cod from Iceland to Greenland waters occurs very seldom and can be ignored in stock assessments (Jonsson 1965, 1986). Migrations from Greenland waters to Iceland can, therefore, be regarded as a one-way migration.

In egg and larval surveys cod eggs have been found in an almost continuous belt from Iceland to East Greenland, along the East Greenland coast, round Cape Farewell and over the banks at West Greenland (Tåning 1937, Anon. 1963). From 0-group surveys carried out in the East Greenland-Iceland area since 1970, it becomes quite evident that the drift of 0-group cod from the Iceland spawning grounds to the different nursery areas at Iceland varies from year to year. The same applies to the drift of 0-group cod with the currents from Iceland to East Greenland (Table 4.1.1). In some years it seems that no larval drift has taken place to the Greenland area, while in other years some, and in some years like 1973 and 1984, considerable numbers drifted to East Greenland waters (Vílhjalmsson and Fridgeirsson 1976, Vílhjalmsson and Magnússon 1984, Sveinbjörnsson and Jónsson 1999). Since 1995, 0-group surveys were continued with the area coverage reduced to the Icelandic EEZ. However, the estimates of the year classes 1997 to 2001 are exceptionally high. In 2001, more than 60% of the 0-group cod were distributed in northern areas off Iceland (Table 4.1.1) and an exceptional high proportion of O-group cod were distributed off East Iceland. However, none of these year classes seem to have drifted in significant numbers to the Greenland shelf.

The 1973 and 1984 year classes have been very important to the fisheries off both West and East Greenland. Tagging results have shown that when these two year classes became mature, they had migrated in large numbers from West to East Greenland and, to some extent, to the spawning area off the southwest coast of Iceland. This migration of mature cod from Greenland to Iceland influences the assessment of these stocks (Schopka, 1993) and it cannot therefore be ignored in the assessments.

Year class	Dohrn Bank	SE Iceland	SW Iceland	W Iceland	N Iceland	E Iceland	Total

### 5 COD STOCKS IN THE GREENLAND AREA (NAFO AREA 1 AND ICES SUBDIVISION XIVB)

## 5.1 Cod off Greenland (offshore component)

Prior to 1996, the cod stocks off Greenland have been divided into West and East Greenland or treated as one stock unit for assessment purposes to avoid migration effects. Fjord populations (inshore) have always been included. In 1996, the offshore component off West and East Greenland, the so called Bank Cod, was assessed separately as one stock unit and distinguished from the inshore populations for the first time. The completion of a re-evaluation of available German sampling data for the offshore catches back to 1955 enabled such an analysis given in the 1996 North-Western Working Group report (ICES 1996/Assess:15). Due to the severely depleted status of the offshore stock component, the directed cod fishery was given up in 1992, the final year in the VPA. Since then, no adequate data were available to update the assessment. Therefore, the present report includes the summary table and figures of the 1996 assessment only appended by long term management considerations and updated survey results and catch information.

# 5.1.1 Trends in landings and fisheries

Officially reported catches are given in Tables 5.1.1 and 5.1.2 for West and East Greenland including inshore catches, respectively. Landings as used by the working group are listed in Table 5.1.3 by inshore and offshore areas and gear for both West and East Greenland combined, their trends being illustrated in Figure 5.1.1. Until 1975, offshore landings have dominated the total figures by more than 90%. Thereafter, the proportions taken offshore declined to 40–50% and inshore landings have dominated the most recent yields since 1993. Otter trawl board catches (OTB) were most important throughout the time series for offshore fisheries. Miscellaneous gears, mainly long lines and gill nets, contributed 30–40% until 1977 but have disappeared since then.

Annual landings taken offshore averaged about 300 000 t during the period 1955–60. Until 1968, figures increased to a higher level between 330 000 t and of 440 000 t in 1962. Landings decreased sharply by 90% to 46 000 t in 1973. Subsequently, the landings dropped below 40 000 t in 1977 and were very variable. The level of 40 000 t was only exceeded during the periods 1980–83 and 1988–1990. Since 1970, there have been large changes in effort, which increased during exploitation of the strong year classes born in 1973 and 1984. The offshore fishery was closed in 1986 and for the first 10 months in 1987. During 1990–92, the landings decreased from 100 000 t by 90% to 11 000 t. Since then, almost no directed cod fishery has taken place offshore and the reported landings varied from 116 t to 736 t. A total offshore catch amounting to 221 t was reported for 2000.

It is important to note that catch figures, especially since 1992, are believed to be incomplete due to unreported bycatches in the shrimp fishery which has recently expanded to all traditional areas of the groundfish fisheries. Discards of finfish by-catches were difficult to record due to the processing of the shrimp catch on board. A first assessment of the catch taken by the shrimp fishery amounted to 32 t or 110 000 individuals of cod in 1994. This estimate was added to the catch figures used by the Working Group for the 1992–95 period.

# 5.1.2 Surveys

# 5.1.2.1 Results of the German groundfish survey off West and East Greenland

Annual abundance and biomass indices have been derived using stratified random groundfish surveys covering shelf areas and the continental slope off West and East Greenland. Surveys commenced in 1982 and were primarily designed for the assessment of cod (*Gadus morhua* L.). A detailed description of the survey design and determination of these estimates was given in the report of the 1993 North-Western Working Group (ICES 1993/Assess:18) and Working Doc. 10. Figure 5.1.2 indicate names of the 14 strata, their geographic boundaries, depth ranges and areas in nautical square miles (nm²). All strata were limited at the 3 mile line offshore except for some inshore regions in Strata 6.1 and 6.2 off East Greenland where there is a lack of adequate bathymetric measurements. In 1984, 1992, and 1994 the survey coverage was incomplete off East Greenland partly due to technical problems.

# 5.1.2.1.1 Stock abundance indices

Table 5.1.4 lists abundance and biomass indices for West and East Greenland, respectively and then combined for the years 1982–2001. Trends of the abundance and biomass estimates for West and East Greenland were shown in Figures 5.1.3 and 5.1.4, respectively, including the adult stock parts. These Figures illustrate the pronounced increase in stock abundance and biomass indices from 23 million individuals and 45 000 t in 1984 to 828 million individuals and 690 000 t in 1987. This trend was the result of the recruitment of the predominating year classes 1984 and 1985, which were mainly distributed in the northern and the shallow strata 1.1, 2.1 and 3.1 off West Greenland during 1987–89. Such high

indices were never observed in strata off East Greenland, although their abundance and biomass estimates increased during the period 1989–91 suggesting an eastward migration. During the period 1987–89, which were years with high abundance, the precision of survey indices was extremely low due to enormous variation in catch per tow data. Since 1988, stock abundance and biomass indices decreased dramatically by 99% to only 5 million fish and 6 000 t in 1993. The 2001 survey results confirmed the severely depleted status of the stock, although they represent the highest stock size since 10 years. The total abundance and biomass indices amounted to 16 million individuals and 18 000 t, respectively.

## 5.1.2.1.2 Age composition

Age disaggregated abundance indices for West, East Greenland and the total are listed in Tables 5.1.5–7, respectively, and are based on 1 242 individual age determinations. In 2001, the recruiting year classes 1998, 1999 and 2000 are considered weak as compared to the strong 1984 and 1985 year classes. The year class 1999 at age 2 however is estimated as the third strongest year class since 1982 and thus to provide some recovery potential in the next few years. The O-group indices are considered unrepresentative of year class strength at age 3 due to gear specifications while the age group 1 seems to be quantitatively estimated and to represent a reasonable recruitment index. (Figure 5.1.5).

# 5.1.2.1.3 Mean weight at age

Mean weight of the age groups 1–10 years for West, East Greenland and weighted by abundance to the total were listed in Tables 5.1.8–10, respectively. Weight (g) at age calculations are based on the regression  $f(x) = 0.00895x^{3.00589}$ , x = length (cm), which has been determined on the basis of 3 482 individual measurements. The trends of these values are illustrated in Figure 5.1.6 for the period 1982–2001. They reveal pronounced area and temperature effects. Age groups 2–10 years off East Greenland were found to be bigger than those off West Greenland. Driven by the high abundance of cod off West Greenland, weighted mean length and weight for the age groups 1–5 displayed a decrease during 1986–87 and remained at low levels until 1991. Since then, the weight at age at ages 3 to 8 years increased significantly and remained at that high level until 2000, when very low values were recorded. However, the 2001 values indicate increased growth rates for most ages.

## 5.1.2.2 Results of the Greenland groundfish survey off West Greenland

Since 1988, the Greenland Institute of Natural Resources has annually conducted a bottom trawl survey off West Greenland (Working Doc. 2). The main purpose of the survey is to evaluate the biomass and abundance of Northern shrimp (*Pandalus borealis*), but data on most fish spices have been recorded. The survey covers the offshore areas at West Greenland between 59°00'N and 72°30'N from the 3-mile limit to the 600 m depth contour line and the inshore area Disko Bay (Figure 5.1.7). The survey area is divided into NAFO Divisions, which were further subdivided into three depth strata (0-200, 201-400 and 401-600 m) on basis of depth contour lines. The area surveyed has, however, changed throughout the years. From 1988 to 1990 the survey area included Division 1AN to 1D. In 1991 the Division 1AN was not covered. In 1992 the survey area was extended to include Division 1AN to 1F and Disko Bay (Division. 1AX), and this area is now surveyed annually. The survey was originally designed as a shrimp survey and sampling of fish data was not complete in the period 1988-1991. Since 1992 the sampling of fish has improved and the survey is now considered as a combined groundfish/shrimp survey. The survey period was July to September.

The survey is designed as a stratified-random trawl survey. A minimum of two hauls per stratum is always planned. Due to lack of information of the bottom topography Division 1AN and Disko Bay are considered as two single strata. The number of valid hauls by year and stratum is listed in Table 2. The trawl is a Skjervoy 3000/20 with bobbin gear and double bag. The mesh size in the codend is 20 mm. The standard trawling time offshore is 15-60 minutes at a mean towing speed of 2.5 knots. Stratified abundance and biomass estimates were calculated from catch-per-tow data using the stratum areas as weighting factor (Cochran, 1953). The coefficient of catchability was set at 1.0, implying that estimates are merely indices of abundance and biomass. Confidence intervals (CI) were set at the 95% level of significance of the stratified mean.

# 5.1.2.2.1 Stock abundance indices

Tables 5.1.11 and 5.1.12 list abundance and biomass indices of cod by year and stratum. The biomass indices for cod ranged between 4 000-7 000 t in 1988-1990. In 1991, the biomass decreased by more than 95 % to only 250 t and 528 000 individuals and remained at this low until recent years. There are indications of a slight improvement in the abundance of small cod. Abundance indices in 2001 were estimated to 1.6 million individuals, which is the highest estimate in the abundance time series. In 1999 to 2001 a significant amount of cod was captured in area 1AS, 1AX and 1BN for the first time.

## 5.1.2.2.2 Age composition

Age disaggregated abundance indices are listed in Table 5.1.13. In 2001, the recruiting year classes 1997, 1998 and 1999 dominated the stock by 94% with equal shares. Their abundance at ages 2 to 4 represent highest or second highest values of the time series, respectively.

## 5.1.3 Biological sampling of commercial catches

No commercial sampling data were available to assess recent catch in numbers, weight and maturity at age.

#### 5.1.4 Results from the 1996 assessment

The historical stock status was assessed based on the terminal Fs derived from an XSA tuning run applying 1992 as the final year.

Trends in yield and fishing mortality are shown in Figure 5.1.8. An increasing trend in Fbar from 0.1 to 0.4 was determined during the period 1955–68. During the same period, the yield increased from a level of 280 000 t to 380 000 t but decreased drastically to 100 000 t in the early 70s. Thereafter, the fishing mortality was highly variable and seemed to be dependent on the changes in effort directed to the exploitation of individual strong year classes. Periods when Fbar for ages 5–8 years exceeded 0.5 were 1974–1977, 1980–1984 and 1988–1992.

Trends in spawning stock biomass and recruitment were shown in Figure 5.1.9. During 1955 to 1973, the spawning biomass decreased almost continuously from 1.8 million t to 110 000 t, a decrease of 94%. Thereafter, the spawning stock biomass averaged 50 000 t. During the period 1955–73 before the spawning stock decreased below 100 000 t, the recruitment at age 3 varied enormously between 4 million and 700 million and averaged 220 million. Since 1974, the spawning stock varied around the mean of 50 000 t and produced an average recruitment of 41 million representing a mean reduction by 95% and 80%, respectively. The long term mean recruitment was not exceeded for 8 of 19 years from 1955 to 1973, while it has been below that value for 17 of 19 years since then. During the last 30 years, only 2 year classes have reached the long term mean recruitment level at age 3, namely those produced in 1973 and 1984.

#### 5.1.5 State of the stock

The two surveys, the German survey off West and East Greenland and the Greenland shrimp survey off West Greenland, do confirm that the offshore component of the cod off Greenland is at a very low level.

Both surveys indicate increased recruitment of the year classes 1997, 1998, 1999 and 2000, the year class 1999 being the third strongest at age 2 since 1982 in the German survey. However, the recruiting year classes cannot be described as strong being estimated to be less than 10 % of the most recent previous strong year class of 1984. Although rebuilding to previous high stock sizes cannot be expected to occur based on these year classes, they suggest that the process of rebuilding may have begun.

The age composition of the stock indicates high mortality rates of juvenile cod for the past decade, especially off West Greenland.

#### 5.1.6 Estimation of management reference points

Input parameters for the estimation of long term yield and spawning stock biomass per recruit are listed in Table 5.1.14 for age groups 3–12. Maturity and weight at age vectors were calculated as long-term means covering the period 1955–92. The natural mortality M was increased to 0.3 for age groups 5 and older to account for an emigration to Iceland. The exploitation pattern was derived as Fbar from the three most recent years from the final VPA. Determined F-factors for  $\mathbf{F}_{0.1}$  and  $\mathbf{F}_{max}$  were scaled according to the mean reference F over the age groups 5–8. The resulting estimates of yield and spawning stock biomass per recruit are illustrated in Figure 5.1.10. The values of  $\mathbf{F}_{0.1}$  and  $\mathbf{F}_{max}$  are indicated by arrows and amounted to 0.3 and 0.72, respectively. The lack of a well definite peak in the yield per recruit curve is due to increased natural mortality.

Recruitment at age 3 is plotted against the spawning stock biomass in Figure 5.1.11.  $\mathbf{F}_{med}$  amounted to 0.09. The corresponding spawning stock biomass per recruit was as high as 4.5 kg.  $\mathbf{F}_{high}$  amounted to 0.59 with the accompanied spawning stock biomass per recruit of 1.0 kg.

However, neither the determined Beverton & Holt nor the Ricker model fitted the observed recruitment-spawning stock biomass points well. The Beverton & Holt curve quickly reached the long term mean recruitment level affected by the strong 1973 and 1984 year classes related to low biomass values and extremely poor year classes 1969–72 produced by spawning stock sizes exceeding 250 000 t. The Ricker curve did not reach a maximum over the available range of observed spawning stock sizes. The time series, however, includes a remarkable variation in several parameters; larval drift from Icleland, changes in hydrographical regimes and a substantial reduction (extinction) of the West Greenland spawning stock. These conditions impede the use of total time series for estimation of biomass reference points.

## 5.1.7 Management considerations

Cod is described a common species in the Greenland fauna, although reaching here its ecological boundary. Given suitable environmental conditions, cod in the offshore areas of Greenland are considered to be self-sustaining. The size of the SSB was identified to have a major impact on recruitment at age 3 in the period 1955-89 (r2=0.41; Rätz et al., 1999), supported by the evidence of spawning in Greenland waters (Wieland and Hovgård, 2002). However, even with sizeable SSBs present and spawning occurring, water temperature may be so cold that eggs and larvae will not survive. An example of hampered recruitment was identified for the period 1969–72 when a continued cold event off West Greenland and an almost complete recruitment failure was observed (Figure 5.1.11). If cold water conditions persist for a sufficiently long time period, they may result in very low biomass of offshore cod. Although it is well documented that cod is always present at Greenland, it is similarly well documented that there have been periods of very low abundance (e.g. in the XIXth century), presumably due to persistent periods of cold temperature (Jensen and Hansen, 1931; Vilhjálmsson, H. 1997). Stock parameters, slow growth and poor conditions, suggest that to be sustainable, exploitation rates would need to be low, particularly in periods of cold water. In productive periods, higher exploitation rates could be sustainable, but it would be advisable to maintain a spawning stock biomass sufficiently large to buffer for brief periods of cold water.

The former VPA assessment of the offshore cod stocks off Greenland revealed that over-fishing was an important cause for the collapse of this unit in the beginning of the 70s. Since that time, the spawning stock has remained below 100 000 t and has not been able to produce adequate recruitment. Relatively strong year class were produced in 1973 and 1984 despite the low SSBs, but these are believed to have emigrated from Iceland as larvae. An increase in effort directed towards the strong 1973 and 1984 year classes at a young age resulted in a rapid decrease in abundance. The migration back to Iceland as mature fish further diminished the contribution of those year classes to local egg production. Recruitment pulses from Iceland could contribute to a substantial recovery of the offshore component in the short term. However, strong recruitment pulses are rare events (2 known occurrences in the last 30 years). In addition, strong year classes originating from Iceland may have a tendency to go back to Iceland when they mature. Therefore, increases in biomass from immigrating eggs and larvae may not be sustained. The links between the cod stocks off Iceland, Greenland and along the Canadian Atlantic shelves through egg and larval drifts are currently investigated by an ICES/GLOBEC project.

No fishing should take place until a substantial increase in stock size is evident. Technical measures to avoid the bycatch of juvenile cod should be maintained (mandatory use of a 22 mm sorting grid since October 1, 2000).

# 5.1.8 Comments on the assessment

The present assessment is based on survey indices only, due to the termination of the cod directed offshore fishery in 1992.

The VPA assessment conducted in 1996 was affected by several uncertainties in data as well as ecological factors. The effect of emigration was only directly covered for the 1973 and 1984 year classes and had been taken into account by an increase of the natural mortality to 0.3 for age groups 5 and older. The sampling of commercial catches was historically rather inconsistent and did not cover the 30% taken by miscellaneous gears, mainly longlines and gill nets up to 1977. Since 1991, catch at age and weight at age data had to be calculated using survey data. Maturity data were poorly reported implying uncertainties in spawning stock estimates.

No XSA tuning could be applied since 1997 when low levels in landings, effort and stock abundance were observed. The age disaggregated survey indices had to be adjusted to account for incomplete coverage of the survey area in 1992 and 1994.

## 5.2 Inshore cod stock off Greenland

In the last decade, the inshore cod fishery at West Greenland has contained cod from two different spawning areas. Icelandic cod spawned off South-western Iceland, which in some years are carried by the Irminger Current to settle off South Greenland, and local fjord populations. Spawning cod are found in several fjords of the West Greenland, especially in NAFO Divisions 1B, 1C and 1D. Although tagging experiments suggest a high degree of residency for fjord populations, the recruitment seems to be correlated between the different fjords (Engelstoft 1997).

## 5.2.1 Trends in Landings and Effort

Historically, the inshore landings have been minor compared to total landings accounting for only 5–10% of the total international catch in NAFO SA 1. Annual landings of 15 000–20 000 t have been taken inshore during the period 1955–1973. Since then the landings have been varying consistently with the recruitment of strong year classes to the offshore fishery. High landings of about 50 000 t in 1980 and 1989 have been followed by periods of very low landings. In recent years the landings has decreased dramatically from about 2000 tons annually in 1993–1995 to only 307 tons in 2000. No catch figure is available for 2001.

NAFO Div	1993	1994	1995	1996	1997	1998	1999	2000*	2001*
1A	333	209	53	41	18	9	360

Total	1926	2115	1710	948	904	319	622	307	

* no landing statistics available

The inshore fishery takes place from small vessels (< 40 GRT). Pound nets, gillnets and handlines are used to take about 95% of the inshore catch. A commercial pound net CPUE series is available since 1992 (Table 5.2). The mean catch pr pound net setting has decreased from 804 t in 1994 to 284 in 1999. No commercial catch or effort data from 2000 was available for 2001.

# 5.2.2 West Greenland young cod survey

A survey using gangs of gill nets with different mesh-sizes has been conducted since 1985 with the objective to assess the abundance and distribution of pre-recruit cod in inshore areas of Greenland. The survey has usually been carried out in three inshore areas off West Greenland: Qaqortoq (NAFO Division 1F), Nuuk (Division 1D) and Sisimiut (Division 1B). The Greenland inshore cod stock is not distributed in the Qaqortoq area, but occasional in  $\mathbf{F}_{low}$  of pre-recruited cod from East to West Greenland shows up here. Technical problems caused that only Division 1D was covered in 1999, and again in 2000 only Division 1D and Division 1F was covered. A more detailed description of the survey is provided in the 2001 report. No survey took place in 2001.

The recruitment index of 2-year old cod is shown in Figure 5.2 and reveals a strong 1985 and 1987-year class, a moderate 1990- and 1993-year class and four successive weak year classes up to 2000. The survey results confirm the severely depleted status of the stock, although the very low 1997- and 1998- class year might not be representative due to insufficient survey coverage.

# 5.2.3 Assessment of the stocks

No commercial input data have been available for the group since 2000 to assess the latest stock status of the inshore cod. Previously a Schaefer general production model was fitted to the Greenland inshore cod landing data using the commercial pound net CPUE results for 1993 to 1997 as an index of stock biomass. Lack of contrast in data impeded the model to run satisfactory.

The decreasing CPUE series and the present recruitment failure of the stock indicate that the severely depleted stock situation has continued until 2000.

# 5.2.4 Biological reference points

No specific values can be put forward as reference points due to the depleted state of the stocks.

## 5.2.5 Management Considerations

The inshore fishery exploiting possible self-sustained local fjord populations off West Greenland has historically been small, and the fishery has never been constricted by catch regulations. The data presented indicate that the stock has undergone a series of recruitment failures in recent years. The latest year classes are all estimated to be very poor in the juvenile survey. No fishing should take place until a substantial increase in recruitment and biomass is evident.

### 6 GREENLAND HALIBUT IN SUB-AREAS V AND XIV

### 6.1 Landings, Fisheries, Fleet and Stock perception

Total annual landings in Divisions Va, Vb and Sub-area XIV are presented for the years 1981–2001 in Tables 6.1.1–6.1.5 and from 1961 in Figure 6.1.1. Landings during the decade prior to the extension of the EEZ to 200 nm by coastal nations in 1976 were in the order of 20-35 kt. From 1976, landings increased from a low of 5kt to above 30 kt after 1982. In the years 1987–1989, landings increased to about 61 kt, followed by a decrease to about 35-40 kt during 1992-96. After 1996, landings declined to 20 kt in 1998 and 1999. Since 2000 an increase in landings has been observed, to nearly 26 kt in 2000 and about 28 kt in 2001. Landings not officially reported to ICES have been included in the assessment.

Catches in Icelandic waters have, due to quota regulations, decreased from 37 kt in 1990 to 11 kt in 1998 and 1999, but again rising to 14 kt in 2000 and about 16 kt in 2001. Faroese catches in Vb increased from of 1 kt in 1981–1991 to 6.5 kt in 1996, but have been of the order of 4-5 kt in the last 5 years. Catches in division XIVb have increased from below 1 kt in 1987–1991 to 8.5 kt in 1997 followed by a decrease to 5 kt in 1999. Since then catches have increased to about 7 kt.

Most of the fishery for Greenland halibut in Divisions Va, Vb and XIVb is a directed fishery, only minor catches in Va by Iceland, and in XIVb by Germany and the UK are by-catches in redfish fisheries. A detailed description of the fishery performance and areas is given in NWWG report 1998. No major changes were observed in 2001. Table 6.1.6 describes the working group best landing estimates for the year 2001 with respect to area and gear.

#### Stock perception

The current definition of the Greenland halibut in East Greenland, Iceland and Faroe waters as one stock, specified by ICES in 1976 was "based on a strong probability that the spawning grounds [for Greenland halibut in these waters] are the same". A summary of the current state of knowledge on Greenland halibut in the above mentioned waters shows that key information on the life cycle is lacking (Woll 2000). Information on the spawning location and spawning time of the stock is very limited. It is hypothesised, based on information on one scientific bottom trawl cruise in 1977, that the major spawning grounds are located on the continental slopes west of Iceland at depths around and below 1000 m (Magnusson 1977; Sigurdsson 1977; Sigurdsson and Magnusson 1980). In recent years (1995 and 2000), some spawning has been observed in East Greenland waters (62°N and 64°N) in August (Gundersen *et al.* 1997; Fossen and Gundersen 2000).

Standard 0-group fish surveys have been carried out annually in early fall (mainly in August) in Icelandic and in East Greenland waters since 1970. Larvae are mainly observed along the shelf region off East Greenland and are in some years abundant all over the shelf area south to 60° N, which is the southernmost limit of the survey area. Highest abundance is observed on the continental shelf north of 64° N and just east off the continental shelf south of 64° N. 0-group larvae are only occasionally observed on the Icelandic shelf in very limited numbers. Nursery grounds for young Greenland halibut (ages 1-3, fish less than 45 cm long) are well known in West Greenland waters, where they are most abundant from Store Hellefiske Bank to Disko and in Disko Bay between 66°-69° latitude on depths of about 200 m (Riget and Boje 1988). When it comes to knowledge on young fish in East Greenland and Icelandic waters, information is very sparse. A gillnet survey targeting for young Greenland halibut, modelling of advection of eggs and larvae with currents from assumed spawning areas in Icelandic and East Greenland waters (Woll 2000), and results of historic Greenland ichtyoplankton surveys (Boje 1997) indicated that larvae were transported to Southwest Greenland waters before settling, mixing with specimens from the Greenland-Canadian stock complex. Analyses of shrimp surveys in Icelandic and Greenland waters (Boje and Hjørleifsson 2000) concluded that nursery grounds were neither to be found in Icelandic nor in East Greenland waters.

The highest aggregation of commercial sized Greenland halibut is found just south of the Greenland-Iceland ridge. In this area the major portion of the annual catch in the past 10 to 15 years has been taken, mainly at depths between 500 and 1000 meters. Other locations of Greenland halibut in exploitable densities (for trawl fisheries) are found along the north and east coast of Iceland, mainly at depth between 500 to 700 meters, in waters of Faroe Islands as well as along the continental slope off East Greenland. The size of the Greenland halibut in the trawl fisheries depend largely on location and depth, and to some extent on the season. In Icelandic waters, smaller fish are found along the east and north coast, with somewhat larger fish in the deeper waters south of the Faroe-Iceland ridge. Largest fish are, however, always found on the main fishing grounds between Iceland and Greenland.

# 6.2 Trends in Effort and CPUE

Indices of CPUE for the Icelandic trawl fleet for the period 1985–2001 (Table 6.2.1) were estimated from a GLIM multiplicative model, taking into account changes in the Icelandic trawl catch due to vessel, statistical square, month, and year effects. All hauls with Greenland halibut exceeding 50% of the total catch were included in the CPUE estimation. The CPUE indices from the Icelandic trawling fleet in Division Va were used to estimate the total effort for each year (y) for all the fleets fishing for Greenland halibut in areas V and XIV according to:

 $E_{y,V\&XIV} = Y_{y,V\&XIV} / CPUE_{y,Va_{travel}}$ 

where E is total effort, Y is the total reported landings in region V and XIV.

The CPUE series as derived in 2001 differs from the present and also from former series, due to a change in the species selection from the logbook database.

Catch rates of Icelandic bottom trawlers decreased for all fishing grounds during 1990–1995, but stabilised in 1995–1997. In 1998, an increase of 50% in CPUE was observed for all fishing grounds coinciding with a drastic (60%) reduction in effort (Table 6.2.1, Figure 6.2.1). Since 1999 further increases in CPUE have been observed (8-20%). The total effort increased up to 1989, decreased somewhat in the next two years, but increased steeply from 1991 to a maximum in 1993. Effort during 1998-2001 has been less than half of that in 1995-97. The CPUE was relatively stable in 1985–1989, but declined thereafter by 70% to a historic low in 1996 and 1997. With the increase during the last 3 years the CPUE is now around 60% of the maximum value (Table 6.2.1).

For division XIVb, CPUE from logbooks in the years 1991–2001 were standardised using a multiplicative model taking into account locality, fleet, season and year (Table 6.2.1). CPUE increased from 1991 to 1993, thereafter it remains relatively stable. Effort increased continuously until 1996, but declined by 30% until 1999. Since 1999 the effort increased and is record high in 2001 However, the fishery in XIVb is just starting out and catches have increased from below 500 tons annually before 1991 to about 7000 t in the last three years. The fishery was therefore assumed to be in the process of learning in the beginning of the CPUE series.

Information from logbooks from the Faroe otterboard trawl fleet (> 1 000 hp) was available for the years 1995-2000 (Table 6.2.1). The logbooks were standardised using a multiplicative model taking into account locality, fleet, season and year. The fishery in the area has increased from about 1000 t in 1992 to 5000 t in 2000. It is a fairly new fishery and the location of the fishery has changed from the eastern side of the islands in 1995-1998, to the western side in 2000. Therefore, the fishery is assumed to be in the process of learning. The CPUE is stable throughout the period.

# 6.3 Catch at Age

Age-length keys for 2001 were from: the Icelandic trawl fleet operating in Icelandic waters (252 otoliths). This key was used to obtain catch in number for the length samples for each of the following commercial fleets and areas:

Gear	Area	Landings	No. samples	No. fish	A/L-Key
Bottom trawl	Iceland-west	14423	52	6394	Icelandic bottom trawl
Bottom trawl	Iceland-north & east	1223	11	1479	Icelandic bottom trawl
Bottom trawl	Iceland-southeast	1106	10	2339	Icelandic bottom trawl
Gill Net (&line)	Faroe Islands	2812	12	4535	Icelandic bottom trawl
Bottom trawl	Faroe Islands	1241	5	606	Icelandic bottom trawl
Long line	East Greenland	983	18	2478	Icelandic bottom trawl
Bottom trawl	East Greenland	6233	14	1532	Icelandic bottom trawl
Total		28021	122	19363	

The following length-weight relationships were applied to convert sampled lengths to weights:

Gear	Area	Length - weight key	Comments
Bottom trawl	Iceland	W = 0.01758 * L ^{2.84387}	Same key as 1999
Bottom trawl	East Greenland	W = 0.00161 * L ^{3.4457}	Commercial trawl N=2468, same as 2001
Bottom trawl	Faroe Islands	W = 0.00202 * L ^{3.398}	Trawl survey, N=1916
Gill Net (&line)	Faroe Islands	W = 0.00202 * L ^{3.398}	Trawl survey, N=1916
Long line	Iceland	W = 0.01758 * L ^{2.84387}	Same key as 1999
Long line	East Greenland	W = $0.00208 * L^{3.373}$	Longline survey, N=664, same as 2001

The total catch in numbers (Table 6.3.1) was obtained from the sum of the above weighted with the catch within each group. Apart from 1994 and 1996 – 2000, only Icelandic data has been available.

# 6.4 Weight at Age

The mean weight at age in 2001 (Table 6.4.1) was derived from the weighted average of the above groups. Weights at age in the catch are also used as weights at age in the stock.

# 6.5 Maturity at Age

Maturity data were not updated for 2001 as visual determination of maturity has been questionable as stated in 2001 report.

# 6.6 Survey information

An October groundfish survey in Icelandic waters, covering the distributional area of Greenland halibut within the Icelandic EEZ, was started in 1996. The survey is a fixed station stratified random survey consisting of 300 stations on the continental shelf and slope down to a depth of 1300 m. An increase in the fishable biomass of Greenland halibut (fish of length equal to or greater than 50 cm) is observed from 1996 to 2001 (Figure 6.6.1). Abundance indices of smaller fish (<50 cm) indicate signs of improved recruitment in 1998 and 1999 that may account for the increase in the estimated fishable biomass over the period. Aged indices from the Icelandic survey are not yet available and were therefore not possible to use the survey as input into age-based model.

Since 1998, a Greenland survey for Greenland halibut has been carried out in East Greenland waters from 60°N to 67°N at the main commercial fishing grounds at depths of 400-1500 m in late June/early July. In 2000 a total of 75 stations were hauled. No survey took place in 2001. Total estimated biomass was estimated to 23 kt compared to 15 kt in 1999 and 21 kt in 1998. The increase is, however, dependant on the inclusion of new strata since 1998. Since the age composition in the catches does not indicate changes in recruitment to the area, the increase in biomass must be considered to be within the error margin of the estimates.

# 6.7 Stock Assessment

# 6.7.1 Age based assessement

Age-disaggregated CPUE values for age groups 7–12 from the Icelandic trawling fleet operating in Division Va, have previously been used in the XSA tuning assessments. Since 2000 the XSA assessment have been considered unreliable due to poor diagnostics and was thus rejected as a base for advice. This year the working group ran an XSA assessment with the same settings as in 2000 report as an exploratory exercise. Since the diagnostics of the model was of similarly poor quality (see log(q) residuals in Figure 6.7.1.1 and retrospective pattern of F in Figure. 6.7.1.2), the working group decided that an XSA model was not a reliable estimator of recent stock history.

# 6.7.2 Stock production model

The group decided to proceed with the stock-production model approach ASPIC, fitted to indices and catches. The model requires series of catch data and indices of stock biomass, either corresponding effort, CPUE, or survey catch rates. Corresponding catch and effort data is available for Division Va (formerly used as a tuning fleet in the XSA) and in addition several CPUE series (Figure 6.2.1) were available:

Fleet and index	Period	Division
Icelandic trawler CPUE from GLIM	1973-2001	Va
Icelandic fall groundfish survey	1996-2001	Va
Greenland deepwater bottom-trawl survey	1997-2000	XIVb
Faroese trawler CPUE from GLIM	1995-2000	Vb
Icelandic shrimp fishery	1986-1994	Va
Icelandic shrimp survey	1987-2000	Va

The Icelandic shrimp fishery no longer exploits Greenland halibut, because of implementation of sorting grids in recent years. It does thus not provide indices of recent stock trends and was thus not included in the model. Since the shrimp survey covers a relatively limited area, the index was also excluded as an input candidate into the model. A run using the remaining four indices showed conflicting signals for the Faroese trawlers and the East Greenland survey compared with each other and with the Icelandic trawler and survey series, i.e. negative correlations of the CPUE indices. As ASPIC will not run on negatively correlated data series, these two indices were also omitted. For the two remaining indices — Icelandic trawler standardized CPUE and Icelandic groundfish survey — ASPIC was run with a reduced commercial time-series from 1985-2001 and the fall groundfish survey from 1996-2001. The decision of using only a reduced time series is because the CPUE index from 1973 to 1985 may not be reliable because it is based on limited logbook material and may cover a learning period at the the beginning of the fishery.

ASPIC requires starting guesses for *r*, the intrinsic rate of increase, MSY, B1/ $\mathbf{B}_{MSY}$  ratio and *q*, catchability coefficients. Initially ASPIC was run with different starting guesses of these parameters to explore stability of parameter estimation. For an appropriate range of input values, ASPIC results were very stable. The parameter estimates from ASPIC were comparable to last year (Table 6.7.2.1.). MSY is estimated to 37 kt and  $\mathbf{B}_{MSY}$  to 98 kt. Biomass in 2002 is estimated to be about 30% below  $\mathbf{B}_{MSY}$  and fishing mortality in 2001 slightly above  $\mathbf{F}_{MSY}$ . Observed and estimated CPUE's are given in Figure. 6.7.2.1.

The state of the stock relative to  $\mathbf{F}_{MSY}$  and  $\mathbf{B}_{MSY}$  is given in the Figure 6.7.2.2. Biomass is increasing from a record low in 1997-98 and in 2002 is about 25% below  $\mathbf{B}_{MSY}$ . F has in the last decade been very high (60% above  $\mathbf{F}_{MSY}$ ), but since 1998 is estimated to be near or above  $\mathbf{F}_{MSY}$ .

Retrospective analyses were carried out for both  $B/B_{MSY}$  and  $F/F_{MSY}$  in order to exploit the consistency of ASPIC with the currently used cpue series (Figure. 6.7.2.3). Within the last three years ASPIC behaved very consistent, due to contrasting cpue data, but omitting more years from the cpue series would prevent ASPIC to give consistent output.

# 6.7.3 Stock projection

From calculated stock-dynamic parameters and input fishing regimes, ASPIC can project forward trajectories of population biomass and fishing mortality including uncertainty estimates based on bootstrapping. In all forward projections it was assumed that the catch in 2002 would be maintained at 30 kt. This is based on the following: TAC in Icelandic waters is maintained at 20 kt and expected to be caught. Given that the landings in Vb and XIV will be the same as in 2001 and that the Icelandic fleet will catch all its quota, it is anticipated that total landings in the year 2002 also will be in the order of 30 kt. Three different trajectories were produced using the following options:

1)  $F(2002-10)=2/3F_{MSY} \sim F_{pa}$ , 2)  $F(2002-10)=F_{sq}$ 3) Catch(2001-2010)=30,000 t.

Plots of B-ratios (B/ $\mathbf{B}_{MSY}$ ) are given in Figure. 6.7.3 and biomass trajectory for option 1 only is given in Table 6.7.3. By fishing at  $\mathbf{F}_{pa}$  (2/3 $\mathbf{F}_{MSY}$ ) it is expected that the biomass will increase to  $\mathbf{B}_{MSY}$  by 2005. Fishing at  $\mathbf{F}_{sq}$  (~ $\mathbf{F}_{MSY}$ ) is, however, expected to reach  $\mathbf{B}_{MSY}$  by 2007, although the confidence interval is wide. Fishing at 30 kt annually is expected to allow recovery to  $\mathbf{B}_{MSY}$  by 2007, but with a significant risk (80% confidence intervals) that the stock will remain low. Landings in 2003 associated with the trajectories are 23 000 t at  $\mathbf{F}_{pa}$  and 34 000 t at  $\mathbf{F}_{sq}$ .

# 6.7.4 Biological reference points

Defined reference points for Greenland halibut have previously been defined on the basis of an age-based analytical assessment. The working group considers it appropriate to define  $\mathbf{F}_{pa}$  as 2/3 of  $\mathbf{F}_{MSY}$  estimated from the stock-production model. Using 2/3 as  $\mathbf{F}_{pa}$ ,  $\mathbf{F}_{lim}$  could be calculated using  $\mathbf{F}_{lim}=\mathbf{F}_{pa}*e^{1.645\sigma}$ , when  $\sigma$  could be 0.30.

# 6.8 Management Considerations

No formal agreement on the management of the Greenland halibut exists among the three coastal states, Greenland, Iceland and the Faroe Islands. The regulation schemes of those states have previously resulted in catches well in excess of TAC's advised by ICES. A likely scenario is therefore a continuation of *status quo* catch at 30kt in the short term. This will most probably result in a steady recovery of the biomass in the near future, but with a risk that the stock will remain low.

# 6.9 Comments on the Assessment

Analytical assessment (XSA) was attempted with same settings as in 2000 and 2001, but was rejected due to poor diagnostics and a substantial new perception of the stock size. Both former XSA and this years stock production model suggest that the Greenland halibut stock biomass has been falling since the late 1980'ies. Also according to both assessment methods, the fishing mortality has been substantially above  $\mathbf{F}_{pa}$  for a decade. The decline in biomass seems to have been halted since 1998, but biomass is still well below  $\mathbf{B}_{MSY}$ . A combination of unreliable maturity data and age readings from recent years still impede any age-disaggregated assessment and therefore also any estimate of SSB and its use in relation to  $\mathbf{B}_{pa}$  and SSB as a reference point for management advice for the stock.

The stock production model used to assess the status of the stock relies on the same trawlers CPUE series as previously used in the XSA. Output estimates of biomass and fishing mortality of the production model cannot be taken face value, but should rather be good estimates of state of the stock in relation to MSY parameters.

# 7 REDFISH IN SUBAREAS V, VI, XII AND XIV

The genus *Sebastes* is very common and widely distributed in the North Atlantic, where it is found off the coast of Britain, along Norway, in the Barents Sea and Spitzbergen, off the Faroe Islands, Iceland, East Greenland, West Greenland, and along the east coast of North America from Baffin Island to Cape Cod. All *Sebastes* species are viviparous. The extrusion of the larvae takes place in late winter - late spring/early summer but copulation occurs in autumn-early winter.

# 7.1 Description of problems regarding stock identity of the species and stocks in the area

In ICES Subareas V, VI, XII and XIV there are at least 3 species of redfish, *S. marinus*, *S. mentella* and *S. viviparus*. The last has only been of minor commercial value. Iceland has started to fish *S. viviparus* in 2 small areas south of Iceland at depths of 150 - 250 m. The landings of *S. viviparus* decreased continuously from 1,160 t in 1994 to only 21 t in 2001.

During recent years, the existence of more than one stock of *S. mentella* in the area was discussed. Historically *S. mentella* was fished on the shelves and banks of the Faroe Islands, Iceland and East Greenland and was considered as one stock. With the start of a new pelagic fishery in the open Irminger Sea in 1982, a new stock was defined for management purposes for *S. mentella* inhabiting the Irminger Sea. In 1992, the Study Group on Redfish Stocks distinguished between these types as deep-sea *S. mentella* (shelf redfish) and oceanic *S. mentella* (Irminger Sea redfish). In the early 90's, the pelagic fishery in the open Irminger Sea moved to deeper layers beyond 500 m. Some researchers considered that some of the fish caught pelagically deeper than 500 m were different to those living shallower than 500 m and resembled more the deep-sea *S. mentella* living on the shelves. *S. mentella* living deeper than 500 m has been called "pelagic deep-sea *S. mentella*". Recently, it has become apparent that distribution of pelagic *S. mentella* in the upper 500 m has extended significantly south-westerly, compared with the early 1990's into the NAFO Convention Area. It is not known if these types are more than one stock and different hypotheses have been put forward:

A single stock hypothesis: All *S. mentella* from the Faroe Islands to the Grand Banks constitute one stock, segregated according to age/size.

A two stock hypothesis: *S. mentella* living on the shelves (deep-sea *S. mentella*) and that living in deeper pelagic waters of Irminger Sea (pelagic deep-sea *S. mentella*) constitute one stock unit which is separated from the oceanic *S. mentella* living in upper layers of the Irminger Sea.

A three stock hypothesis: The described components constitutes a distinct stock.

The uncertainty about stock identity is high but extensive research is presently ongoing (EU-QLK5-CT1999-01222). The project is an internationally coordinated research directed to answer important questions related to the biology and exploitation of the highly migratory and straddling redfish resources. The research focuses on three main areas: 1. "Population structure", 2. "Reproductive strategies" and 3. "Abundance and demography". In part 1, extensive work seeking for species and stock identification markers has been conducted and by now at least over 25 markers for stock identification have been found and for stock structure and stock origin analysis of *S. mentella* and *S. marinus* at least 10-13 suitable markers have been identified. Now, as markers have been found, continued screening will reveal whether the observed variations in such markers do represent stock structures.

In 1999, The Faroese Fisheries Laboratory initiated a research to study the stock structure *of S. mentella* in the North-East Atlantic. Sampling of *S. mentella* was carried out from different locations and depths in the Irminger Sea, off Iceland, Faroes and in the Barents Sea. Several different stock identification methods (incl. morphometrics, fatty acid analysis, electrophoresis and DNA analysis) were applied on the same fishes by researchers from several countries. Some of the analyses are finished and the results (i.e. from the fatty acid analysis and electrophoresis) have been submitted for publication. Some results have been presented supporting multi-stock theory (Joensen 2001) and will be available within the next months as a part of a Dr. Scient thesis.

# 7.2 Nominal catches and splitting of the landings into stocks

The official statistics sent to ICES do not report catch by species/stocks (Tables 7.2.1 - 7.2.5).

Various information (i.e. proportion in samples taken from different fishing areas, information on products etc.) from different laboratories is used to split catches into species/stock. The technique and data for such splitting was described in the 1998 NWWG report.

# 7.3 Abundance and distribution of 0-group and juvenile redfish

Available data on distribution patterns of 0-group and juvenile *S. marinus* indicate that there are nursery grounds in Icelandic and Greenland waters only. No nursery grounds are known around the Faroe Islands. In the 1983 Redfish Study Group report (ICES C.M. 1983/G:3) and in Magnússon and Jóhannesson (1997), the distribution of 0-group *S. marinus* off East Greenland was evaluated, showing that there are considerable amounts of *S. marinus* at East Greenland mixed with *S. mentella* (Magnússon et al., 1988 and 1990) in variable proportions in different sub-areas and periods (ICES CM 1998/G:3). In Icelandic waters, nursery areas for *S. marinus* are found mostly west and north of Iceland at depths between 50 and approximately 350 m, but also in the South and East (ICES C.M.1983/G:3; Einarsson, 1960; Magnússon and Magnússon 1975; Pálsson *et al.* 1997). As length (age) increases, migration of young *S. marinus* along the north coast to the west coast takes place towards the most important fishing areas around Iceland.

Indices for 0-group redfish in the Irminger Sea and at East Greenland areas were available from the Icelandic 0-group surveys from 1970 - 1995. Thereafter, the survey was discontinued. Above or average year class strengths were observed in 1972, 1973-74, 1985-91, and in 1995.

Abundance, biomass indices and length compositions have been derived using German annual groundfish surveys covering shelf areas and the continental slope off West and East Greenland down to 400 m depth (WD 11). Due to difficult identification, juvenile redfish (< 17 cm) were only classified to genus as *Sebastes spp*. Trends in survey abundance for juvenile redfish (< 17 cm) are shown in Figure 7.3.1 for West and East Greenland. Since 1993, *Sebastes spp*. were very abundant and distributed mainly off East Greenland. The 1999-2001 survey results indicate low abundance and biomass, similar to those observed in the late 1980's.

# 7.4 Discards and by-catch of small redfish

# 7.4.1 Discards of redfish in East and West Greenland

An offshore shrimp fishery with small meshed trawls (44 mm) began in the early 1970s off the west coast of Greenland and expanded to the east coast in the beginning of the 1980s, mainly on the shallower part of the Dohrn Bank and on the continental shelf from 65° N to 60° N. Observer samples derived from the Greenland Fishery Licence Control showed that redfish is a bycatch in the shrimp fishery off Greenland. There was no information available to quantify the by-catches and their length composition in recent years. Since the 1st of October 2000, sorting grids have been mandatory but their actual effect on the bycatch in the commercial fishery has not yet been documented.

# 7.5 Special Requests

In the ToR for the Working Group, there are several questions regarding stock structure, distribution and fishery information of *S. mentella* in the area. The following paragraphs deal with ToR c, e, and f and special request b) and c) from NEAFC. Under different redfish chapters, the Working Group also deals with these questions, in some cases in more detail.

ToR c) Detailed descriptions of the fishery of different nations are given in chapters 8.2, 9.2 and 10.2, based on various working documents. WD07 gives the geographical fishery overview of five nations which together are fishing over 70% of the total catches in recent years. Figure 7.5.1 shows the geographical distribution of the catches by months in 2001 and Figure 7.5.2 gives the distribution by year from 1995-2001. Based on data from these nations (Germany (1995-2001), Iceland (1989-2001), Norway (1990-2001), Russia (1999-2000) and Greenland (1999-2001)) it was concluded that the fishing pattern has been similar in the last four years. WD 4 gives the locations of a part of the Spanish fishery in the Irminger Sea, and it shows that they had same pattern in 2001 as the above-mentioned fleets (Figure 7.5.3). The same applies for the Russian fleet in 2001 (Figure 7.5.4).

Fishing started in April, and up to the end of June, it was prosecuted in area east of 32°W and north of 61°N. In July and August, the fleet moved about 400-500 nautical miles to areas south of 60°N and west of about 36°W where the fishery continued until October. In the third quarter of the year, the fishing has, in general, moved towards the southern part of the area within Sub-area XII as well as in the NAFO Convention Area, both outside and inside the Greenlandic EEZ. There has traditionally been very little fishing activity from November until late March, and in 2000/2001 no activity was reported during that time.

Although no depth information from all fishing nations was available, the general pattern is that the fishing in the first and second quarter of the year in the north-eastern part is mostly conducted deeper than 500 m. Haul depth data from Spain, Faroe Islands, Greenland and Iceland confirms this (WD's 4,8,15). In the third quarter, fishing occurs mostly at

depths shallower than 500 m. Further, although no depth data on haul-by-haul information of the German catches were available, WD12 describes that the fishery in the first two quarters was characterised by fishing deeper than 500 m and at shallower depths during the third and fourth quarters in 1995-2001.

However, it is important to note that the described fishing pattern of the different fleets has changed significantly prior to 1996 mainly in terms of area and depth expansion. The reasons for such changes do not necessarily reflect stock changes only but might also be due to commercial considerations.

Although the fish in all seasons are sexually mature, the mean length in the second half of the year, in Sub-area XII and in NAFO Convention Area is about 8 cm shorter than in the first half of the year in Subarea XIV (Figure 7.5.5).

As has been reported in earlier reports of the working group, Iceland has classified its pelagic catches between oceanic and pelagic deep-sea redfish according to a contentious method. The results of this classification have shown that the proportion of fish classified as oceanic type redfish did decrease from about 70% in 1995 down to only about 5% in 2000. In 2001, the percentage did increase again up to about 1/3 of the catch, this being largely a result of increased effort in the south-western fishing area at depths shallower than 400m. Based on the samples, the results indicate that at depths shallower than 500-600 m, the proportion "oceanic" is between 85-100%, and the proportion deeper than 600 m is usually between 0-20%. The increase in 2001 is due to the effort regulations in the fishery. Each vessel was forced to fish at least 1/3 of it's catches south of around 62°N in order to spread the effort.

The above observations indicate that in last three years a) the fishery in the north-eastern area in the first half of the year is occurring at depths deeper than 500 m and catching larger fish, and b) the fishery in the south-western area in the second half of the year is mainly occurring at depths shallower than 500 m catching smaller fish.

The working group recommends that NEAFC requests all nations participating in the pelagic redfish fishery to provide ICES with information on the trawling depth (headline depth for each haul as a log-book data), so ICES can give a more detailed description of the fishery by season and areas as a basis for advice on this resource.

ToR e and NEAFC special request b) and c). New information presented at the meeting (WD19 and WD17) supports the one stock theory. WD19 deals with analysis of genetic material and WD17 deals with analysis of biological characteristics and peculiarities of infestation with parasites. Genetic structure of the species was also the issue of a newly published article (Roques et. al, 2002), concluding that there is a lack of genetic differences and lack of genetic isolation by geographic distance among samples from the Panoceanic zone, from the Faroe Islands to the Grand Banks. In an ICES paper (Joensen 2001), results based on chemometry of the fatty acid profile in selected tissues supports a multi-stock theory. Based on the available information and information described in previous working group reports and published articles, the NWWG concluded that there are still uncertainties in the stock structure of *S* .mentella in ICES Sub-areas V, XII and XIV and the NAFO Convention Area (see Figure 7.1). In accordance with the precautionary approach the units should at present, be managed such that each component is not overexploited. This implies that fishing effort and catches should be spread out.

ToR f) Limited information is available for describing the distribution of the stock(s) in the area throughout the year and the new information from the international trawl-acoustic survey in 2001 does not add much to the current knowledge. Information from various acoustic estimates in recent years only describes the distribution at one time of the year (June/July). Information from the fishery of various nations cannot be used alone as a description of the distribution. These sources are thus not considered adequate to describe the seasonal distribution of the various components. In chapter 10, a description of the distribution from the 2001 international acoustic survey and description of the fishery are given. Compared with acoustic results in June/July 1999, the pelagic redfish shallower than 500 meters is now found more westerly and southerly, into the NAFO Convention Area (see Figure 10.3.2). In 1999 and 2001, about one third of the stock was distributed in the NAFO Convention Area. Substantial fishery in NAFO Convention Area was also observed in 2001. In the data available to the working group, all information supports that the fishery in the NAFO Convention Area is from the same stock as fished in western part of ICES Sub-area XII (WD4,WD6, WD8, WD 13, WD16).

# 8 SEBASTES MARINUS

### 8.1 Landings and Trends in the Fisheries

Since the early 1980'ies total catches have decreased more than 70%. from about 130 000 t in 1982 to 37 000 t in 2001 (Table 8.1.1In recent years catches have been stable around 40 000 t, a slight increase in 1999-2000 are due to increased catches in Sub-areas Va and VI (Table 8.1.1).

The catches of *S. marinus* in Va in recent years are the lowest since 1978. Catches declined from about 63 000 t in 1990 t, to a low (34 000 t) in 1996. Since then catches varied between 35 000 and 41 000 t, with the lowest catch in 2001. The low catch in 1994 was partly due to area closures imposed on the fishery by Iceland in order to reduce the catches of *S. marinus*, and to reduce the effort on the nursery grounds. However, landings in 1995 increased to approximately 42 000 t. The length distributions in the Icelandic landings in 1989-2001 along with measurements from the commercial trawler fleet are shown in Figure 8.1.1. Number of measured fish by statistical square are given in Figure 8.1.2, and the fishing grounds are shown in Figure 8.1.3. About 90-95% of the total *S. marinus* catches in area Va have in recent years been taken by bottom trawlers (both fresh fish and freezer trawlers; length 48-65 m) targeting on redfish. The remainder is taken partly as bycatch in gillnet and longline fishery. In 2001, as in previous years, most of the catches were taken along the shelf of W, SW and to SE of Iceland, mostly between 12°W and 27°W (Figure 8.1.3).

In Division Vb, catches have dropped continuously since 1985 from 9 000 t to 1 500 t in 2001. (Table 8.1.1). Most of the *S. marinus* catches in Vb have been taken by pair trawlers and single trawlers (< 1000 HP). The CPUE decreased from 1996-1999 by 40% and has been low in 2000 and 2001 with 13 and 8% of the 1999 value, respectively (Figure 8.1.4). No length distribution from the catches was available for 2001.

The catches in Sub-area VI increased since 1978, reaching almost 600 t in 1987, followed by a decline to 1992 and since increased to about 800 t (Table 8.1.1) in 2000 and 500 t in 2001. No length distribution from the catches was available for 2001.

In Sub-area XIV catches have been more variable than in the other Sub-areas and Divisions. Since the highest catch on record (31 000 t), in 1982 a rapid decrease was observed to about 2 000 t in 1985. During the next 10 years catches varied between 600 and 4 200 t. In 1995-1997 almost no directed fishery for *S. marinus* or *S. mentella* occurred. A minor directed fishery occurred in 1998 and catches increased to 175 t. In 2000 and in 2001 the catch is estimated to be less than 100 t. from direct redfish fishery of large bottom trawlers targeting at *S. mentella*. Some bycatch is reported from the shrimp fishery in the area.

The following text-table shows the fishery related sampling by gear type and Divisions.

Area	Nation	Gear	Landings	Samples	Fish measured
Va	Iceland	Bottom trawl	34,693	262	52,444
Va	Germany/UK	Bottom trawl	232		
Va	Faroe	Line/hooks	62		
Vb	Faroe	Bottom trawl	1,513

VI	UK	Bottom trawl			
XIV	Norway	Longline			

#### 8.2 Assessment

# 8.2.1 Trends in CPUE and survey indices

Figure 8.2.1 shows the *S. marinus* abundance index with 95% confidence intervals using Icelandic groundfish survey (IGS), data (<400 m depth). The index is a biomass index of the fishable stock, computed by using a sharp fishable stock ogive (from 34-36 cm,  $L_{50} = 35$  cm) The survey (see Pálsson *et.al*, 1989) is stratified (Figure 8.2.3). In Table 8.2.1 the contribution of each stratum to the index is given. The index indicates a decrease in the fishable biomass from 1999, and is now comparable with 1996-1998. The lowest index was in 1995, only about 30% of the maximum in 1987. The increase in the survey index in 1999 was not supported by the results in March 2000 and 2001, but in 2002, the index increased significantly. The results since 1995 might indicate that the catchable biomass estimate have been increasing slowly from the record low index of 1995.

Length distributions from IGS show that the peak (Figure 8.2.4) which has been followed during the last years (first in 1987) now has reached the fishable stock. The increase in the survey index since 1995 therefore reflects the recruitment of a strong year class (1985 year class and the 1990 year class). This indication of strong year classes is also confirmed by age readings.

The 1985 year class has dominated the catches since 1995 (Figure 8.2.5), and in 2001 that year class contributed to almost 30% of the total catch in Va. The survey results have also shown that 1990/1991 year classes are also strong, and contributing with nearly 30% of the total weight in the catch in 2001, indicating that it might be at similar size as the 1985 year class was at similar age. The 1990 year class (age 11) contributes about 15% of the total catches in 2000, according to the age readings. The average Z, estimated from this 7 year series of catch at age data is 0.24 for age groups 15+ and about 0.21 for age 20+. In WD 11 in the NWWG report 2001, age reading results are compared between readers and otolith preparation methods in terms of bias and precision. There were significant differences between readers and between methods, mainly for the older fish (> 20 years). Precision estimates, involving the high longevity of redfish, were relatively good compared to previous age reading comparisons on redfish species.

CPUE indices for the Icelandic trawl fleet for the period 1985-2001 are estimated from a GLIM multiplicative model, taking into account changes in the Icelandic trawl catch due to vessel, statistical square, month and year effect. All hauls at depths above 500 m with redfish exceeding 10% of the total catch, were included in the CPUE estimation (Figure 8.2.6). Also, a simple CPUE was calculated (sum of catch / sum of hours trawled for each year, each haul where redfish exceeded 10% of the total catch in each haul). The results from the trawler fleet reflect the situation shown in the groundfish survey. Although the CPUE was low in recent years it increased in 1997 and was relatively stable in 1998-2000. A considerably increase was observed in 2001 and the GLIM index is now above 80% of the1986 value, which is the first year in the series. The raw index is now higher than it was in 1986.

In summary, the Icelandic groundfish survey, as well as the CPUE series, seem to indicate a considerable decline in the fishable biomass of *S. marinus* during the period from 1986 to 1994. The stock seems to have started to recover but it is still low according to the survey index. A large proportion of the catches in recent years is caught from two year classes.

The Icelandic groundfish survey indices (U) may be assumed to be related to overall biomass (B) by a simple linear relationship (U=kB). If catches are assumed to be proportional to stock size and effort (Y=cEB), then it follows that catch over survey index is proportional to effort (Y/U=aE, see Table 8.2.3) and this allows a one-year prediction of catch, assuming a status-quo effort level.

Although calculated confidence limits in the groundfish survey are quite low, year to year variation in catchability/availability will affect the results drastically while using only the last observation value as a basis for extrapolation of catches in the coming year, based on a constant effort. By using a running average over few years (3 as a minimum), one would reduce the variation in the catch prediction, based on the above assumptions. The following text table gives the running mean of the IGS index given in Table 8.2.3.

The following text table gives the running mean of the IGS index given in Table 8.2.3.

running average																

In Division Vb, CPUE of *S. marinus* were available from the Faroes groundfish survey 1983- 2000. After an increase in the period from 1995-1998 there is a decrease in 1999 -2000. The results also indicate a high variability in the series, and the values are based on only 43 hauls each year (20-61 hauls). The value in 1999 - 2000 is only about 70% of the average value for the whole period since 1983 (Figure 8.2.7).

The new Faroes summer survey (see chapter 2) that has been conducted since 1996 shows a constant decreasing trend throughout the series. The index in 2000 and 2001 is only about 1/3 of the CPUE in 1995 and about the same level as in 1999 and 1998 (Figure 8.2.8).

For the period 1982-2001, abundance and biomass indices from the German groundfish survey for *S. marinus* >17 cm are illustrated in Figures 8.2.8 and 8.2.9. From 1986-1995, an almost continuous reduction in survey biomass has occurred. However, in 1998 and 2000 a weak signal of possible recovery was observed, although the values are very low compared with the period before 1990. It can be taken from Figures 8.2.8 and 8.2.9 that redfish around Greenland were mainly distributed off the East coast, as the abundance and biomass indices off West Greenland decreased to
almost zero. The length frequencies from the German groundfish survey are illustrated for West and East Greenland in Figures 8.2.11-8.2.12, along with the length distributions in the IGS. The adults seem to remain almost depleted in East Greenland waters.

During the Greenland halibut survey (400-1500m) in XIVb in June/July 2000, *S. marinus* was only observed between 400 and 600 m. *S. marinus* was caught in 12 of the 55 hauls taken. The length distribution ranged from 19 to 54 cm with a peak in the length of 29 cm. The survey was not conducted in 2001.

# 8.2.2 Alternative assessment methods

At the 1999 working group meeting, an alternative model (BORMICON(BOReal MIgration and CONsumption model)) was applied to the stock. The model is described in WD 18 in ICES CM 1999/ACFM:17 and has been presented in different forum during the last years.

The BORMICON model was run using the same settings as last year. Simulation period is from 1970 to 2002. Two time steps are used each year. Results from the runs are shown in Figures 8.2.12 - 8.2.14 and comparison with last years results in Figure 8.2.15. As may be seen the stock estimate this year is relatively similar, although little lower, the difference probably driven by the survey and possibly length distributions from the catch. (In last years assessment the length distributions for 2000 were not included). Survey indices for this species increased since 1993 to a maximum of 377 in 1999. Since then indices have been in the range 221-260. Indices have been attended with relatively high CV's (Table 8.2.5). In spite of increase in the index from 2001 to 2002 the index is still below the values in 2000 and especially 1999 and could be pulling the results down. The CV of the survey index in 2002 is on the other hand lower than has been for a number of years.

Natural mortality is set to 0.15 for the youngest decreasing gradually to 0.05 for age 5 and older. Alternatives with other values on natural mortalities (M=0.1 for age 5+) were tested. They gave worse fit, and are therefore not incorporated here. The ages used are 1 to 30 years. The oldest age is treated as a plus group. Recruitment was at age 1. Prior to 1989 length at recruitment was 7.1 cm, but 8.1 cm in later years. This was supposed to reflect length of the 1985 and 1990 year classes in the groundfish survey.

As in last years model runs, the 1991 year class is nearly as big as the 1990 year class which has previously been considered as much bigger than the 1991 year class.. To throw light on this problem, length at recruitment was estimated separately for the 1990 and 1991 year classes, and the selection of the commercial fleet was allowed to change annually since 1998. The results are shown in Figures 8.2.14, 8.2.15 - 8.2.17. The figures show that the difference between the 1990 and 1991 year class has now increased and the stock size is closer to what was estimated last year. The estimated value of L50 is shown in Table 8.2.4. The change in recent years could be due to several factors; that the fishermen are keeping/targeting smaller fish, the model is wrong, or that the data comes increasingly from sampling programs aimed towards area closures. However, the samples included are a mixture of harbour samples and samples taken by inspector aboard the vessels. The first mentioned possibility could explain some of the difference as some of the trawlers have, during the last years, been equipped with a "small-redfish fillet-machine".

Using a fixed selection pattern and estimating length at recruitment for the 1990 and 1991 year class increases the difference between the 1990 and 1991 year class (though not as much as when the selection is variable) but the catchable biomass does not change from the base case.

The groundfish survey in March 2002 does not indicate any improvement in redfish recruitment which has been bad since 1990-1991. The estimated average year class size in 1992-2001 is 80 million (at age 0). Maximum yield per recruit is 250g so this recruitment can only sustain an annual catch of 20 000 tonnes. According to the predictions here, the stock is going to be stable for the next years with an annual catch of 30-35 000 tonnes. This value might though have to be reduced every year when no sign of good recruitment is seen.

Finally, the runs shown here have used M = 0.05. M = 0.1 gives similar or better fit. Figure 8.2.18 shows the results using M=0.1.

In 2001 the model was also run with the total S.marinus catch in ICES Divisions XIV, Va and Vb. This addition increased the estimated stock size as the catch increased. The proportion of the catch taken in Division Va has though been relatively stable since 1985, with about 85-90% taken in Va. As the tuning data are identical, similar trends in the stock size are to be expected in recent years, with about 10% higher biomass in 2000 than when using only the data from Va.

The main indicator for recruitment is the groundfish survey, which does not indicate any strong year class after the 1990/1991 year class. Simulations were used to determine the value of  $\mathbf{F}_{max}$ . A year class was started in 1970 and caught using fixed fishing mortality and the estimated selection pattern. The total yield from the year class was then calculated.  $\mathbf{F}_{max}$  was calculated 0.165 using 40 years simulations, and  $_{F0}$  was estimated to be 0.09. Here, F is not fishing mortality, but close to it when small time steps are used, or mortalities are small. It is also the mortality of a fish where the selection is 1.

Different catch options were tested in the future simulations for fixed catch. As may be seen on Figure 8.2.12, 8.2.13 and 8.14-8.17, the catchable biomass will increase until 2005, using fixed catch after the year 2002 for all catch options below 40 000 t. The total biomass will at the end of the period be lower than it is now for catches exceeding about 35 000 t annually.

From the above mentioned runs, it is clear that if the groundfish survey is to be accepted as a measure of recruitment, no new large year class will recruit within the next 10 years.

## 8.2.3 State of the stock and catch projections

All available survey information and CPUE data from Division Va show that the *S. marinus* stock decreased considerably from 1985 to the lowest recorded biomass in 1995. An improvement in fishable biomass has, however, been seen in the recent years due to improved recruitment. Standardised CPUE in Va did increase by 20% from 2000 to 2001. During the last few years, the 1985 year class has contributed significantly to the fishable stock, and the 1990 year class did also contribute significantly to the fishable biomass in the last years. It is expected that those year classes will dominate the catches in the next few years. In Division Vb, survey indices as well as CPUE from the fleet do all indicate a very bad situation in the area. The adult stock of *S. marinus* in Sub-area XIV has nearly been exhausted in the most recent years. There are no indications of any recruitment of significance in area XIV.

By assuming same effort in 2003 as in 2001 (see chapter 8.2.1) the predicted catch in Va will be around 33 000 tonnes, using the following formula,  $Catch_{2002} = Average Survey index_{2000-2002} * Effort_{2001}$ .

Based on the BORMICON model, the fishable biomass will increase in the next few years. Thereafter a decrease is expected for all catch options above about 35 000 t. This is due to the poor recruitment after the 1990/91 year class. Based on the results from the BORMICON model, a TAC of about 35 000 t in the next 5 years would provide a fishable stock size above  $U_{Pa}$  at the end of the period. A large proportion of the catch is from the two year classes from 1985 and 1990. Based on the BORMICON model, the estimated average year class since 1992 is about 80 millions (at age 0) and maximum yield per recruit is about 250 gr. Therefore, after these two strong year classes have passed the fishery, one can not expect higher yield than about 20 000 t from the year classes that come into the fishable stock in the next years.

In Division Vb the CPUE from the Faroes winter survey shows an increase in 1996-1998, but decrease in 1999 – 2000. The new summer survey shows a decrease during the entire period since 1996. In Sub-area XIV the fishable stock of *S*. *marinus* is almost depleted.

In order to protect the two strong year classes, any fishing effort on this stock should be kept low to prevent a decrease in the near future. It should also be kept in mind that, based on the groundfish survey, there is no indication of new, strong, year classes after the 1990 year class. Therefore, as stated in 8.2.2, the year classes 1985 and 1990 needs to be preserved, since it is unlikely that other year classes will contribute substantially to the catches in the next years. Therefore, the Working Group recommends **that**, **in order to keep the stock within safe biological limits**, **the catch should remain below current level of about 35,000 tonnes.** 

## 8.3 Biological reference points

*S. marinus* is mainly caught in Division Va and the relative state of the stock can be assessed through survey and a CPUE index series from that Division. ACFM accepted the proposal of the working group of defining reference points in terms of current state with respect to  $U_{lim} = U_{max}$  /5 and  $U_{pa} = 60\%$  of  $U_{max}$ .  $U_{pa}$  corresponds to the fishable biomass associated with the last strong year class. Based on survey data, the highest recorded biomass was reached in 1987. Based on these definitions, the stock has been below, but close to  $U_{pa}$  during the last years. Based on the BORMICON model the corresponding values for reference points (for the period 1985-1999) are then  $U_{max} = 250$  (in 1985);  $U_{lim} = 50$  and  $U_{pa} = 150$ , and the stock seems to have been below  $U_{pa}$  in the period from 1993- 1997. The survey index series is only available back to 1985.

# 8.4 "Giant" S. marinus.

No additional information was obtained in 2001 compared to the NWWG report from 2001.

## 9 DEEP-SEA S. MENTELLA ON THE CONTINENTAL SHELF

Traditionally, the *S. mentella* on the shelves and banks around the Faroe Islands, Iceland and at East Greenland have been treated as one stock unit, with a common area of larval extrusion to the SW of Iceland, a drift of the pelagic fry towards the nursery areas on relatively shallow waters at East Greenland, and feeding and copulation areas on the shelves and banks around Faroe Islands, Iceland and at East Greenland. In Faroese waters spawning has been observed in some years to the south and west of the islands, implying that there could be a local component in the area; no nursery areas have, however, been found so far (Reinert, 1990). A relationship to other ICES areas (II and IV) has also been suggested (Reinert *et al.*, 1992; Reinert and Lastein, 1992). The question of a possible relationship between the deep-sea *S. mentella* on the shelf in Subareas V and XIV and the pelagic deep-sea *S. mentella* in the Irminger Sea has been raised several times. The ICES Working Group on the Application of Genetics in Fisheries and Mariculture (WGAGFM) states that the presence of significant genetic differences between these two deep-sea *S. mentella* on the shelf as a separate self-contained stock unit. For management purposes the Icelandic authorities separate the deep-sea *S. mentella* on the shelf (some of which are caught in pelagic trawls) from the pelagic *S. mentella* in the Irminger Sea (both oceanic and pelagic deep-sea type) by straight lines through three positions (Figure 9.1.1).

## 9.1 Landings and Trends in the Fisheries

The total annual landings of deep-sea *S. mentella* from Divisions Va and Vb and Subareas VI and XIV varied considerably in the 1980s mainly in the range 30 000 to 60 000 t. In 1990, the landings were 44 000 t, and reached 67 000 t in 1991, decreased slightly in 1992 (63 000 t) but increased to about 83 000 t in 1994. Since then the landings decreased to approximately 38,000 t in 2000 and in 2001 the catches decreased to only 23 000 tonnes, which are the lowest catches since 1980 (Table 9.1.1).

From Division Va, total landings in 2001 were 17 000 t. about 45% reduction from the catches of 2000. This is the lowest recorded catch since 1988. In general, the landings have been decreasing from the record high in 1994 of 57 000 t. In the 1980s landings varied from 10 000-40 000 t. From 1990 to 1994 the landings doubled from 28 000 t to 57 000 t. This increase in the catch coincides with the introduction of large pelagic trawls used by a part of the Icelandic fleet during the autumn and early winter months. This pelagic fishery has now decreased to 465 t, which is less than 5% of the 1994 landings. The catches in the autumn decreased considerable in 2001, compared with the latest years (Figure 9.1.2). The reason for this drop in the catches seems be connected with decreased effort at that time of year, but some fishermen report that the reason for the decreased effort is a lack of redfish in the traditional fishing areas west and southwest of Iceland. About 95% of the total deep-sea *S. mentella* landings in area Va in 2001 have been taken by bottom trawlers (both fresh fish and freezer trawlers). Length distributions measured by the Icelandic observers in 1989-2001 are shown in Figure 9.1.3 for the bottom trawl fishery and in Figure 9.1.4 for the pelagic fishery since 1994. An increase in the number of small fish have been shown in recent years, and from the length distributions peak of about 32 cm in 1994 can been followed by 1 cm growth annually in 1996-2001. Length distributions from the pelagic fishery show decrease in the mean length in 2000-2001, with a peak of about 39-40 cm. If the proportion of redfish below 33 cm in the catches exceeds 20% in numbers in Division Va the, fishing area is closed.

In Division Vb annual landings of deep-sea *S. mentella* varied from 5 000–8 000 t until 1984. Then landings increased rapidly to about 15 000 t in 1986. The landings declined again to 9 000 t in 1990. They increased to about 13 000 t 1991. Since then they remained very low until 2000 as it increased to 8 000 t, mainly due to Russian catches of more than 2 500 t, which were reported to Faroese authorities (Table 9.1.1). The catches in 2001 decreased again to about 5 000 t. The CPUE from the Faroese trawlers (>1000HP) are shown in Figure 9.1.5. No biological sampling was available to the working group on the catches.

In Subarea VI the annual landings were highest in 1980 (1 100 t), but have varied from 130 - 880 t during recent years, except for 1996 when the landings were about 1 050 t, the highest recorded in the series since 1980 (Table 9.1.1). The limited information on the redfish catch in 2001 indicates that only about 40 t were caught in 2001. No biological sampling was conducted on redfish catches.

In Subarea XIV, annual landings have varied considerably. In the beginning of the 1980s, the landings were between 10 000-15 000 t, but then decreased to 6 000 t in 1987-1992 and increased to 19 000 t in 1994. At that time the fleet was mainly fishing very small redfish. Since then there was a decrease to only 200 t in 1997, which was a bycatch in the shrimp fishery. In 1998, Germany started again a directed fishery on the juveniles with a total catch of about 1 400 t. This fishery has continued and the total landing in 2000 was about 1000 t, and the effort was similar as in 1998-1999 (Table 9.1.2). In 2001 the total effort decreased and the catches were 800 tonnes. No biological sampling was conducted on redfish catches.

The 2001 biological sampling from catch and landings of deep-sea *S. mentella* from the continental shelf in each Division and by gear type is shown in the text table below.

Area	Gear	Landings	Nos. samples	Nos. fish measured
Va	Pelagic trawl	465	8	988
Va	Bottom trawl	1,7103	91	18,796
Vb	Bottom trawl	4,439		
XIVb	Bottom trawl	866		

#### 9.2 Assessment

### 9.2.1 Trends in CPUE and survey indices

CPUE of the Icelandic trawler fleet for deep-sea *S. mentella* in Division Va is based on bottom trawl tows taken below 500 m depth and where the total catches of redfish compose a certain percentage of the total catch in each tow (10, 50 and 90%). Data prior to 1986 are poor. In the period from 1986 -1989 CPUE was rather stable. From 1989 to 1994

CPUE declined to only 488 kg/h (for 10%; see text table below and Figure 9.2.1), and it has remained rather low since then although it increased again in 1999-2000. The 2001 value showed a slight decrease again, compared with 2000 and there seems to be steeper reduction in the fourth quarter.

Indices of CPUE for the Icelandic trawl fleet for the period 1986-2001 are also estimated from a GLIM multiplicative model, taking into account changes in the Icelandic trawl catch due to vessel, statistical square, month and year effects. All hauls with redfish at depths deeper than 500 m, exceeding 50% of the total catch were included in the CPUE estimation (Figure 9.2.1.a). There is some discrepancy between the results of the model now and in 2000. The reason for the difference is due to changes in the database where the hauls for the calculations are selected. Ling, blue ling, tusk and greater silver smelt were added to the database in 2001 and consequently the total catch as reported in the database for each haul changed. The trawler fleets started to fish greater silver smelt in 1997 in significant amount but the catches were not included in the logbook database and hence affected the selection of hauls for the CPUE calculations. The effort that is used is therefore higher than real effort and hence, the CPUE is underestimated in some years. The difference in highest in 1998, but in that year the same trawler fleet fished almost 14,000 t. of Greater silver smelt. The results of the "corrected" GLIM model show a similar trend as unstandardised CPUE, i.e. a relatively stable situation between 1986-1991, a sharp decline from there until 1995 and thereafter a stable, very low level until 1998. The GLIM model shows thereafter an increase both in 1999 and 2000, but a minor decrease in 2001. The index is now about 70% of the 1986 value.

Year	CPUE 50%	CPUE 10%	Total	Effort
	Glim	raw	landings	(Glim/raw)
1986	1000	943	18,898	20 / 18
1987	1090	977	19,293	19 / 17
1988	989	877	14,290	16 / 14
1989	946	974	40,269	41 / 42
1990	904	806	28,429	35 / 31
1991	907	771	47,651	61 / 52
1992	705	611	43,414	71 / 61
1993	636	549	51,221	93 / 80
1994	569	488	56,720	116 / 99
1995	583	515	48,708	94 / 83
1996	588	489	34,741	70 / 59
1997	617	565	37,876	67 / 61
1998	621	545	33,125	60 / 53
1999	661	620	28,590	46 / 43
2000	696	636	30,696	48 / 44
2001	678	571	17,313	30 / 25

The effort in Division Va in the time when the stock was considered in stable condition i.e., from 1986 -1990 was 20 000-40 000 hours. During the period since 1986, the effort increased drastically until 1994. Since then, the effort has decreased by less than 10% each year until 2000 (the advice of ICES has been a 25% reduction annually from 1995-2000). The effort in 2001 has, decreased by about 40% compared with the effort in 2000. The effort in 2001 is thus reduced by 75% from the record high effort in 1994.

Icelandic groundfish survey in Division Va only covers depths down to approximately 500 m and there seem not to be any nursery grounds of major importance in Division Va, these results add little to the current stock evaluation (WD08). A recently started deep-water survey (covering depth approx. 500-1200 m) around Iceland in autumn may, however, add valuable information about the fishable stock of deep-sea *S. mentella* in near future.

In Division Vb a CPUE-series (1985–1997) of deep-sea *S. mentella* was presented in the 1997 Working Group report. The series shows a decrease since 1993, which seems to have stabilised below 50% of the maximum in the time series. The continuation of the series (Figure 9.1.5) shows a slow increase in the CPUE 1996-1999, but a slow decrease in 2000 and 2001. It should however be noted that the series are not completely comparable as they are calculated differently.

The new summer survey in Division Vb (see chapter 2.4.5), show nearly continuous decrease in the catch rate, from less than 10 kg/hour to about 3 kg/h, except in 1999 when the catches were over 10 kg/h.

In Division XIV all redfish catches in the period 1982-1997 was as bycatch. Since 1998, there was a directed fishery for redfish along the continental slope of East Greenland where *S. mentella* was the targeted species. The effort was similar in both years, and the CPUE in 1998 was about 638 kg/h, decreased to 352 kg/h in 1999 and has increased again in 2000 to 433 kg/h and further to 746 kg/h in 2001.

Survey abundance and biomass estimates for deep sea *S. mentella* ( $\geq$ 17 cm) are presented in Figures 9.2.3-9.2.4, broken down by stratum, West and East Greenland, Iceland and aggregated to total. The trends in stock size in numbers are illustrated in Figures 9.2.5-9.2.6. The abundance figures are clearly dominated by the occurrences off East Greenland, while there were only negligible parts distributed off West Greenland and Iceland at depths of 0-400 m. It can be derived from those figures that the surveys do cover only the immature part of the stock (recruits) since the figures also are dominated by a single strong year class recorded in 1989 for the first time at a mean length of 20 cm (Figure 9.2.5). This cohort grew about 2 cm a year and recruited to the survey gear until 1997 (Figure 9.2.6), when it reached its maximum abundance and biomass at a length of about 27 cm (total abundance 7 billion and biomass 1.5 million tons). During the following years, this year class seems to have left the surveyed area. Most recently, there are indications of further recruiting year classes which seem, however, to be significantly less abundant.

## 9.2.2 Production model

The group tried again the ASPIC (Prager 1992) stock production model for the stock. The model requires catch data and corresponding effort or CPUE data that are reasonable indices of the stock biomass. Corresponding catch and effort data is available for Division Va using the GLIM CPUE index from the Icelandic trawl fishery from 1986 onwards and the total catches in Divisions V, VI and XIVb during the same period. The model requires starting guesses for r, the intrinsic rate of increase, MSY, B1/**B**_{MSY} ratio and q, catchability coefficients. Initially ASPIC was run with different starting guesses of these parameters to explore stability of parameter estimation. For an appropriate range of input values, ASPIC responds very stable for the changes that were tried.

The program was run with the time-series from 1985-2001 including Icelandic corrected CPUE's. MSY is now estimated around 50 000 t for all the options tried and  $\mathbf{B}_{MSY}$  around 200 000 (Table 9.2.1) Biomass in 2001 is estimated to be over 30% above  $\mathbf{B}_{MSY}$  and the fishing mortality in 2001 is estimated to be about 50% below  $\mathbf{F}_{MSY}$  Observed and estimated CPUE's are given in Figure 9.2.7 and state of the stock relative to Retrospective runs (Figure 9.2.8.) show rather stable situation, but indicates that B/  $\mathbf{B}_{MSY}$  has been underestimated and F/  $\mathbf{F}_{MSY}$  overestimated systematically in recent years. The changes compared with the results in last year's report are due to the changes (correction) in the input series (see 9.2.1). The biomass is slowly increasing from the record low in 1995. Although the retro runs show relatively consistency between years, the parameters that are used as a basis for calculating MSY,  $\mathbf{F}_{MSY}$ ,  $\mathbf{B}_{MSY}$  (K and r) are changing over time. Further, the r (intrinsic rate of increase) is very high for such a long-lived species and it also change considerable depending of the length of the input series, as shown in the texttable below.

Range	MSY	K	r	K/r
1996-2001	50120	426000	0.470	906383
1996-2000	51480	381600	0.539	707978
1996- 1999	51830	372900	0.556	670683
1996- 1998	52790	349500	0.604	578642
1996- 1997	55410	296900	0.747	397723

The model allows trajectories of population biomass and fishing mortality based on bootstrap estimates. Trajectories were performed for  $\mathbf{F}_{pa}$ , (2/3 $\mathbf{F}_{MSY}$ ~ $\mathbf{F}_{pa}$ , Plot of B-ratio (B/ $\mathbf{B}_{MSY}$ ) along with biomass trajectory is given in Figures 9.3.1.

Fishing at  $\mathbf{F}_{pa}$  will keep the stock well above  $\mathbf{B}_{MSY}$  within the next years. The ASPIC model results shows that catching at  $\mathbf{F}_{pa}$  would result in a total catch of 47 000 t in 2003. Those catches apply for the whole distribution area.

# 9.2.3 State of the stock

All CPUE indices as well as the production model show a drastic reduction from highs in the late 1980s, but indices indicate that the stock seems to have started a slow recovery in the middle of 1990s from being close to 50% of the maximum in 1994-1996. Fishermen have reported of less *S. mentella* in the fishing areas Southwest and West of Iceland during recent years and this is confirmed by the low CPUE and catches in the fourth quarter of 2001 in Va and could indicate worse situation. The increase in the fishable biomass in Division Va since 1996 seems to be related to recruiting fish, most likely from East-Greenland. It is, however, uncertain to what extent the juvenile *S. mentella* observed at East-Greenland will recruit to this stock.

In Division Vb development in CPUE resembles that in Division Va, i.e., the CPUE seems to have stabilised at below 50% of the maximum in the time series (1985–1997), and the new CPUE series indicate a deteriorating situation since then.

Based on survey results the SSB of deep-sea *S. mentella* on the continental shelf in area XIV remains severely depleted. The strong recruiting cohort(s) observed in 1993-97 emigrated in 1998-2000 and have seemingly recruited to both the pelagic redfish stock and the stock at the shelf.

# 9.3 Catch projections

It is possible to compute effort as well as a TAC corresponding to different effort for deep-sea *S. mentella* by using a similar approach as described for *S. marinus*, although for the deep-sea *S. mentella*, the survey index is replaced by CPUE index. The management advice for current year is to not increase the effort from the 2000 level. That would corresponds to a catch of 31 000 t in Va in 2003 and lower than 35 000 for the whole stock.

# 9.4 Biological reference points

The relative state of the stock can be assessed through survey and CPUE index series (U) from the commercial fishery, which imply a maximum,  $U_{max}$ , as well as the present state. Given these data, it has been proposed by ACFM that reference points be defined in terms of the current state with respect to  $U_{lim} = U_{max}/5$  and  $U_{pa} = U_{max}/2$ . Based on these definitions, the stock could be considered above  $U_{pa}$ .

# 9.5 Management considerations

The two types of pelagic redfish in the Irminger Sea (i.e., the oceanic and the pelagic deep-sea *S. mentella*) in the present context are treated separately from the deep-sea *S. mentella* on the continental shelf. It can, however, not be excluded that there may be a relationship between the demersal deep-sea *S. mentella* on the continental shelves of the Faeroe Islands, Iceland, Greenland and the pelagic deep-sea *S. mentella* in the Irminger Sea and this should be considered in the management of this stock (see also chapter 7.5).

In Division Va, the catches in 2001 were considerable lower than the set quota for the quota year. That could be due to different reasons such as increased effort towards other species such as cod, but it should not be excluded that the explanations could be related to a deteriorating stock situation. Also, a joint quota has been given for *S*.*marinus* and *S*. *mentella* and in recent years the proportion of *S*. *mentella* /*S*. *marinus* catches have been close to the advice. Although the catches of those two stocks in Va have decreased by 27%, the decrease in the *S*. *marinus* only decreased by 15% as the *S*. *mentella* decreased by 43%. In order to let the ratio not deviate from advice ratio, the working group recommends that the TAC of demersal redfish stocks should be given separately.

The management strategy to reduce the effort in Division Va has resulted in an increase in the catchable biomass since 1995, according the data from the fishery. The WG recommends that effort should be kept low and **no higher than it was in 2000**. That could correspond to a catch of no more than about 30 800 tonnes in 2003in divison Va.

All signs from the fishery indicate decreasing abundance in Subarea Vb. Therefore the Working Group recommends that the **effort in Division Vb should be decreased from current level**.

In Division XIV the Working Group recommends maximum protection of the juveniles and **no directed** fishery in order to maximise the probability of stock recovery to safe biological limits.

**Figure 9.1.4** Length distributions of deep-sea *S. mentella* catch and landings from the Icelandic pelagic trawl fishery in 1994-2001.

**Figure 9.1.5** CPUE from the Faroese bottom trawl fleet.

**Figure 9.2.1** CPUE, relative to 1986, from the Icelandic bottom trawl fishery for deep-sea *S. mentella* on the continental shelf, based on a GLIM model (a) and based on simple mean (b). The GLIM model shows the modelled development using GLIM including hauls where redfish deeper than 500 m compose 50% or more of the total catch in each haul. Simple mean means CPUE calculated on hauls where redfish deeper than 500 m compose 10% (50, 70 and 90% lines are also shown) or more of the total catch in each haul.

Figure 9.2.8 Retrospective analysis of the ASPIC model. The used CPUE index is also shown.
## 10 PELAGIC SEBASTES MENTELLA

This section includes information on the pelagic fishery for *S. mentella* both shallower and deeper than 500 m in the Irminger Sea (Subarea XII, parts of Division Va, Subarea XIV and eastern parts of NAFO Divisions 1F, 2H and 2J).

Under chapter 7.5, comments are made on special requests in the ToR. Aside from what is said there, the WG refers to last years' reports on the matter of stock/delineation in the area.

## 10.1 Fishery

### **10.1.1** Historical development of the fishery

Russian trawlers started fishing pelagic *S. mentella* in 1982. Vessels from Bulgaria, the former GDR and Poland joined those from Russia in 1984. Total catches increased from 60 600 t in 1982 to 105 000 t. in 1986. Since 1987, the total landings decreased to a minimum in 1991 of 28 000 t. The main reason for this decrease was a reduction in fishing effort, especially by the Russian fleet. Since 1989, the number of countries, participating in the pelagic *S. mentella* fishery gradually increased. As a consequence, total catches have also increased after the 1991 minimum and reached a historical high of 180 000 t in 1996 (Tables 10.1.1–10.1.2). In 2000 and 2001, the WG estimate of the catch has been 126 000 and 118 000 t, respectively.

In the period 1982–1992, the fishery was carried out mainly from April to August. In 1993–1994, the fishing season was prolonged considerably, and in 1995 the fishery was conducted from March to December. In 1997 and 1998, the main fishing season occurred during the second quarter, but fishery was also longer. The pattern in the fishery has been reasonably consistent in the last 3-4 years: In the first months of the fishing season (which usually starts in early April), the fishery is conducted in area west of 32°W and north of 61°N; in May and June the fishery is more or less at same areas, but in July (August), the fleet moves to areas south of 60°N and west of about 32°W where the fishery continues until October (see figures 7.5.1-7.5.6). There is very little fishing activity in the period from November until late March or early April when the next fishing season starts. The fleets participating in this fishery have continued to develop their fishing technology, and most trawlers now use large pelagic trawls ("Gloria"-type) with vertical openings of 80–150 m. The vessels have operated in 1998-2001 at a depth range of 200 to 950 m, but mainly deeper than 600 m in the first and second quarter but at depths shallower than 500 m in third and fourth quarter.

The following text table summarises the available information from fishing fleets in the Irminger Sea in 2001:

Faroes	3 factory trawlers
Germany	7 factory trawlers
Greenland	1 factory trawler
Iceland	25 factory trawlers and 1 freshfish trawlers
Norway	4 factory trawlers
Russia	28 factory trawlers
Spain	6 factory trawlers

A summary of the catches by depth by nation as estimated by the Working Group is given in Table 10.1.2.

### **10.1.2** Description on the fishery of various fleets

### 10.1.2.1 Faroes

The Faroese fishery for pelagic redfish in the Irminger Sea and adjacent waters started in 1986. In the first years, only 1-2 trawlers participated in the fishery. Fishing depths were mainly shallower than 500 m although some trials were made down to about 700 m. From 1992 onwards, several trawlers have made trips to this area fishing almost exclusively deeper than 500-600 m.

In 1999, the Faroese fishery in the international parts of the Irminger Sea started in late April and continued until late August with 5 trawlers participating in the fishery and all hauls being deeper than 600 m. From September, two of the trawlers fished within the Greenlandic EEZ; all hauls were shallower than 600 m.

In 2000 as well as in 2001, the Faroese fishery started in international waters in the NE part of the Irminger Sea in the middle of April (ICES Division XIV). Up to late July, the fishing area was mainly between 61°N-62N and 27°N-

30°00'W, then they moved to the SW, to south of 60°N and west of 37°W (ICES Division XII), fishing mostly within the Greenlandic EEZ. Two trawlers participated in 2000, and 3 in 2001. The fishing depth from the beginning of the fishery to July was nearly exclusively deeper than 600 m, but from July onwards, the fish was taken at shallower depths than 600 m.

### 10.1.2.2 Germany

The reported German fishing effort in 2001 was only slightly higher than the low effort in 2000, the lowest observed in the last seven years, and amounted to 13 000 trawling hours only, a 26 % decrease as compared with 1999. As observed in previous years, the majority of the 2001 effort was applied during the second and third quarters by 7 vessels. During the second quarter in 2001, the hauls were almost exclusively distributed in NEAFC Regulatory Area of ICES Subarea XIV between the Greenland and Icelandic EEZs. In 2001, there was reduced fishing effort exerted in the NAFO Div. 1F mainly within the Greenland EEZ during the third quarter as compared with 2000. The decrease of annual catches continued since 1996 with a catch of 10 700 tons in 2001. In 2001, 8 % or 800 tons of the total catch were taken in the NAFO Div. 1 F. During 1995-1999, the overall unstandardised CPUE decreased from 2 055 kg/h by 53 % to 970 kg/h. In 2000 and 2001, the CPUE remained low. Catch rates recorded in NAFO Div. 1F are slightly higher than observed in the adjacent ICES Subarea XII, especially inside the Greenland EEZ. Given the technical, temporal, geographical and depth changes of the fishing activities the relevance of the estimated reduction in CPUE as indicator of stock abundance remained difficult to assess. However, the continued reduction in CPUE during 1996-1999 should be interpreted as reaction of the stock to removed biomass.

## 10.1.2.3 Greenland

The Greenlandic fleet was fishing in the same area as the Icelandic fleet (see below), and therefore, the Greenlandic logbook data were included in the figure of the Icelandic fishery.

#### 10.1.2.4 Iceland

Catches in 1995-2000 were generally taken in the area between the Greenlandic EEZ and the Reykjanes Ridge. Since 1996, the catches have mostly been taken close to or inside the 200-mile boundary Southwest of Iceland. In recent years, the fishery has started in April close to the Icelandic 200-mile boundary and then moved northward in May-July. In the springtime and until June, the largest proportions of the catches were taken deeper than 500 m. In 1998, the fishery expanded further north in July-September. In 1999, a similar pattern was observed, except that the fishery did not continue close to the shelf of Iceland. The few vessels that had quota left after that, moved about 480 nautical miles to southwest, to the area S-SE of Cape Farewell (Subarea XII), where they fished shallower than 500 m depth in July-September. In 2000, the fishery started in April at the same locations as in the past and moved slowly northward until the fishery ended in July due to quota limitation. The Icelandic trawlers fished mainly at a depth of 600-800 m during the period 1995-2000 (Figure 10.1.1). In 2000, less than 8% of the catches in the log-books were reported shallower than 500 m depth and no catches were reported at depths shallower than 400 m.

In 2001, the fishery started in May, and total of only 3000 tonnes were reported in that month, all taken in the area close to the Icelandic 200 miles boundary. In June and until middle of July, the fishery was exclusively within the Icelandic EEZ moving slowly in northward direction. In May – July over 90% of the catches were taken at depths deeper than 600 m. According to the fishermen, the fishery in that period was mainly from the same "school". The legislation for the fishery changed in 2001, compared with the previous years. Every vessel was forced to fish 1/3 of its catches south of about 60 in order to spread the effort. Therefore, the fishery continued in August in the area southeast of Cape Farwell, mostly between 38 and  $42^{\circ}W$ . In September and October, the fishery continued in the same area. About 1/3 of the Icelandic catches were taken in the "south-western" fishing area and nearly all that catches were taken shallower than 400 m depth. The length distribution from the catch is shown in Figure 10.1.2.

#### 10.1.2.5 Norway

Information on the fishery in 1998 and 1999 indicated a depth shift in the fishery, from fishing 95% of its catch shallower than 500 m in 1998 to fishing exclusively deeper than 500 m in 1999. The catches in 1999 were taken in areas XII and XIV from April to August, at a ratio of about 2:3. In 2000, Norway fished 6 075 t whereof 3 823 t were taken in ICES Subarea XIV and 2 252 t in Subarea XII. The fishing season was from April – September. In 2001, the fishery started in April, close to the Icelandic 200 miles boundary (Subarea XIV). The fishery continued there until beginning of June, when the fleet moved to Subarea XII between 55 and 58°N and between 40 and 42°W. There is no information on the trawling depth or about length distributions in the catches.

### 10.1.2.6 Russia

The regular Russian commercial fishery for pelagic redfish in the Irminger Sea started in 1982. Total catch of redfish taken by the USSR/Russia makes up about 0,76 mill. t or 43% of the total world catch for a whole period of the fishery in the Irminger Sea. In 1982-1988, the annual Russian catch of redfish constituted 60-85 thou. t. The fishery duration was 4-4,5 months. In 1989-1994, the catch decreased to 9-25 thou. t. Fishing efficiency of STM-type vessels was 10-15 t per a vessel/fishing day. A shift of the fishery to the depths deeper than 500 m, and due to an increase in trawl size, an increase in fishing efficiency was observed in 1994. A reduction in redfish catches from the depths deeper than 500 m has been observed since 1997. The extension of fishing period to 8 months and extension of areas due to the increased fishery within the 200-mile zone of Greenland and adjacent areas of the Labrador Sea occurred simultaneously.

In 2001, the Russian fishery for pelagic redfish in the Irminger Sea and adjacent waters of the NAFO Regulatory Area lasted from March to October. It was conducted by 28 trawlers of different types. 72 % of the total catch and 70 % of the fishing effort were recorded in June-July. As in 2000, fishing effort and the catch of redfish increased. Scouting for commercial concentrations began in late March. In April, the fishery started in the traditional area near the Icelandic EEZ. During the second quarter of the year, redfish was fished at 550-850 m depth in the open part of Subarea XIV. During the third quarter redfish fishery shifted south-westwards to Subareas XIV and XII and was conducted at 200-900 m depth in the international waters and in the Greenlandic EEZ. Total catch in ICES Subareas XII and XIV made up preliminary 28360 t (WD 16). In early August, 4 Russian trawlers started a fishery in the NAFO Regulatory Area at 150-350 m depth. In September, fishing conditions were much worse and vessels left the area. The total catch in all NAFO Divisions made up preliminary 1652 t.

# 10.1.2.7 Spain

Four Spanish freezer trawlers fished pelagic redfish in 1995-1997, increasing to 6 vessels since 1998. The fleet has used a Gloria-type pelagic trawl, with a maximum vertical opening of 80-120 m.

The Spanish pelagic fishery in ICES Subareas XII and XIV and in NAFO Div. 1F shows a persistent seasonal pattern in terms of its geographical and depth distribution. The main fishing occurs in the second and third quarter each year. In the second quarter, the fishery takes place in Subarea XIV between the Greenland and Iceland EEZs deeper than 500 m, capturing fish of bigger size. The proportion of females in the catches is greater than for the males. The yields obtained in this quarter are larger and the mean trawling time of the hauls is shorter than in the third quarter. In the third quarter, the fleet moves towards the Southwest to ICES Subarea XII and NAFO Div. 1F, and the depth of hauls is shallower than 500 meters. The length distributions in the catches are lower than in the second quarter and are unimodal and relatively stable in time. The proportion of males in the catches is higher than for the females. The yields are smaller and the mean trawling time of the hauls is greater than for the females. The yields are smaller and the mean trawling time of the hauls is determined to the females.

#### 10.1.2.8 Other nations

No information on the fishing areas, seasons and depths of the fleets of other nations was available for the Working Group.

#### 10.1.3 Discards

Icelandic landings of oceanic redfish were raised by 16% prior to 1996 to into account discards of redfish infested with *Sphyrion lumpi*. This value of was based on measurements from 1991–1993 when the fishery was mostly on depths shallower than 500 m. In May-July 1997, discard measurements on 10 vessels showed a discard rate of 10%. This was added to the landings in 1996 and 1997. A new measurement from 1998 shows that the discard rate has decreased to 2%. Information from observers in 2000 and 2001 indicated that discards were negligible, and therefore no catches were added to the Icelandic landings.

Norwegian fishermen currently report approximately 3% discards of redfish infested with parasites. This percentage has in recent years become less due to a change in the production from Japanese cut to mainly fillets at present.

The Spanish discards are based on measurements made by the scientific observers. However, it can be safely assumed that these reflect approximately the behaviour of the rest of the non-surveyed Spanish trawlers. Discard of *Sebastes mentella* of the Spanish fleet were often composed of fish infested with *Sphyrion lumpi*. The discard quantities vary annually. In 1995, about 4% of the total catches were discarded, while in 1996, it was 6.5 %. From 1997-2000, the discards of the Spanish fleet have been insignificant. In 2001, 4.4 % of the total catches were discarded. This variability can also be observed for depth strata, the discarded percentage being much larger in the stratum >500 meters. Since 1997, this variability can be due to that the percentage of discards does not depend directly on parasite fish by *Sphyrion* 

*lumpi*, but it is related with the haul catch. When the haul catch is very high, the fish is discarded under worse conditions by the lack of time to elaborate the whole catch. When the catches are between the standard values there is enough time to elaborate the whole fish, even the infested ones, and there are no discards.

No information on possible discards was available from other countries participating in this fishery.

### **10.1.4** Trends in landings and fisheries

A Working Group estimate of catches in 2001 is estimated to be about 118 000 t, which was similar to the total catches observed since 1997. In 1995 and 1996, the catches amounted 176 000 and 180 000, respectively, representing the highest catches on record (Table 10.1.1-10.1.2). The actual catches in 2001 might increase due to the lack of reporting from some countries participating in the fishery.

At the beginning of the fishery in 1982, catches of pelagic redfish were reported from both Subareas XII and XIV. But most of the catches were taken in Subarea XII (40 000-60 000 t) until 1985, and then the greater part of the catches was reported from Subarea XIV. The landings from Subarea XII were again in the majority in 1994 and in 1995 with 94 000 t and 129 000 t landed respectively. In 1996–1999, the main part of the total catch was taken from Div. Va and Subarea XIV (Table 10.1.1). In 2000, considerable amounts of the catches were taken in NAFO Div. 1F, as observed in this magnitude for the first time. In 2001, about 200 t of pelagic *S. mentella* were caught by Lithuania in NAFO Div. 2H, and about 1300 t by Russia in NAFO Div. 2H and 2J.

Pelagic *S. mentella* fishery in ICES Div. Va started in 1992. The catch varied from 2 000-14 000 from 1992-1995. Since 1995, the catches in Div. Va have increased to about 45 000 t in 2000 (Table 10.1.1). In 2001, they have decreased to about 28 000 t.

Length distributions of pelagic *S. mentella* from German, Icelandic, Russian and Spanish commercial catches were reported for 2001 and are given in Figure 10.1.2. A bimodal distribution over the past 4 years could be observed as a reflection of the samples being taken from different areas. Figure 10.1.3 illustrates the depth effect on the length distributions in the German and Spanish catches, taken shallower and deeper than 500 m.

The 2001 biological sampling from catches and landings of pelagic *S. mentella* in each Subarea/Division and by gear type is shown in the text table below.

Country	Area	Gear	Landings (t)	No. of samples	No. of fish measured
Germany	XII, XIV and NAFO 1F	Pelagic	10669	81	70079
Iceland	XIV and Va	Pelagic	42472	36	2634
Russia	XII, XIV, NAFO 1F, 2H, 2J	Pelagic	30012	?	52802
Spain	XII, XIV and NAFO 1F	Pelagic	10083	156	28428

#### 10.1.5 Age readings

Several nations have increased their effort to age pelagic redfish, using different ageing methods and thus making a comparison of age readings difficult.

The catches in 1999 and 2000, and also the acoustic survey in 1999, suggested that a new cohort is entering into the fishable stock of pelagic redfish. Age readings within an otolith exchange between Germany, Iceland and Norway, based on material collected in July 1999 (WD9), showed that this cohort is mainly consisting of 10 year old fish and that ageing error for fish older than 20 years is relatively high. Applying a tolerance level of  $\pm$  5 years disagreement between age readers, however, around 90% total agreement can be reached. This indicates that age-structured models could be possible on a 3- or 5-annual basis.

#### 10.2 Assessment

#### 10.2.1 Acoustic assessment

#### 10.2.1.1 Acoustic assessment shallower than 500m

The 2001 trawl-acoustic survey on pelagic redfish (*S. mentella*) in the Irminger Sea and adjacent waters was carried out by Germany, Iceland, Russia and Norway in June/July (ICES CM 2002/D:08 Ref.ACFM). Approximately 420 000 square nautical miles were covered, which is the most extended coverage for acoustic assessment pelagic redfish in the Irminger Sea. The stock size measured with the acoustics was assessed to be about 715 000 t at depths down to the deep-scattering layer or about 350 m, with redfish having a mean length of 34.6 cm. Table 10.2.1 informs about the estimated trend in stock size and the increased survey areas covered. The acoustic survey results (shallower than 500 m) indicate a stable stock situation size compared with the 1999 results.

A decreasing trend in the proportion of females was observed during the last decade, but whether it is related to overexploitation of the females is not known. Recruits with a peak length about 26-27 cm were recorded, particularly in the western most area of the investigation, the western part of NAFO Div. 1F but also in the eastern parts of 2H and 2J. The lengths of these pre-recruits were similar to the length of the abundant juveniles growing up at the shelf of East Greenland.

In 2001, as well as in 1999, the stock shallower than 500 m was observed more south-westerly and deeper than it has been during former acoustic surveys in the last decade. During the same period, a gradual increase in temperature in the observation area has been observed. This may have influenced the distribution pattern of the redfish in June-July as the highest concentrations were found in the colder, *i.e.* south-western part of the survey area. In June/July 2001, about half of the total acoustically estimated stock biomass was found in the NAFO Convention Area shallower than 500 m omitting the Canadian EEZ (Table 10.2.2).

Since 1994, the results of the acoustic estimate show a drastic decreasing trend. The estimate was only 0.7 million tonnes in 2001, compared with 2.2 and 1.6 and 0.6 million tonnes in 1994, 1996 and 1999, respectively. This represents a reduction of about 1.5 million tonnes in the period. During the same period, the total catch has been about 800 000 tonnes. Therefore, the catch alone cannot explain the changes in the stock estimate. During the same period, the fishery has also developed towards greater depth and towards bigger fish, and in recent years, the majority of the catch has been caught at depths deeper than 500 m. Thus, acoustic estimates cannot be considered accurate measures of relative changes in stock size of the upper layer fish, as availability may have changed during the surveyed period. Information suggests that fish inhabiting the upper layer may have migrated out of the surveyed area, both horizontally and vertically (deeper).

Since the early 1990s, national and international trawl-acoustic surveys have been carried out in the Irminger Sea and adjacent waters. Since 1995, the surveys have been carried out in June/July when the hydro-acoustic conditions (minimum impediment by the deep scattering layer) are favourable. It must be noted that none of the consistent international June/July surveys of the past decade has succeeded in identifying the horizontal and vertical distribution boundaries of pelagic *S. mentella*. Because of the limited depth range coverage (down to less than 500 meters) the surveys have mainly covered the oceanic *S. mentella*, and should therefore only be used as an estimate on redfish above the deep scattering layer.

#### **10.2.1.2** Trawl estimate

In addition to the acoustic measurements, an attempt was made to estimate the redfish within and below the deep scattering layer. This was done by correlating catches and acoustic values at depths between 100 and 450 m. The obtained correlation was used to convert the trawl data at greater depths to acoustic values and from there to abundance (ICES CM 2002/D:08). For that purpose, standardised trawl hauls were carried out at different depth intervals (three depths intervals in hauls deeper than 500 m and 2 depth intervals in shallower hauls), evenly distributed over the survey area. Data for the correlation calculations between trawl catches and the acoustic results were obtained during trawling only. In addition, scrutinised acoustic values were only taken from exactly the same position and depth range as covered by the trawl. Low correlation between catch and the acoustic values used for the abundance estimation make the method questionable and also the assumption that the catchability of the trawl is the same, regardless of the trawling depth. Estimate based on above described calculations both above and below 500 m depth, must be considered as a very rough measure with high uncertainty as the applicability of the method can only be verified after replicate measurements.

By applying the trawl approach, biomass in the depth layers from 0-500 depth, including layer where the redfish that was mixed with the deep scattering layer, was estimated to about 1.1 mill. t. Such estimates are not directly comparable with the acoustic estimates shallower than 500 m depth and should be interpreted with care due to their innovate nature.

About 1.1 mill. t was estimated by the trawl-acoustic method deeper than 500 m. At these depths, the densest concentrations were found in the NE part of the area (Fig. 10.2.1). The average length of the fishes caught deeper than 500 m was 39.5 cm. Hydrographic observations indicated that the highest concentrations of redfish deeper than 500 m were associated with eddies and fronts.

In June/July 2001, one third of the biomass obtained with the trawl method of about 2 mill. t was found in the NAFO Convention Area omitting the Canadian EEZ (Table 10.2.2).

In June/July 2003, an international hydroacoustic survey on pelagic redfish will be carried out with participation of Iceland, Russia and Germany.

# 10.2.2 CPUE

In Table 10.2.3, the CPUE series for Bulgarian, German, Icelandic, Norwegian, Russian, and Spanish fleets are given. Figures 10.2.3.a and 10.2.3.b show the overall CPUE from different fleets in recent years, in depths shallower and deeper than 500m, respectively. In Figure 10.2.3.a, the estimated biomass derived from the international and Russian hydroacoustic surveys is given. The trend in CPUE in depths shallower than 500m indicates a steep downward trend since 1995, and the 2001 acoustic estimate confirms these changes compared with the beginning of the last decade. In recent years, there is no clear signal in CPUE, but it should be noted that CPUE has decreased from 2000 to 2001 for most indices, both shallower and deeper than 500 m (Figures 10.2.3.a-10.2.3.b). Information from Russia does, however, not confirm the above status, as the average catch per day in 2001 was about 17.8 tonnes, increasing from 15.3 tonnes in 2000 (about 16% increase).

In Figure 10.2.3.c, the standardised CPUE, derived from a GLM CPUE model (WD 7) incorporating data from Germany (1995-2001), Iceland (1995-2001), Greenland (1999-2001) and Norway (1995-2001) is given. The model takes into account year, month, vessel and area (ICES statistical square). The model shows that the index did decrease until 1997 and increased thereafter until 2001 when it decreased by about 15% from 2000 value. Overall, the GLM model indicates a stable CPUE since 1995 both shallower and deeper than 500 m.

#### 10.2.3 Ichthyoplankton assessment

The traditional ichthyoplankton survey, conducted by Russia in 1982-1995 has not been carried out since 1996. The historical series of ichthyoplankton surveys was presented in the 2000 Working Group report.

## **10.2.4** State of the stock

Table 10.2.1 shows available survey estimates of stock size by acoustic and trawls. The biomass can be estimated acoustically for depths less than 500m. Acoustic biomass estimates have been relatively stable during 1991 to 1995, but they have declined substantially since from 2.48 million tonnes in 1995 to 0.72 million tonnes in 2001. The acoustic estimates from the last three surveys are considered minimum biomass estimates because trawl sets during those surveys have shown that there was considerable redfish biomass deeper than the depths where biomass can be estimated acoustically. However the proportion of fish above and below 500m is not known to be stable over years and it cannot be concluded that acoustic biomass estimates prior to 1996 are minimum biomass estimates, because of high variances in the acoustic surveys for those years. These possible changes in the depth distribution above and below 500m combined with the differences in geographic coverage in different years mean that the acoustic biomass series cannot be interpreted as a consistent series showing relative changes in stock size. It is not known if the trawl survey acoustic biomass estimates are minimum or if they can overestimate stock size.

Adding the trawl biomass estimate below 500m to the acoustic estimates (1.8 million tonnes) or adding the two trawl biomass estimates together (2.1 million tonnes) indicates that the biomass in 2001 is probably in the order of 2 million tonnes, distributed also in large portions of the NAFO Convention Area down to depth of 1000m.

Given the technical, seasonal, geographical and depth changes of the fishing activities, the relevance of the national CPUE series as indicator of stock abundance remains difficult to assess. However, from the standardised CPUE series, it can be concluded that the pelagic redfish CPUE remained stable since 1995 for all fishing areas as well as separated above and below 500 m depth. The models do not indicate significant stock reductions since 1995.

Taking into account the uncertainty in stock indicators, it is not known if the exploitation rate generated by recent catches is above or below the 5% exploitation rate.

## **10.3** Estimation of reference points

The former proposed MBAL biomass reference of 1.5 Mill. t is considered inappropriate as it was derived from a production model disregarding the increased knowledge about the stock distribution and expanded fishing grounds. None of the available data series are considered appropriate to develop reference points (ASPIC models were run with various conditions without success).

## 10.4 Management considerations

The working group did again experience difficulties in gaining catch estimates from the various international fleets like in the past.

An update on the pelagic fishery, in particular with respect to seasonal and area distribution, was requested in the ToR. Catch rates shallower than 500 m remained steady but low, and deeper than 500 m remained steady. The main new feature of the fishery was an increasingly clear distinction between two widely separated grounds fished at different seasons and different depths. In 2000 and 2001, the more south-westerly fishing ground extended into the NAFO Convention Area. The parameters analysed so far do suggest, however, that the newly discovered aggregations in the NAFO Convention Area do not form a separate stock component. The 1999 and 2001 surveys indicated that about one third of the stock is distributed in the NAFO Convention Area. The genetic structure of the pelagic and demersal stocks of deep-sea redfish (*S. mentella*) in the North Atlantic remains poorly known, but further research is currently being carried out.

Given this pattern of seasonally localised fishing, a seasonal or geographic dimension for management of the fishery on the different grounds could be considered from a management perspective. This would also account for depth separation and reduce the risk of overexploitation or depletion of possibly separate stocks or components, which will exist as long as they are managed under a common TAC.

The recent exploitation level seems not to cause stock size reduction.

#### 10.5 Precautionary approach

Based on the status of the knowledge of the stock(s) in the area, the Working Group could not come up with any information on reference points.

Considering the uncertainty related to definition of stock units, action must be taken in accordance with the precautionary approach and attempts be made to assess each stock component separately until better knowledge on the relationship between each stock or stock components are known. Such assessment must be based on what information is currently available. Furthermore, there exists considerable concern about the precision of the used stocks indicators.

Table 10.1.1	Pelagic S. mentella. Landings (in tonnes) by area as used by the Working Group. Due to the lack
	of area reportings for some countries, the exact share in Sub-areas XII and XIV is just approximate
	in latest years.
