Advisory Committee on Fishery Management

ICES CM 2003/ACFM:19
Ref. D,F,C

REPORT OF THE

Working Group on North Atlantic Salmon

ICES Headquarters
31 March–10 April 2003

International Council for the Exploration of the Sea

Conseil International pour l'Exploration de la Mer

Palægade 2–4 DK–1261 Copenhagen K Denmark

1 INTRODUCTION

1.1 Main Tasks

At its 2002 Statutory Meeting, ICES resolved (C. Res. 2002/2ACFM03) that the Working Group on North Atlantic Salmon [WGNAS] (Chair: Dr W Crozier, UK) will meet at ICES headquarters in Copenhagen, Denmark, from the 30 March-10 April 2003 to consider questions posed to ICES by the North Atlantic Salmon Conservation Organisation (NASCO). The terms of reference and sections of the report in which the answers are provided, follow:

a) With respect to Atlantic salmon in the North Atlantic area:	Section
i. provide an overview of salmon catches and landings, including unreported catches by country and catch and release, and worldwide production of farmed and ranched salmon in 2002;	2.1 & 2.2
ii. report on significant developments which might assist NASCO with the management of salmon stocks;	2.4
iii. provide long-term projections for stock rebuilding, focusing on trajectories for restoring stocks to target levels above conservation limits	2.5
iv. provide a compilation of tag releases by country in 2002.	2.7
b) With respect to Atlantic salmon in the North-East Atlantic Commission area:	Section
i. describe the events of the 2002 fisheries and the status of the stocks;	3.1-3.3
ii. evaluate the extent to which the objectives of any significant management measures introduced during the last five years have been achieved;	3.6
iii. further develop the age-specific stock conservation limits where possible based upon individual river-based stocks;	3.4
iv. provide catch options or alternative management advice, if possible based on a forecast of PFA, with an assessment of risks relative to the objective of exceeding stock conservation limits;	3.5
v. further refine the estimate of by-catch of salmon post-smolts in pelagic trawl fisheries for mackerel and provide estimates for other pelagic fisheries that may catch salmon;	3.7
vi. advise on an appropriate methodology to improve knowledge on the distribution and movements of escaped farmed salmon;	2.6
vii. identify relevant data deficiencies, monitoring needs and research requirements.	6
c) With respect to Atlantic salmon in the North American Commission area:	Section
i. describe the events of the 2002 fisheries and the status of the stocks;	4.1 & 4.2
ii. evaluate the extent to which the objectives of any significant management measures introduced during the last five years have been achieved;	4.3
iii. update age-specific stock conservation limits based on new information as available;	4.4
iv. provide catch options or alternative management advice with an assessment of risks relative to the objective of exceeding stock conservation limits;	4.5
v. provide an analysis of existing biological and/or tag return data, and recommendations for required data collections, to identify the origin Atlantic salmon caught at St Pierre and Miquelon;	4.6
vi. identify relevant data deficiencies, monitoring needs and research requirements.	6

d) With respect to Atlantic salmon in the West Greenland Commission area:	Section
i. describe the events of the 2002 fisheries and the status of the stocks;	5.1 & 5.2
ii. evaluate the extent to which the objectives of any significant management measures introduced during the last five years have been achieved;;	5.3
iii. provide information on the origin of Atlantic salmon caught at West Greenland at a finer resolution than continent of origin (river stocks, country or stock complexes);	5.1
iv. provide catch options or alternative management advice with an assessment of risks relative to the objective of exceeding stock conservation limits;	5.5
v. provide a detailed explanation and critical examination of any changes to the model used to provide catch advice and of the impacts of any changes to the model on the calculated quota;	5.6 & 5.7
vii. identify relevant data deficiencies, monitoring needs and research requirements.	6
e) review the appropriateness, and possible development of, an experimental tagging programme for investigating the behaviour of escaped farmed salmon;	2.6

The Working Group considered 39 Working Documents submitted by participants (Appendix 1); other references cited in the report are given in Appendix 2.

1.2 Participants

Amiro, P.	Canada
Caron, F.	Canada
Chaput, G.	Canada
Crozier, W (Chair)	UK (Northern Ireland)
Erkinaro, J.	Finland
Fontaine, P.M.	Canada
Gudbergsson, G.	Iceland
Hansen, L.P.	Norway
Holm, M.	Norway
Jacobsen, J.A	Faroe Islands
Kanneworff, P.	Greenland
Karlsson, L.	Sweden
Legault, C.	USA
MacLean, J.	UK (Scotland)
Meerburg, D.J.	Canada
Ó Maoiléidigh, N.	Ireland
Prusov, S.	Russia
Reddin, D.G.	Canada
Russell, I.C.	UK (England & Wales)
Sheehan, T.	USA
Smith, G.W.	UK (Scotland)
Trial, J.	USA
Vauclin, V.	France
Whoriskey, F.	Canada

A full address list for the participants is provided in Appendix 3.

2 ATLANTIC SALMON IN THE NORTH ATLANTIC AREA

2.1 Catches of North Atlantic Salmon

2.1.1 Nominal catches of salmon

The nominal catch of a fishery is defined as the round, fresh weight of fish that are caught and retained. Total nominal catches of salmon reported by country in all fisheries for 1960-2002 are given in Table 2.1.1.1. Catch statistics in the North Atlantic also include fish farm escapees and, in some north-east Atlantic countries, relatively small numbers of ranched fish (see Section 2.2.2).

The Icelandic catches have traditionally been split into two separate categories, wild and ranched, reflecting the fact that Iceland has been the only North Atlantic country where large-scale ranching has been undertaken with the specific intention of harvesting all returns at the release site. The release of smolts for ranching purposes ceased in Iceland in 1998. While ranching does occur in some other countries, this is on a much smaller scale. Some of these operations are experimental and at others harvesting does not occur solely at the release site. The ranched component in these countries has therefore been included in the nominal catch.

Figure 2.1.1.1 shows the nominal catch data grouped by the following areas: 'Northern Europe' (Norway, Russia, Finland, Iceland, Sweden and Denmark); 'Southern Europe' (Ireland, UK (Scotland), UK (England and Wales), UK (Northern Ireland), France and Spain); 'North America' (including Canada, USA and St Pierre et Miquelon); and 'Greenland and Faroes'.

The provisional total nominal catch for 2002 was 2,625 tonnes, 439 t below the confirmed catch for 2001 (3,069 t). The 2002 catch was a little above the average of the last five years (2,598 t), but over 500 t below the average of the last 10 years (3,151 t). For the majority of countries, catches in 2002 were lower than those in 2001, although in five countries catches rose slightly on 2001. Catches were above the mean of the previous five years in nine countries, and in six of these countries catches were also above the 10-year mean.

Nominal catches in homewater fisheries split, where available, by sea-age or size category are presented in Table 2.1.1.2 (weight only) and Table 2.1.1.3 (numbers and weight). The data for 2002 are provisional and, as in Table 2.1.1.1, include both wild and reared salmon and fish farm escapees in some countries. Different countries use different methods to partition their catches by sea-age class and these are outlined in the footnotes to Table 2.1.1.3. The composition of catches in different areas is discussed in more detail in Sections 3, 4, and 5.

Table 2.1.1.4 presents the nominal catch by country in homewater fisheries partitioned according to whether the catch was taken in coastal, estuarine or riverine areas. Overall, coastal fisheries accounted for 57% of catches in North East Atlantic countries in 2002, in-river fisheries 37% and estuarine fisheries 6%. In North America, coastal fisheries accounted for 10% of the catch in 2002, while in-river fisheries took 76% and estuarine fisheries 14%.

There is considerable variability in the percentage of the catch taken in different fisheries between individual countries. For some countries the entire catch is taken in freshwater, in other countries the majority of the catch is taken in coastal waters. Estuarine catches, where these occur, commonly comprise less than 25% of the nominal catch. Catch and release has become increasingly commonplace in some countries and these fish do not appear in the nominal catches. Data aggregated by region are presented in Figure 2.1.1.4. Overall in the NEAC northern area (Iceland, Norway, Russia, Finland and Sweden) around half the catch over the period 1995 to 2002 has been taken in estuarine waters and half in rivers; coastal catches comprise no more than 2% of the total. There is no trend over the period in the percentages taken in each area. In the NEAC southern area (France, Ireland, Spain, UK (N. Ireland), UK (Scotland) and UK (England & Wales)) estuarine fisheries have comprised a small (<20%) and relatively stable part of the catch. However, the percentage of the catch taken in coastal fisheries has increased over the period (50% in 1996 to 64% in 2002). This is thought to reflect increasing use of catch and release, since catches and effort in coastal fisheries has been reduced in many countries over the period. In North America, the majority of the catch has been taken in freshwater, and this has increased over the period (69 to 78%).

2.1.2 Catch and release

The practice of catch and release (also termed hook and release or live release) in rod fisheries has become increasingly common as a salmon management/conservation measure in light of the widespread decline in salmon abundance in the North Atlantic. In some areas of Canada and USA, catch and release has been practiced since 1984, and in more recent years it has also been widely used in many NEAC countries both as a result of statutory regulation and through voluntary practice.

The nominal catches presented in Section 2.1.1 comprise fish which have been caught and retained and do not include salmon that have been caught and released. Table 2.1.2.1 presents catch-and-release information from 1991 to 2002 for six countries that have records; catch-and-release may also be practiced in other countries while not being formally recorded. There are large differences in the percentage of the total rod catch that is released: in 2002 this ranged from 16% in Iceland to 80% in Russia, reflecting varying management practices among these countries. Within countries, the percentage of fish released has tended to increase over time, and the rates in 2002 are the highest in the time series for three countries and among the highest for two other countries. There is also evidence from some countries that larger MSW fish are released in higher proportions than smaller fish.

Concerns have been expressed about the survival of fish following catch and release. However, various research studies have demonstrated that if fish are appropriately handled, mortality following capture is low and a large proportion of fish survive to spawn (Anon., 1998; Webb, 1998a and b; Whoriskey *et al.*, 2000; Dempson, *et al.*, 2002; Thorstad *et al.*, 2003). It is recognised, however, that fish are more likely to die when water temperatures are high (>20^{o}C) or if fish are 'played' for an extended period. In deriving river-specific conservation limits, Canada (various regions) and UK (England & Wales) make a small allowance for catch-and-release mortality. These correction factors vary: up to10% for Canadian Regions and 20% for UK (England & Wales).

2.1.3 Unreported catches

Unreported catches by year (1987-2002) and Commission Area are presented in Table 2.1.3.1. A description of the methods used to evaluate the unreported catches was provided in ICES 2000/ACFM:13 and updated for the NEAC Region in ICES 2002/ACFM:14. In practice, the estimation methods used by each country have remained relatively unchanged and thus comparisons over time may be appropriate. However, the estimation procedures vary markedly between countries. For example, some countries include only illegally caught fish in the unreported catch, while other countries include estimates of unreported catch by legal gear as well as illegal catches in their estimates. For France, the illegal catch is included in the nominal catch. Over recent years efforts have been made to reduce the level of unreported catch in a number of countries (e.g. through improved reporting procedures). The introduction of carcase tagging programmes in Ireland and UK (N. Ireland) in the last two years is also expected to lead to reductions in unreported catches.

The total unreported catch in NASCO areas in 2002 was estimated to be 1,039 t, a decrease of 12% on the estimate in 2001. The unreported catch in the North East Atlantic Commission Area in 2002 was estimated at 940 t, that for the North American Commission Area 83 t, with 10 t estimated for the West Greenland Commission Area. Figure 2.1.3.1 shows that the unreported catch has remained a relatively constant percentage of the total catch (~25-30%) since 1987.

Estimates for 2002 are presented by country in Table 2.1.3.2. Expressed as a percentage of the total North Atlantic catch (nominal and unreported), unreported catches for individual countries range from 0 to 15%. Relative to national catches, unreported catches range from 2% to 64% of country totals.

In the past, salmon fishing by non-contracting parties is known to have taken place in international waters to the north of the Faroe Islands. A total of 16 surveillance flights were made over the area in 2002, 14 by the Norwegian coastguard and 2 by the Icelandic coastguard. No sightings of vessels were made during these flights. However, none of the flights took place in the period from mid-September to late March, which is the period when previous salmon fishing has been reported. Nonetheless, there were no reports from ports in Norway, Faroes or elsewhere indicating that vessels fishing for salmon may be operating in international waters.

2.2 Farming and Sea Ranching of Atlantic Salmon

2.2.1 Production of farmed Atlantic salmon

The production of farmed Atlantic salmon in the North Atlantic area rose slightly in 2002 to 705,307 t a 1% increase on 2001 and a 15% increase on the mean of the previous 5 years (Table 2.2.1.1 and Figure 2.2.1.1). Most of the North Atlantic production took place in Norway (62%) and UK (Scotland) (23%). Production increased over the previous years in most countries, but fell by around a half in USA and Iceland.

World-wide, production of farmed Atlantic salmon in 2002 topped one million tonnes for the first time. Total production is estimated at 1,058,307 t, an increase of 30% on 2001 (Table 2.2.1.1 and Figure 2.2.1.1). Production outside the North Atlantic increased by 74% on 2001 to 353,000 t. The largest contribution to the farmed production outside the North Atlantic area was in Chile (273,000 t). World-wide production of farmed Atlantic salmon in 2002 was over 400 times the reported nominal catch of Atlantic salmon in the North Atlantic. Farmed salmon therefore dominate world markets.

2.2.2 Production of ranched Atlantic salmon

Ranching has been defined as the production of salmon through smolt releases with the intent of harvesting the total population that returns to freshwater (harvesting can include fish collected for broodstock) (ICES 1994/Assess:16). The total production of ranched Atlantic salmon in countries bordering the North Atlantic in 2002 was 10 t, a reduction of 4 t on 2001 and the lowest value since 1980 (Table 2.2.2.1 and Figure 2.2.2.1). Salmon ranching (smolt releases) ceased in Iceland in 1998. Small catches of ranched fish were recorded in each of the three other countries reporting such fish (Ireland, UK(N. Ireland), and Norway). Production in these three countries includes catches in net, trap, and rod fisheries.

2.3 Update on the estimation of natural mortality at sea of Atlantic salmon

2.3.1 Methods and estimates of natural mortality (M) at sea

In 2002 the Working Group reviewed theoretical and empirical methods for estimating M for Atlantic salmon and applied the inverse-weight model to observations from the River Bush as well as to growth and abundance data of the River Trinité, LaHave River and Northwest Miramichi River (Canada) (ICES CM2002/ACFM: 14). The Working Group also considered a maturity schedule method to derive estimates of natural mortality at sea for stocks which mature at two or more different ages. Based on the analyses reviewed, the Working Group decided to continue use of the inverse-weight method as the basis of estimating M because the maturity schedule method yielded values of M that varied temporally and spatially, and it was not clear whether it was appropriate to apply values from this method to all stocks and the entire time series. However, the group determined that the most appropriate growth function for use with inverse-weight method was linear rather than the previously used exponential function. This change in growth function, plus analysis of data from additional rivers, resulted in the instantaneous monthly mortality rate used in the run-reconstruction model for the North American and NEAC areas to be changed from 0.01 to 0.03.

The Working Group reviewed an analysis of a more extensive data set from 5 rivers of the NEAC area and 6 rivers in the NAC area. The rivers with suitable data extended from the Scorff (France) to the North Esk (Scotland) and north to the Vesturdalsa River (Iceland). On the North American side, hatchery and wild stock data sets extended from the Scotia-Fundy region to the north shore of the St. Lawrence (Quebec) (Table 2.3.1.1). The time period analysed was from 1981 to 1999 in the NEAC area and 1970 to 1999 in the NAC area.

Both the inverse weight method and the maturity schedule method were applied to the sets with appropriate data. The analysis of the river-specific growth data supported the previous conclusion that a linear function characterized the observed weights at age in the marine phase better than the exponential function (Figure 2.3.1.1).

The results from the inverse-weight modelling using the linear growth function are summarized in Figure 2.3.1.2. The estimates of integrated monthly mortality in the second year at sea ranged from 1.4% to 4%, increasing from south (Scorff in France) to north (Vesturdalsa in Iceland). The mortality rate on the hatchery stock (Shannon River) was higher than on the wild stocks of the southern NEAC area.

For North America, the monthly mortality rates in the second year at sea ranged from 1.5% (de la Trinite River) to a high of just under 8% for the wild stocks but ranging to just under 10% for the hatchery stock of the LaHave River (Figure 2.3.1.2). The hatchery stock mortality rates were higher than the wild stock mortality rates.

The mortality rate estimates from the maturity schedule method were higher than those derived from the inverse-weight method. For the NEAC stocks, monthly mortality rates ranged between 5% and 19% in the second year at sea and for the NAC stocks, the mortality rates ranged from less than 1% to almost 22% per month (Figure 2.3.1.3). There is high interannual variation in the estimates.

Both the inverse-weight model and the maturity schedule model estimate mortality in the second year at sea based on the numbers of salmon alive at the 1SW and 2SW stages. If there are no fisheries on these age groups, then the mortality rates equate to M (natural mortality). If there are fisheries on the age groups and the removals are accounted for in the abundance at 1SW or 2SW, then the mortality estimates also equate to M. In cases where exploitation occurs in marine fisheries and the harvests are not accounted for, the mortality estimates equate to the total instantaneous mortality ($Z = F + M$). As an example, the estimates of Z for the Shannon River hatchery stock were derived using returns to the coast (factored from tag recoveries in the commercial fisheries) compared with returns to the hatchery in river (Table 2.3.1.2). The differences in the estimates represent the exploitation rate in the fishery. An analysis of changes in Z over time may provide an indication of the changes in F resulting from changes in exploitation if M is assumed to be constant over time.

The Working Group acknowledged that the additional analyses confirmed the previous conclusion that monthly mortality in the second year at sea was greater than 1% and distributed around 3%, at least for the wild fish. There are important differences among stocks and even regions which are not accounted for in the generalization over the entire NEAC and NAC areas. Exploration of the maturity schedule model for mortality requires inputs of abundance at sea by age of both males and females, a value which has to be frequently assumed for smolts and adult returns because of insufficient sampling. Adult sex ratios should generally be easy to obtain since these fish are exploited in fisheries. The sex ratio of smolts is more difficult to obtain because the research objective is to have the least impact on the population being monitored. However, hatchery stocking programs should at least attempt to confirm the sex ratio of the released smolts as this information will greatly enhance the exploration of trends in mortality at sea.

2.3.2 Calculation of marine mortality for two rivers in Quebec

The St-Jean and Trinité rivers provide information about smolt production and adult returns in Québec. This enables calculation of freshwater survival from egg to smolt , as well as marine survival from smolt to adult return.

A mark-recapture program has been used to estimate the smolt run. Annual smolt estimates have been available since 1989 (with the exception of 1997) on the St. Jean River and since 1984 on the Trinité River. Adult return is estimated by visual count in September on the St. Jean River and using a trap count on a fishladder on the Trinité River. Maiden spawners are 1SW or 2SW and, on the St-Jean River, a small proportion of 3SW.

Return rate of St. Jean River smolt varied from 2.1% in 1989 to 0.7% in 1996, for a mean value of 1.3% (Fig 2.3.2.1). Return rate of the year 2000 smolt cohort was 1.7%, higher than the average and the third highest value in the 11-year time series. Return rate of the 2001 cohort is known for 1SW returns. It was 0.5%, higher than the mean value of 0.4%.

On the Trinité River, smolt return rate at sea has fluctuated from 5.4% in 1988 to 0.7% in 2001 and shows a mean return rate of 2.5% (Figure 2.3.2.1). Return rate of the 2000 smolt cohort, the last one fully available, shows the lowest sea survival encountered in the 17-year time series, with a low of 0.4%. Sea return rate of the 2001 cohort is known for 1SW returns. It was 0.6%, two times higher than previous year, but only 40% of the mean value of 1.5%.

The downward trend observed with regard to return rate after the 1991 smolt year seems to be reversed in recent years on the St-Jean River but continues on the Trinité River, reaching a new low.

2.4 Significant developments towards the management of salmon

2.4.1 Trends in sub-catchment populations of salmon in the River North Esk, UK (Scotland)

Recent declines in nominal catches of salmon across the species range (ICES 2002/ACFM:14) have focused attention on current management practices and on the assessment methodologies which advise such practices. Ideally, management units should correspond to the way in which the salmon resource is structured. Our current understanding of the population structure of salmon returning to rivers in UK (Scotland) has been informed by a number of scientific investigations. Long term tagging studies associated with fish traps on upper catchment tributaries suggest that homing units, or populations, are spatially distributed over distances as small as ca. 10km (Youngson *et al*, 1994). Radio tracking studies of returning adult salmon have demonstrated that the time of entry into freshwater is related to spawning destination (Laughton and Smith, 1992; Webb 1998; Smith *et al,* 1998; Smith and Johnstone 1996; Webb, 1992; Walker and Walker, 1991) and that, within each sea age class, early running salmon tend to spawn in the upper areas of catchments while later running salmon, spawn in the lower reaches. This pattern is consistent among a range of river types (eg. large/small, complex/simple). Thus, run-timing is related to spawning destination, and furthermore, run timing has been shown to be a heritable attribute (Stewart *et al*, 2000).

The present study set out to investigate trends in stock size among particular sub-catchment groups within the river North Esk over the last 20 years, and the effects of recent local management initiatives aimed at protecting early running MSW salmon.

On the North Esk, a monitored river on the east coast of Scotland, a fish counter allows a direct count of adult fish past a particular point on the lower reaches of the river throughout the year. Such counts, together with the catch data from local fisheries allows estimates to be made of the fishery performance and stock levels at identifiable points within the lower river. Further, partitioning these counts and catches into seasonal components, permits such assessments to be made at sub-catchment scales. In the current study, trends in the fisheries and stock of the North Esk were assessed at a whole river level and for four age/seasonal run-timing components (early 1SW, late 1SW, early MSW and late MSW) for the period 1981-2001.

Analysis of annual count and catch data at whole river level shows that there has been a decreasing trend in the abundance of North Esk salmon to coastal waters, and similar decreasing trends in exploitation and catch, resulting in a stable number of salmon entering the river. Decreasing trends in in-river exploitation and catch have resulted in an increasing trend in potential spawners.

Although it was not possible to estimate the abundance of each seasonal component in coastal waters, analysis of the trends in abundance, exploitation and catch in the lower river for each of the four age/seasonal components of the stock suggest that there has been no trend in abundance over the study period (Table 2.4.1). However, the significance of the observed downward trends in lower river exploitation varies among the groups and as a result, increasing trends in the upper river abundance are significant for only the early 1SW and early MSW components. Due to the absence of any significant trends in exploitation and catch in the upper river, the increasing trends in lower abundance for the two early running components are also evident in the estimated abundance of potential spawners.

In summary, the results show that although the overall abundance of North Esk salmon returning to coastal waters has decreased, reduced exploitation has resulted in an increasing trend in the abundance of potential spawners. Further, local management actions to protect early running fish, the stock component thought to be most at rapidly declining (Youngson *et al*, 2002), appear to be having some effect. More generally, the analysis illustrates that trends in the abundance may vary among different stock components within a river system, as will the results of management measures that are implemented non-uniformly over a fishing season. There is thus a need to develop assessment methods that operate at scales that more closely mirror the population structure within river systems.

2.4.2 Gyrodactylus salaris in Sweden

The monogenean parasite *Gyrodactylus salaris* spread from the Baltic region to Norwegian rivers in the 1970s and its devastating impact on Norwegian wild salmon is well known (Johnsen and Jensen 1991). However, the effects of the parasite on Swedish west coast salmon have not been well described. The parasite was first found in this region in 1989 and since that time it has spread gradually. By autumn 2002, 11 out of a total of 23 wild salmon rivers harboured the parasite. These rivers are mainly located along the southern part of the west coast. A programme implemented to monitor the spread of the parasite to new rivers has been gradually improved, and parasite infestations in three infected rivers are also monitored annually.

Evidence that the parasite has had a negative impact on salmon in the region comes from trends in parr densities over time in infected and uninfected populations. In uninfected rivers, densities of older salmon parr, and to a smaller extent also 0+ parr, have generally been trending upwards between 1988 –2002, whereas in the same time period a number of infected rivers have had exhibited significant downward trends in parr densities. However, other factors such as low water discharges, may be partially responsible for the observed decreases.

Concurrent experimental infection trials were conducted in 2002 in both the laboratory (Veterinary Institute, Oslo) and in a streamside system using natural water and food from Sweden's Enningdalsälven River. Fish from a number of west coast populations were tested at both sites. Results from the Oslo work showed that while all the salmon were initially susceptible to the parasite, those from one system (Gullspångsälven) showed a decrease in infection levels with time. By contrast, in the streamside experiments, impacts of the infection were more varied. Initially, two groups showed high mortalities, but these may have been due to dramatic increases in temperature, low Flows, and the development of fungal infections. An increase in $\mathbf{F}_{low}$ rates eliminated the fungus and stopped the mortalities. Some of the fish from the Enningdalsälven River died from the infection later in the experiment, whereas others successfully fought it off. In addition, fish from the Rolfsån and Gullspångsälven systems did not show increased mortalities toward the end of the experiment, and 50% of the Gullspångsälven fish had freed themselves of the parasite by the time the trial terminated. The lesser impacts of the parasite under these more natural conditions may be due to water chemistry. One possible explanation is that the level of labile inorganic aluminium in the water used for the Swedish experiments was higher than that in the Oslo water (about 65 mg/l versus < 2 mg/l). Increased levels of inorganic aluminium have a negative impact on *G. salaris*, particularly at low pH (Soleng et al. 1999).

A large scale survey of the parasite in the Baltic river Torneälven in 2001 revealed that the parasite was common on salmon parr. This was in contrast to earlier investigations. The prevalence and intensity varied among different parts of the river (from 0% infected to 100% infected with up to 330 parasites per fish) which suggested that earlier studies on geographically limited scales studies may not have been able to adequately describe infestation levels. It is also possible that the abundance of the parasite has increased in recent years, when the parr densities in most Baltic rivers have increased dramatically, boosting the probability of transmission. It is not known if the parasite is also common in other Baltic salmon rivers.

Management approaches for *Gyrodactylus salaris* infestations in Sweden were similar to those adopted elsewhere in the Baltic region, where only few cases of negative impacts of the parasite have been described. In the last few years Sweden has begun to take the threat of the parasite more seriously, and infection with *Gyrodactylus salaris* became a notifiable disease in Sweden in 2002. There are also regulations concerning the release of fish in non-infected wild salmon rivers of the west coast. Releases of fish are allowed if they are from a hatchery free of the parasite. At this time it is also allowed to treat infected fish to kill the parasites before release, but this option is under debate and may be abolished.

2.4.3 Considerations for examining the effects of fisheries on biological characteristics of Atlantic salmon stocks

Fisheries are most frequently managed to ensure the achievement of spawning stock biomass or spawner objectives which are expected to ensure the long term sustainability of the resource. Fisheries can be selective for particular sizes of fish, because of the gear being used, or selective to particular run components because of restrictions in seasons. As a result responses to fisheries in addition to returns and spawners may be evident in other features of the salmon stock including:

- Increased juvenile abundance resulting from improved spawning escapement (which can be beneficial to future abundance)
- Variations in size of salmon (if sea fisheries are size selective, which may be beneficial to future abundance)
- Variations in proportions of age groups (if sea fisheries are age selective, which may be important for persistence)
- Variations in post-spawner and repeat spawner survival (which may be important for persistence)
- Variations in run-timing of fish into fresh water (which may benefit resource users, and benefit the resource).

The Working Group examined some examples of stock characteristics which could be used to evaluate the consequences of fisheries management, both in homewater and distant high seas fisheries. To address the issue of distant water fisheries which exploit primarily one maturing age group, a stock indicator (1SW-2SW relation) was presented which shows the benefits to home water returns of reductions in marine fisheries which may not be discernible by simply looking at abundance.

In 1984, the commercial fisheries of the Maritime provinces (Canada) were closed and anglers were prohibited from retaining large salmon (>= 63 cm fork length). The Newfoundland commercial fisheries were closed in 1992, in 1998 in Labrador, and by 2000 in all of eastern Canada.

Returns as indicators of stock responses to variations in fisheries exploitation:

A trends analysis of returns of small and large salmon to rivers of eastern Canada indicated that most of the rivers of Newfoundland showed an increasing trend in returns to rivers as a result of the commercial moratoria of 1992 but no such effect was evident in the Maritimes rivers where the local commercial fisheries had been closed since 1984 (Chaput and Prevost 1999). Returns of 1SW salmon and 2SW salmon did not improve in all rivers of the Maritimes after 1984. The closure of the remaining commercial fisheries in 1992 to 2000 did not result in increased returns to the rivers relative to the 1984-1991 period and in some cases, the abundance declined after 1992.

Egg depositions and juvenile abundance:

There were significant improvements in egg depositions in the Miramichi River but no improvements were observed in the Saint John River after the closure of the commercial fisheries in 1984 (Figure 2.4.3.1). The further closure of the remaining commercial fisheries post 1991 did not result in any improvements in egg depositions in the Miramichi but a significant decline in egg depositions was observed for the Saint John River post-1991 (Figure 2.4.3.1). The greatest increase in fry abundance occurred post 1991 in both the Northwest and Southwest Miramichi branches (Figure 2.4.3.1). Improvements in the parr abundance lagged those of fry and it wasn't until post-1991 that the average parr abundances increased in the Miramichi. Increased parr abundance was noted in the LaHave River through the 1972 to 1983 period but the juvenile abundance increased significantly after the closure of the commercial fisheries and imposition of mandatory catch and release (Figure 2.4.3.1). This contrasts with the Nashwaak River in which the parr densities declined after the 1984 closure and have since remained unchanged.

Increases in return rates of salmon to rivers:

Returns of adults adjusted for the number of smolts which produced them are the true indicators of benefits to stocks of reduced exploitation. Return rates of hatchery origin salmon were highest in the 1970s prior to the commercial fishery moratoria in the Maritimes of 1984 and the Newfoundland commercial fishery moratoria of 1992 (Figure 2.4.3.2). Had commercial fisheries been in operation, the return rates to rivers would have been lower still. In stocks where salmon mature at two sea ages, return rates alone are insufficient to infer levels of marine survival. In the Trinité River, survival in the first year at sea declined whereas measured survival in the second year at sea increased following the reductions and subsequently closure of the commercial fisheries in 1992 (Figure 2.4.3.2). This presents a different picture from that based on return rates which suggested that 2SW return rates were declining (Figure 2.4.3.2).

Increases in occurrence, abundance and return rates of repeat spawners:

Atlantic salmon returning to the Miramichi have been sampled during the entire spawning migration period at estuary trapnets from 1971 to 2002. After the closures of the commercial fisheries in 1984 and the mandatory release of all large salmon, the relative proportion and the absolute abundance of repeat spawners in the returns of large salmon have increased (Table 2.4.3.1). Since 1995, salmon with six previous spawnings have been observed in the returns to the Miramichi and salmon on the third to fifth spawnings are more abundant since 1992 (Table 2.4.3.1; Figure 2.4.3.3). There are fewer repeat spawner components in the Saint John River than in the Miramichi and there has not been any change in relative proportions over time as was seen in the Miramichi (Table 2.4.3.2). The post-spawner survival in the Saint John River is likely constrained by downstream fish passage through 2 to 3 hydro-generating facilities which cannot be managed like the fishing exploitation rates on the Miramichi stock. For the Saint John River, therefore, reduced fisheries exploitations have not resulted in improved post-spawner survivals.

Repeat spawner return rates for 2SW have been the highest during the 1992 to 2000 period whereas 1SW repeat spawner return rates have not increased significantly over the past 30 years (Figure 2.4.3.4). Since the return rates are relative to the abundance of maiden fish prior to in-river exploitation, return rates of 1SW salmon would be lower than on 2SW salmon because the former are still exploited in Native and recreational fisheries.

In addition to being more abundant in recent years, repeat spawners from the Miramichi grow substantially between spawning events and 1SW maiden salmon on their second spawning are as large as 2SW maiden fish and 2SW salmon are as large or larger than comparative 3SW salmon in other rivers (Figure 2.4.3.5). These larger fish of proportionally greater abundance in the river are of interest to the recreational fishermen, produce more eggs per fish than maiden spawners, and provide a buffer to the annual spawning escapement when smolt to maiden spawner survivals are low.

Change in size-at-age resulting from size-selective fishing:

Salmon fishing gears are potentially size-selective. In the Miramichi, the mean size of 2SW salmon increased in 1986. The 2SW salmon from 1999 to 2002 are the largest of the time series (Figure 2.4.3.6). The mean size of the 1SW salmon of the last four years is the largest of the time series and the change in size was also first observed in 1986 (Figure 2.4.3.6). An increase in mean size of 1SW salmon was observed in the Nashwaak River where mean size in 1972 and 1973 was 53-54 cm in contrast to the 56-58 cm mean size in the 1990s (Figure 2.4.3.6). In the Saint John River, the mean size of 1SW salmon averaged between 58 and 59 cm prior to 1986 and jumped to between 60 and 62 cm since (Figure 2.4.3.6). The change in mean size occurred in 1986 in both the Saint John and Miramichi samples when the commercial fisheries were supposedly closed in 1984. It is possible that exploitation with nets was still taking place on these stocks in 1984 and 1985.

Variations in run-timing:

Many historical commercial fisheries were prosecuted early in the season and frequently not in proportion to the timing of the fish entering the river. Evidence of the effect of fisheries exploitation in coastal waters relative to the time of entry of salmon to rivers is available from the Millbank index trapnet in the Miramichi River. The date of the 50th percentile of the count of large salmon at Millbank in the 1950 and 1960s was post Sept. 1 and it got rapidly earlier in 1970 to 1972 to the end of June or middle of July (Figure 2.4.3.7). Since 1984, the date of the median count has varied between the end of June and the end of August while in the 1990s, the median date oscillated around mid-August. Run-timing of both small and large salmon is currently bimodal with a peak in July and a second peak in late September.

Indications of homewater effects relative to variations in high seas exploitation:

The fishery at West Greenland exploits predominantly 1SW salmon destined to mature and return as 2SW salmon the following year. Significant associations between 1SW salmon returning to rivers in year and 2SW salmon returns in year+1 have been reported which suggests that there is an underlying stock-specific average maturation schedule for 1SW and 2SW age groups. Deviations from the relationship would result from disproportionate variations in first year and second year mortalities both natural and fisheries induced (because the fishery exploits one age group and not the other), variations in maturation profiles of males and females leading to deviations from average 1SW/2SW relationships (as influenced by the environment, for example). If a fishery exploits the 2SW age group but not the 1SW age group, then the 1SW/2SW ratio should be unnaturally high. If fisheries exploit 1SW age group preferentially, then the 1SW/2SW ratio would be unnaturally low. The absence of exploitation on one age group can be used to assess the relative impacts of the fishery on the other age group. Since 1992, there is essentially no exploitation on 1SW salmon in the marine environment. Variations in 2SW returns to eastern Canada, but specifically variations from the 1SW/2SW relationship, may be exaggerated by variations in fisheries harvests at West Greenland.

This effect was examined using data from the LaHave River, Saint John River at Mactaquac, and the Miramichi River. To assess whether there were any detectable effects on 2SW returns to rivers as harvests at Greenland varied, a covariance model was examined:

Ln(2SW returns in year+1) = Ln(1SW returns in year) + GN1
where GN1 = harvest of North American 1SW salmon at West Greenland in year

In both the LaHave and Southwest Miramichi relationships, the 2SW returns in 1993 are exceptionally low relative to the 1SW returns in 1992 (Figure 2.4.3.8). There is a negative association between the level of harvest at West Greenland and the difference from expected (based on the 1SW/2SW relationship) in the 2SW returns (Figure 2.4.3.9). For all rivers and stocks (wild, hatchery) examined, the correlation coefficient of GN1 was consistently negative.

For the Southwest Miramichi, Northwest Miramichi, and LaHave River wild salmon, including Greenland catch of North American origin 1SW salmon resulted in a reduction in the residuals of the 2SW prediction. For Nashwaak River and the hatchery salmon from the Saint John River, consideration of the Greenland harvest did not contribute to describing the variations in 2SW return corrected for variation in 1SW return the previous year (Figure 2.4.3.9). Variations in high seas exploitation at Greenland can be detected in the returns of 2SW salmon in home waters in the Maritimes, but only after correcting for the 1SW abundance of the same cohort.

Conclusions:

Characteristics other than returns should be considered when evaluating the effects of fisheries on salmon stocks. Responses in juvenile abundances and return rates to rivers provide direct indications of desired responses to stock management. In addition, life history features may also change including the relative and absolute abundances of repeat spawners, growth of salmon with repeat spawning events both of which provide additional spawners to the population and improved recreational fishing quality in rivers. Some commercial fisheries have been size-selective and focused on specific run components. Differential exploitation on faster growing fish or fish returning earlier may have genetic consequences. The examination of such characteristics is recommended since the conservation of Atlantic salmon involves more than maintenance of fish numbers.

The Working Group recommends that life history characteristics of salmon stocks including age structure, length at age, relative and absolute abundance of repeat spawners, run-timing and other such features be examined for Atlantic salmon stocks to ensure that conservation of salmon goes beyond considerations of abundance.

2.4.4 Data Storage Tag (DST) tagging of pre-adult salmon

Within the framework of a Nordic DST tagging programme started in 2002, a new salmon trawl design and a modified “Fish-lifter” (after Holst & McDonald 2000) was developed for the live capture of fish in post-smolt and mackerel investigations in the Norwegian Sea (Section 3.7.1). This was used by Norway, Faroes and Iceland to capture fish for tagging. The modified “Fish Lifter” allows most of the salmon to be taken with little or no external damage, making the catch fit for tagging and release. The new trawl design with lighter trawl doors gave a higher speed through the water (mean ~ 4.5 kt against ~ 3.5 kt previously). Possibly because of the higher trawling speed and maybe also due to lower sea temperatures, the Faroese and Icelandic research vessels captured an unprecedented number of large “autumn” post-smolts/ pre adults during late October 2002 to January 2003 (Table 2.4.4.1). In June –July while the Norwegian research vessel was fishing in the mid part of the Norwegian Sea, the catches of adult salmon stayed low, although a large number of post-smolts were taken. In the summer, however, the post-smolts were too small to be tagged with the DSTs available (38.4 x 12.5 mm)

.
The tags were placed in the body cavity of the salmon through a small incision above the pelvic fins. Two types of tags were used, an “I- button” tag (Dallas Semiconductor) recording only temperature (memory capacity approx. 12,000 recordings) and a depth and temperature recording tag with a memory capacity of 21,738 measurements per parameter (Star Oddi “Micro”). The tags will record these parameters for two years during the time lapse from tagging to retrieval of the tags. The temperature regime encountered and the vertical migration patterns of the salmon can thus be followed for the marine feeding cycle, and in most cases also for the homing back to the river.

A total of 197 post-smolts, pre-adults (fish < 45 cm) and 26 adults were taken; 76 of these were tagged with the “Micro” tags, and 51 with “I-buttons” (Table 2.4.4.1). Figure 2.4.4.1 shows positions and numbers of fish taken in the areas where salmon were captured and released. About 50 % of the 17 adult salmon taken in the Norwegian cruise were fish farm escapees or maturing fish. This, together with the low number captured indicates that the areas around the Voering Plateau probably were surveyed too late to allow for sampling the densest cohorts of wild adult immature fish anticipated to be migrating northwards through these waters. One of the four fish tagged in the Norwegian Sea, turned up 18 days later in the bag net fishery in the Namsenfjord, Norway- a distance of ~ 480 km (Figure 2.4.4.1). The salmon taken in the Faroese tagging expedition were dominated by fish with 2 year smolt age, while 3 year and 1 year smolts made up ~ 20% and ~10 % respectively of the material analysed. In the Icelandic expedition, one fish carried an Irish microtag. All DST tagged fish were adipose fin clipped, but in the Icelandic expedition they were tagged with external tags (Floy tags) in addition. Once the fish are opened, the DST tags will be easily visible due to a fluorescent plastic tube attached to the tag body. The DSTs have a contact address and a reward announcement.

The results so far are a breakthrough in marine tagging of pre-adults and adults. Once the tags start to be returned expectedly starting with the fishing season in 2002, they will yield results of significance for the knowledge of the marine life cycle of the salmon. Records from retrieved tags will shed light on temperature regimes in the salmon habitats during the first and possibly the second winter, temperature preferences at different times of the year, and temperatures recorded may be related to individual growth. Vertical distribution in relation to temperature and diurnal vertical distribution and migrations can be detected. For the management of salmon the vertical distributions and temperature/growth relationships will be particularly valuable for assessing potential of salmon being intercepted by pelagic fisheries and for building predictive models.

2.5 Long-term projections for stock rebuilding

The term of reference (Aiii) to ICES was to “provide long-term projections for stock re-building, focusing on trajectories for restoring stocks to target levels above conservation limits”. Trajectories for stock rebuilding depend on many parameters which are not known with certainty or which may change over time. It is not possible to establish generalised trajectories for all stocks contributing to national or continental stock complexes as the range of uncertainty, both presently and in the future would lead to spurious projections over time on these larger scales. This is because the rate at which a stock complex will recover depends on the existing productive capacity of each individual stock under the prevailing conditions e.g. of exploitation, marine survival and effective intervention. Therefore, in order to address this request the Working Group considered theoretical rebuilding trajectories for stocks with known stock and recruitment parameters (Section 2.5.1) and the probability of extinction under different circumstances for some stocks in the USA which are well below their conservation limits (Section 2.5.2). The programmes for rebuilding salmon stocks in North America are described separately in Section 4.2.6. An example of a large-scale international stock rebuilding programme for Baltic salmon stocks is provided to illustrate the rate of recovery of stocks currently undergoing restoration and rebuilding (Section 2.5.3). The difficulty in rebuilding salmon stocks which have fallen below S_{lim} is illustrated and the need to maintain all salmon stocks at or above this level is emphasised. The conditions under which stock rebuilding can be carried out are simulated and discussed.

2.5.1 Recovery trajectories for reductions in exploitation of Atlantic salmon across a range of stock recruitment functions and uncertainty

Stock and recruitment curves representing highly productive stocks through low productive stocks were applied to a forward projecting stochastic framework that could produce recovery trajectories for a variety of states and exploitations. The purpose of this exercise was to estimate recovery times and frequency of achieving conservation over a 50 year time frame under a range of exploitation.

Parameters for Ricker stock and recruitment functions were obtained from SALMODEL (Anon 2003, Table 4.2) for the rivers Bush, North Esk and Nivelle. Although no North American river examples are presented, the H’ parameters (exploitation at optimum spawning stock abundance) were within the known range of 11 North American rivers. Similarly, the age structure of the River North Esk population is only out of phase by 1 age class compared to many North American stocks.

H’ and R’ (recruitment at optimum spawning stock) parameters were used to obtain the Ricker parameters alpha (α-productivity) and beta (β) for the formula:

$$R = \alpha * S * Exp(-\beta * S)$$

Alpha was calculated according to the formula:

$$\alpha = Exp(H'/(1 - H'))$$

and Beta was calculated as:

$$\beta = H'/((1-H')*R')$$

Spawning stock at optimum recruitment (S_{lim}) was:

$$S_{\text{lim}} = (1-H')*R'$$

Projections were dependent on partial recruitment vectors particular for the river i.e. age structure, relative fecundity and mortality. A fully recruited age structure (i.e. all age classes expected are present and in the correct proportion) is assumed prior to initialisation of the model. Therefore, obtaining recruits for 7 years (the longest period required to obtain complete recruitment) initializes projections at the selected starting stock size before accumulating recruits for any trajectory. Error in trajectories was introduced by selecting a new value of *alpha* and *beta* for each year from the normal distribution of H' and the log normal distribution of R' reported. The reported stock recruitment scale was eggs*m^{-2}. Preliminary exploration of the models indicated the need for an egg density cap to constrain depositions in the stochastic trajectories. This was accomplished by constraining alpha to values less than 20.

Starting spawning stock sizes were 10% of S_{lim} and 50% of S_{lim}. Projections were run using exploitations of 0% (no exploitation), 50% of the current river exploitation, at the current exploitation rate and at H'. Forward simulations were run 10,000 times in an @Risk© framework in Excel© and the aggregated output collected to produce a trajectory with mean and variance for each year. The number of years required to rebuild to S_{lim} as well as the number of years during the 50 year projection below the S_{lim} were recorded for each simulation.

The alpha determinations ranged from a high of 14.93 for the Bush River, 2.13 for the North Esk and a low of 1.85 for the Nivelle (Table 2.5.1.1). Projections typically resulted in occasional highs and lows in a single trajectory however the 90% range of values generally followed the deterministic function (Figure 2.5.1.1). The years to recovery ranged from 1 to 50 years, the limit of the projections (Table 2.5.1.2; Figure 2.5.1.2).

The proportion of years with values lower than S_{lim} ranged from 0.13 to 1 depending mostly on alpha and exploitation. This proportion for populations at less than S_{lim} and at H' was 0.49 for the high alpha, which is the expectation for a productive population managed at H' and based on well-defined parameters (Table 2.5.1.3). However, at lower alpha the frequencies were much greater (0.97 and 1) indicating high sensitivity of S_{lim} to variance in the parameters at low alpha values.

The number of years to recovery was unobtainable in fifty-year projections in a low productivity and possibly unobtainable in a moderate productivity river. This was because the recovery time in years was more dependent on the value of alpha (productivity) than the start point. The time to recovery and the proportion of annual recruitment less than the S_{lim} increased with lower productivity and the starting point. Recovery was particularly sensitive to increasing exploitation at lower alpha.

The data and analysis indicate that there is an increased probability of not achieving S_{lim} with increased exploitation and lower alpha. The model did not incorporate demographic stocasticity i.e. uncertainty in sex ratio, fecundity etc. or environmental stocasticity i.e. annual variations in survival that could eliminate a year class at low populations, that can lead to extirpations. Therefore while this model may not be a reliable indicator of population viability, it can provide reasonable indications of management actions concerning S_{lim} and exploitation. The analysis suggests that increased caution needs to be taken when assigning exploitation to low productivity stocks. It also suggests that current management strategies for mixed stock fisheries are likely to fail to protect "the weakest link" i.e. those stocks that are far below their S_{lim} and of low productivity. Similarly, expected contributions to rebuilding from restocking programmes may also be confounded by prevailing low levels of marine survival, high or variable exploitation rates and even negative interactions between hatchery reared fish and their wild counterparts (McGinnity et al, 1998, Ferguson et al, 2002).

2.5.2 Atlantic salmon population viability analysis for Maine (USA) distinct population segment

A population viability analysis (PVA) model has been developed for Atlantic salmon in Maine. This model incorporates uncertainty in juvenile and adult survival rates, direct and indirect linkages among populations in different rivers, and a number of potential human removals or stocking in a flexible, modular Fortran program named SalmonPVA. The structure of the model is based on a state-space approach with a detailed life history cycle. Multiple cohorts in multiple rivers progress through their life history based on stage specific survival rates and fecundity with limits imposed by riverine habitat capacity. The model projects the populations forward in time, usually 100 years, numerous times with stochastic variables selected based on a Monte Carlo approach to calculate the probability of extinction. This model is being developed with input from scientists and policy makers from NOAA Fisheries, US Fish and Wildlife Service, Atlantic Salmon Commission, and the University of Maine. Results from this model will form the basis for delisting criteria in the Recovery Plan for the Maine Distinct Population Segment which was listed as Endangered in 1999.

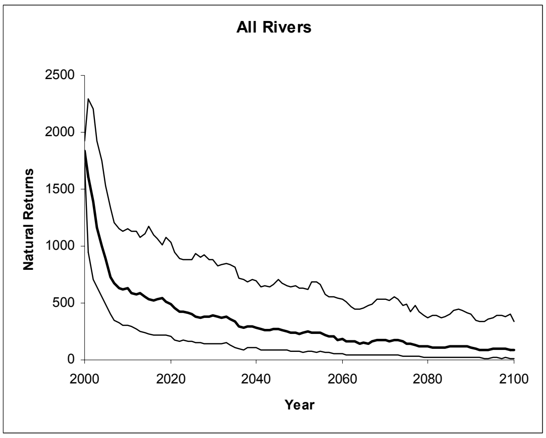
The SalmonPVA model is structured to represent Atlantic salmon life history characteristics in the US. For example, most fish spend two or three years in the river and two years at sea before returning to the river to spawn. However, there is the possibility to return from sea after one or three years and the model will soon be modified to allow five years in freshwater. Inputs to the model allow for a wide range of simulations. The number of rivers is a dynamic variable limited only by the computer running the program. The linkages among rivers are determined on input and allow for various straying hypotheses as well as linkages among juvenile survival rates due to year effects. The habitat capacity limits will soon be expanded to all juvenile life stages. This, combined with the approach used for fecundity, will produce a Beverton and Holt type spawner-recruitment relationship. This will underestimate the probability of extinction when populations are large relative to a Ricker type spawner-recruitment relationship. The populations are currently so low that this concern is minimized. A number of human removals from the populations are allowed, but not required, by the model including interception fisheries at sea, river fishing, and broodstock removals of either returning adults or parr. Stocking of any life stage during any year of the simulation is possible. These stocked fish are followed in a separate matrix in the program from the natural fish to allow for different survival rates or removals. The offspring from the hatchery matrix are added to the natural matrix so that hatchery populations disappear if stocking is discontinued. The model allows direct examination of specific simulations as well as summarizes results from the total number of simulations conducted. The probability of extinction is the most important output, but trends in adult returns can also be enlightening, especially when trends are detected. This is because a five percent chance of extinction in one hundred years has different implications if the overall trend for the population is increasing or decreasing over the projected time series.

The SalmonPVA model was run using example ranges of survival rates for all life stages under conditions of no stocking and initial population sizes set at the conservation spawning escapement levels (CSE) for the eight rivers in the Maine DPS. Assumptions were made regarding straying, fishing, broodstock removal, etc. to demonstrate the bottom line predictive power of the model. Projecting the populations for 100 years for 10,000 iterations produced a low probability (0.2%) of all eight rivers going extinct, with high probabilities (45-84%) of individual rivers becoming extinct (see text table below).

Probability of extinction when all rivers seeded with CSE levels of 2SW returns, no stocking occurs, and example ranges of survival by life stage are assumed.

Rivers : DE=Dennys, EM=East Machias, MC=Machias, PL=Pleasant, NG=Narraguagus, CB=Cove Brook, DT=Ducktrap, SHP=Sheepscot

River	Probability
DE	**18.2**
EM	**12.2**
MC	**6.1**
PL	**27.9**
NG	**6.7**
CB	**83.7**
DT	**44.7**
SHP	**18.3**
ALL	**0.2**



Although the probability of extinction for all eight rivers combined is low, examination of the time trend during the 100 year projection shows that the combined returns are continuing to decline and may go extinct if more years were projected (see panel above).

2.5.3 Baltic Salmon Action Plan

The Baltic Salmon Action Plan (SAP), launched by the International Baltic Sea Fishery Commission (IBSFC) in 1997, aims to prevent extinction of wild salmon populations, to increase the natural smolt production of wild Baltic salmon to a level of 50% of the estimated potential capacity in each salmon river selected for the programme by 2010, and to re-establish wild populations in potential salmon rivers (Ranke 2002, www.ibsfc.org). A central element of the SAP was the reduction of the annual TAC in accordance with the SAP objectives, from the level of 760 000 salmon in early 1990's to a range of 510-540,000 salmon since 1997. Other measures taken to reach the SAP targets include stocking programmes, freshwater habitat restoration and national fishery regulations.

Some national restrictions of fishing effort in the Gulf of Bothnia have been launched in both Sweden and Finland, but the most significant development has been since Finland introduced the new temporal regulations for the Gulf of Bothnia coastal trap net fishery in 1996. After this the wild salmon stocks of many of the northern wild salmon rivers in Sweden and Finland have improved substantially (Romakkaniemi et al. 2003). In a recent EU Study project, the effects of fishing mortality on the returning salmon were modelled and it was shown to have reduced substantially after the coastal fishery regulations were introduced (Anon. 2002). As an example, the salmon catch in the River Tornionjoki, a border river between Finland and Sweden, increased three-to fivefold in 1996-1997 compared to the levels of the early 1990's. As well as the increased catches, the juvenile salmon (0+) densities also showed a marked increase as the mean density in 1998 was 30-fold higher than in early 1990's. Wild smolt production (Ranke 2002), has also increased substantially, and the estimated smolt run in e.g. Rivers Tornionjoki and Simojoki (Finland) have exceeded the 50% SAP reference level during the past three years (2000-2002; Figure 2.5.3.1). The increase in the wild smolt production was thus detectable after only four years following the corresponding management actions taken. It should be emphasised that this fast recovery (Figure 2.5.3.1) was possible when the reduction in fishing mortality coincided with the return of the fish from the strong brood-year class of 1990 (Ranke 2002, Romakkaniemi et al. 2003).

The positive development in the Baltic salmon stocks has, however, been most pronounced in large, wild salmon rivers in the northern Gulf of Bothnia. Many potential salmon rivers in the Gulf of Bothnia have shown little or no signs of recovery. The status of many potential rivers prior to the SAP was very different from the wild salmon rivers, as the stocks were completely extinct and stock rebuilding started from introducing salmon from nearby stocks. The slow development in these rivers compared to that of the wild rivers can be attributed to several factors, ranging from genetic adaptation of the introduced stocks to smaller scale local problems in freshwater environment and fishery management (Erkinaro et al. 2003).

Direct extrapolation of the results from the Baltic SAP to Atlantic salmon situations would require more in-depth comparison of the underlying dynamics (i.e. mortality rates, exploitation rates and productivity) which may be very different. Despite this, it is clear that stock rebuilding is feasible and significant increases in wild stocks can be achieved over a short time frame provided the initial productivity is sufficiently high. Rebuilding from low productivity or even restoring extinct stocks appears to pose similar difficulties in both the Baltic and Atlantic areas. In this regard, the theoretical approaches presented in the previous two sections result in predictions which are consistent with the actual outcome from an ongoing stock rebuilding programme and illustrate the difficulties in rebuilding salmon stocks when stock levels fall below $S_{lim.}$ The Working Group therefore notes that in the provision of advice S_{lim} (MSY) point is the most appropriate limit reference for Atlantic salmon populations.

2.6 Distribution, behaviour and migration of farmed salmon

2.6.1 Movements and distribution

Salmon escape from fish farms at all life stages, to both fresh and salt water. They are caught in ocean fisheries, and should they mature will move to freshwater to spawn (e.g. Hansen et al. 1987; Gausen & Moen 1991; Webb and Youngson, 1992; Youngson et al. 1997; Crozier 1998; Carr et al. 1998; Whoriskey & Carr 2001).

Farmed salmon are taken in large numbers in Norwegian coastal commercial salmon fisheries (about 24% of total nominal catch in 2002). Their proportion is lower in fjord and freshwater catches, but increases in spawning populations. Tagging experiments have shown that farmed salmon from Norway are caught in the Faroes' fisheries (Hansen et al. 1987). The abundance of farmed salmon in oceanic areas at Faroes is high (Hansen et al. 1999). Farmed fish have been captured at much lower frequencies in fisheries in Scotland, Ireland and Northern Ireland, despite the presence of extensive salmon farm production in these regions (ICES CM 2001/ACFM:15). This may be due to differences compared to Norway in the siting of salmon farms in relation to the salmon rivers and fisheries, or it may be due to different dispersal patterns of the farmed fish after they escape.

Wild salmon smolts leave their home rivers in the spring and move quickly into oceanic areas. In the north east Atlantic zone, smolt tagging experiments and post-smolt surveys have strongly indicated that ocean currents are the vectors that force the fish northwards (Holm et al. 2000). Salmon smolts imprint, or learn cues sequentially on their way from the river to the sea, and use that information for homing on the return migration. The homeward migration may be divided in two phases, an oceanic phase with fast movement from the ocean to coastal areas, and a slower migration from coastal areas to the natal river (Hansen et al. 1993). Migration patterns of hatchery-reared salmon released as smolts in freshwater are similar to those of wild salmon. Hatchery smolts released on the coast also tend to return to the area where they were released, but apparently enter any river to spawn (e.g. Carlin 1969; Sutterlin et al. 1982). Hansen & Jacobsen (2000) who captured, tagged and then released wild and farmed salmon in the Northeast Atlantic Ocean north of the Faroes, got 18 recoveries from Norway and one from the west coast of Sweden. These authors speculated that the farmed fish may have escaped from Norwegian cages. The speculation was based on the assumption that farmed salmon return when sexually mature to the areas from where they escaped, and the fact that Norway as the most significant producer of farmed salmon in the Atlantic should contribute many of the escaped farmed salmon observed in that area.

Results from an experiment that released large salmon from two farms on the south and mid- Norwegian coast showed that salmon escaping in the autumn had lower survival rates than fish released in the winter/early spring ((ICES CM 2001/ACFM:15; Hansen 2002). The released fish were recaptured in the sea, as well as in freshwater north of their experimental "escape" point. Some of the fish from the southern farm moved to the southeast and entered freshwater in this area. The movements could be explained by the direction and strength of ocean currents. Assuming that fish entering freshwater had made their final decision on where to spawn, it could be concluded that these farmed salmon were not imprinted to any particular river or marine site, and could therefore be regarded as "homeless". This contradicts Hansen and Jacobsen's (2000) speculation that farmed homed to the area from which they escaped.

Ocean movements of the farmed salmon could be controlled by prevailing currents ((ICES CM 2001/ACFM:15; Hansen 2002). This may explain why so few of the fish released in the autumn in the previously described experiment were ever recovered. These fish could have been transported with the currents so far north that when they attained sexual maturity, they either were too far off route to find a river for spawning, or were simply lost in the cold Artic water. Fish that escape later in the year (closer to maturation) could have a higher probability of entering freshwater to spawn than early escapees, but the low recovery rates (less than 6%) of experimentally late released fish (Hansen 2002) suggest that significant numbers of them are also lost.

Based on the above, the following hypothesis is proposed: Farmed salmon escaping from cages in different countries are displaced with the currents, and any fish that become sexually mature when they are relatively close to the coast enter local fisheries and rivers. The signification of this is that escaped farmed salmon may spread into fisheries and rivers far away from where they escaped.

2.6.2 Methodology to improve knowledge on the distribution and movements of escaped farmed salmon

Farmed salmon that have escaped from sea cages can easily be identified in fisheries and stocks, but it is more difficult to detect fish that escaped as parr or smolt. Sampling and examination of salmon in marine areas at different times of the year, especially in areas that have not been sampled before, would improve the general knowledge of the spatial and temporal distribution of farmed salmon.

At present it is difficult to determine from which country or area farmed fish caught in the ocean originated from. To approach this problem, it would be feasible to tag farmed fish, conduct experimental "escapes", and determine the ultimate fate of the fish. Recoveries could come from existing fisheries, and planned scientific sampling programmes. A number of different tags and tagging procedures could be used, including:

1. External tags (Carlin, Lea, Floy, etc.)
2. Visible implant tags (including visual implant elastomers)
3. Coded wire tags (CWT)
4. Passive Integrated Transponder (PIT) tags
5. Sonic tags
6. Data storage tags (DST)
7. Genetic tags
8. Physiological tags (otholith marking, trace elements in bones and otoliths, fatty acids, etc.)

External tags can be reliably detected in fisheries and scientific sampling programmes. Visible implant tags can be recovered in sampling programmes, but may be difficult to detect for fishermen.

CWT tags are cheap, easy and quick to apply, and suitable for large numbers of fish. They can be easily detected providing an additional external mark is applied, but the removal of CWTs is time consuming. They are usually detected in scientific sampling programmes. In Iceland a mandatory 10 % of the farmed salmon released to coastal net pens are required to be CWT tagged.

PIT tags are easy to implant and detect, but have to be recovered in sampling programmes.

Sonic tags can be used to examine the behaviour of escaped farmed salmon following their escape providing the fish remain within receiver detection range. Fish can be actively tracked, or detected at fixed locations where receivers are moored, however detection ranges may be short (500m). Acoustic tags and equipment are very expensive, which limits the number of fish that can be marked and released.

Data storage tags are new technologies, and are still expensive. However, information on the behaviour (postion, environmental conditions, movements) of the recovered fish will be significant. Tagged fish can be recovered in sampling programmes or by fishermen.

Genetic and physiological tagging are new methods that can be used for mass marking. However, ”tagged” individuals have to be recovered in sampling programmes, and the marks are expensive to identify.

2.6.3 Experimental tagging programme for investigating the behaviour of escaped farmed salmon

To test the hypotheses that salmon escaping from fish farms in the Northeast Atlantic are homeless, transported with the currents, enter fisheries and rivers in other countries than the one they escaped from, or are lost in the Arctic, several tagging programmes using different tag types could be developed. Below a simple programme using individually numbered external tags that can be recovered both from fishermen and in sampling programmes is outlined, including a pilot project to be expanded to a main project. The programme is expected to give information on migration, distribution, survival and growth of escaped farmed salmon.

1. Pilot project

This should be carried out to compare migration and distribution of one single group (500-1000) of farmed salmon released in each of the countries producing farmed salmon (i.e. Ireland, Scotland, Faroes, Iceland and Norway). To maximise the probability for recaptures ((ICES CM 2001/ACFM:15; Hansen 2002) the farmed salmon to be released should be expected to be sexually mature the following autumn and should preferably be released in March/April. External tags of the same origin and type should be used, and the releases should be co-ordinated in time. The recovery information should be used for developing a detailed design of the main project.

2. Main project

Groups of externally tagged farmed salmon should be released sequentially over the year (e.g. monthly, bimonthly etc), or over periods when escapes from salmon farms are known to occur, usually during the winter. The fish should be released in the same countries as suggested above, and the numbers of tagged fish in each group should be optimised based on results from the pilot project. The releases should be coordinated and the same types of tags should be applied. This exercise is expected to give information on variation in migration, distribution, survival and growth of salmon escaping from fish farms at different times of the year.

Given the large numbers of farmed salmon escaping from cages in the Northeast Atlantic, the number of farmed salmon released for the purpose of this experiment will only be a small fraction of the total number of escaping salmon.

2.6.4 Sonic tracking of escapees in Maine (USA)

An experimental release of farmed salmon fitted with acoustic tags is planned to start in the Cobscook Bay region of Maine in autumn, 2003. This region produces the majority of the USA’s east coast farmed Atlantic salmon, and adjoins Canada’s Bay of Fundy region where the Canadian east coast industry is concentrated. The goals of the study are to:

- Document the residency time of “escaped” fish in the vicinity of the cages following the release.
- Track the directions and rates of any movements that the fish exhibit, and correlate them with tidal currents and other environmental cues.
- Based on histories of detection of the tagged fish on the receiver grid, attempt to determine their survival time at sea.
- Maintain a cross border detection grid in order to document the degree to which escapees stray between US and Canadian waters.
- Determine if the fish tend to move to particular rivers in the region at spawning time, presuming they survive for this long.

The project will provide short to medium term information about rates of dispersal of farmed fish, post-escape. Results should help with the development of recapture strategies, or if the program shows that the fish in this region are not likely to be recaptured, it will refocus efforts and scarce resources on ensuring containment.

2.7 Compilation of Tag Releases and Finclip Data by ICES Member Countries in 2002

2.7.1 Compilation of tag releases and finclip data for 2002

Data on releases of tagged, fin-clipped, and marked salmon in 2002 were provided by the Working Group and are compiled as a separate report. A summary of Atlantic salmon marked in 2002 is given in Table 2.7.1.1. About 4.1 million salmon were marked in 2002, an increase from the 3.88 million fish marked in 2001. Primary marks are summarized in three classes: microtag (i.e., coded wire tag), external tag/mark, and adipose clips (without other external marks or fin clips). Tagging with data storage tags (DSTs) is not presently recorded on the database, but the Working Group will include these tags from 2004. Secondary marks, primarily adipose clips on fish with coded wire tags, are also presented in the Annex. The adipose clip was the most used primary mark (3.1 million), with microtags (0.68 million) the next most used primary mark. Most marks were applied to hatchery-origin juveniles (4.0 million), while 64,445 wild juveniles and 13,843 adults were marked. The Working Group noted that a number of commercial fish farms are applying tags to fish placed in sea cages in some countries and hence these might appear in fisheries if escapes occurred. The Working Group recommended that state agencies should provide information on tag codes applied in these instances and this should be included in the tag compilation.

Table 2.1.1.1 Nominal catch of SALMON by country (in tonnes round fresh weight of fish caught and retained), 1960-2002. (2002 figures include provisional data).

Key:

1. Includes estimates of some local sales, and, prior to 1984, by-catch.
2. Before 1966, sea trout and sea charr included (5% of total).
3. Figures from 1991 to 2000 do not include catches taken in the recently developed recreational (rod) fishery.
4. From 1994, includes increased reporting of rod catches.
5. Catch on River Foyle allocated 50% Ireland and 50% N. Ireland.
6. Not including angling catch (mainly 1SW).
7. Weights prior to 1990 are estimated from 1994 mean weight. Weights from 1990 to 1999 based on mean weight for R. Asturias.
8. Between 1991 & 1999, there was only a research fishery at Faroes. In 1997 & 1999 no fishery took place, the commercial fishery resumed in 2000, but has not operated in 2001 or 2002.
9. Includes catches made in the West Greenland area by Norway, Faroes, Sweden and Denmark in 1965-1975.
10. Includes catches in Norwegian Sea by vessels from Denmark, Sweden, Germany, Norway and Finland.
11. Estimates refer to season ending in given year.

Table 2.1.1.2 Nominal catch of SALMON in homewaters by country (in tonnes round fresh weight), 1960-2002. (2002 figures include provisional data).
S = Salmon (2SW or MSW fish). G = Grilse (1SW fish). Sm = small. Lg = large; for definitions, see Section 4.1. T = S + G or Lg + Sm

1. Includes estimates of some local sales, and, prior to 1984, by-catch.
2. Before 1966, sea trout and sea charr included (5% of total).
3. Figures from 1991 to 2000 do not include catches of the recently developed recreational (rod) fishery.
4. Catch on River Foyle allocated 50% Ireland and 50% N. Ireland.
5. From 1994, includes increased reporting of rod catches.
6. Not including angling catch (mainly 1SW).
7. Weights up to 1990 estimated from 1994 mean weight. Weights from 1990-99 based on mean wt. from R. Asturias.

1. MSW includes all sea ages >1, when this cannot be broken down.
Different methods are used to separate 1SW and MSW salmon in different countries:
- Scale reading: Faroe Islands, Finland (1996 onwards), France, Russia, USA and West Greenland.
- Size (split weight/length): Canada (2.7 kg for nets; 63cm for rods), Finland up until 1995 (3 kg),
Iceland (various splits used at different times and places), Norway (3 kg), UK Scotland (3 kg in some places and 3.7 kg in others),
All countries except Scotland report no problems with using weight to catergorise catches into sea age classes; mis-classification may be very high in some years.
In Norway, catches shown as 3SW refer to salmon of 3SW or greater.
2. Based on catches in Asturias (80-90% of total catch).

[1] An illegal net fishery operated from 1995 to 1998, catch unknown in the first 3 years but thought to be increasing. Fishery ceased in 1999. 2001/2 catches from the illegal coastal net fishery in Lower Normandy are unknown.

[2] No nominal catch data is collected for river (rod) fisheries in UK (NI)

[3] Data not available from Denmark

[4] Includes St Pierre et Miquelon.

[5] Estuarine catch included in coastal catch.

Table 2.1.2.1 Numbers of fish caught and released in rod fisheries along with the % of the total rod catch (released + retained) for countries in the North Atlantic where records are available, 1991-2002. Figures for 2002 are provisional.

Notes: Data for 2002 are provisional for many countries.
Where production figures were not available for 2002, values for 2001 were used (Norway, UK (N.Ireland), Canada).
West Coast USA = Washington State
West Coast Canada = British Columbia
Australia = Tasmania
Source of production figures for non-Atlantic areas: miscellaneous fishing publications & Government reports.
'Other' includes South Korea & China.

Table 2.3.1.2. Differences in estimates of monthly mortality rate in the second year derived from returns to the coast relative to those derived from returns to the hatchery in-river (excluding harvests in marine fisheries). The differences in mortality rate represent the exploitation rate in the fishery.

Group	Smolt Year	Mortality rate (A%) returns in-river	returns to coast
Ordinary MSW	1998	4.6%	3.3%
All Female MSW	1998	4.1%	2.7%
Ordinary MSW	1999	4.6%	3.8%
All Female MSW	1999	4.5%	4.0%
Grilse line	1997	4.0%	2.4%
Grilse line	1995	4.5%	2.7%
All Female Grilse line	1995	4.6%	3.1%
Grilse line	1996	4.9%	3.1%
All Female Grilse line	1996	4.4%	2.8%

Table 2.4.1. Results of Spearman's rank correlations, and their associated significance levels, testing for associations between various abundance, exploitation and catch parameters with time for four age/seasonal components of the returning stock.

	Early 1SW	Late 1SW	Early MSW	Late MSW
Lower river abundance	r = 0.329 p = ns	r = 0.109 p = ns	r = -0.136 p = ns	r = -0.268 p = ns
Lower river exploitation	r = -0.455 p < 0.05	r = -0.118 p = ns	r = -0.862 p < 0.01	r = -0.501 p < 0.05
Lower river catch	r = -0.252 p = ns	r = -0.051 p = ns	r = -0.842 p < 0.01	r = -0.604 p < 0.01
Upper river abundance	r = 0.478 p < 0.05	r = 0.160 p = ns	r = 0.508 p < 0.02	r = 0.010 p = ns
Upper river exploitation	r = 0.010 p = ns	r = 0.040 p = ns	r = -0.401 p = ns	r = 0.249 p = ns
Upper river catch	r = 0.244 p = ns	r = 0.056 p = ns	r = 0.059 p = ns	r = 0.239 p = ns
Potential spawners	r = 0.478 p < 0.05	r = 0.126 p = ns	r = 0.517 p < 0.02	r = -0.147 p = ns

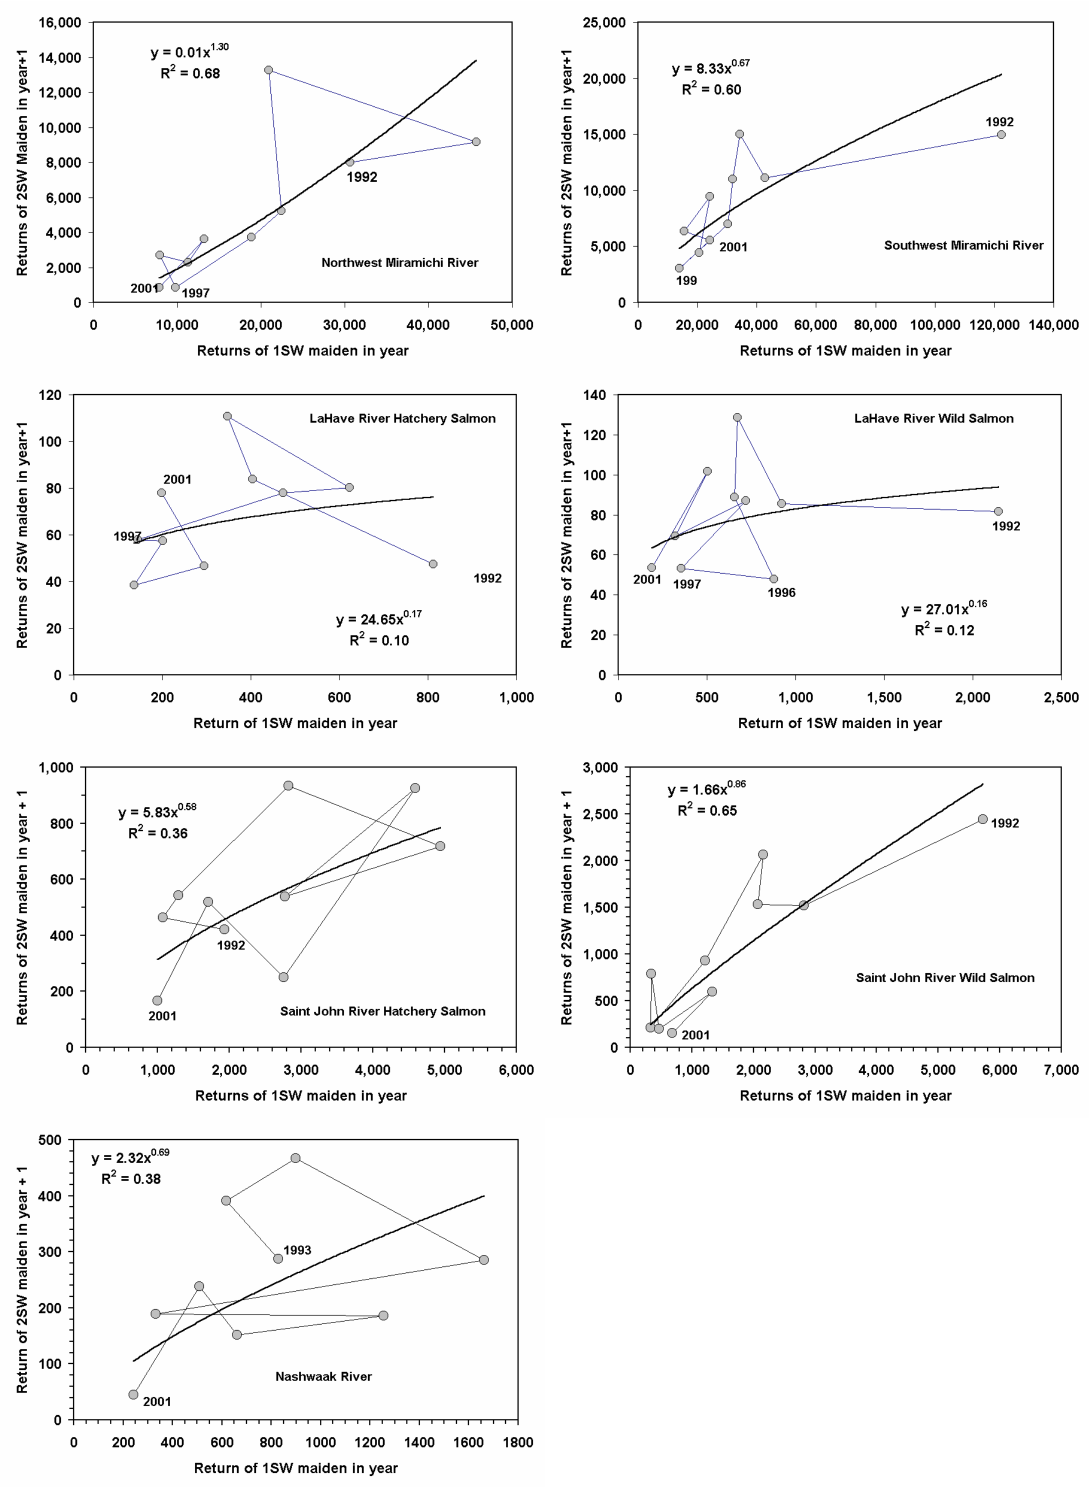

Figure 2.4.3.9. Linear association between residuals from the 1SW/2SW association and harvest of 1SW salmon at Greenland for Southwest Miramichi (upper left panel) and relative error [(obs. – pred.) / obs.] of predicted 2SW return when Greenland harvest of North American 1SW salmon is excluded or included in the 1SW/2SW association for the Southwest Miramichi (upper right panel), LaHave River wild salmon (lower left panel) and Saint John wild salmon (lower right panel).

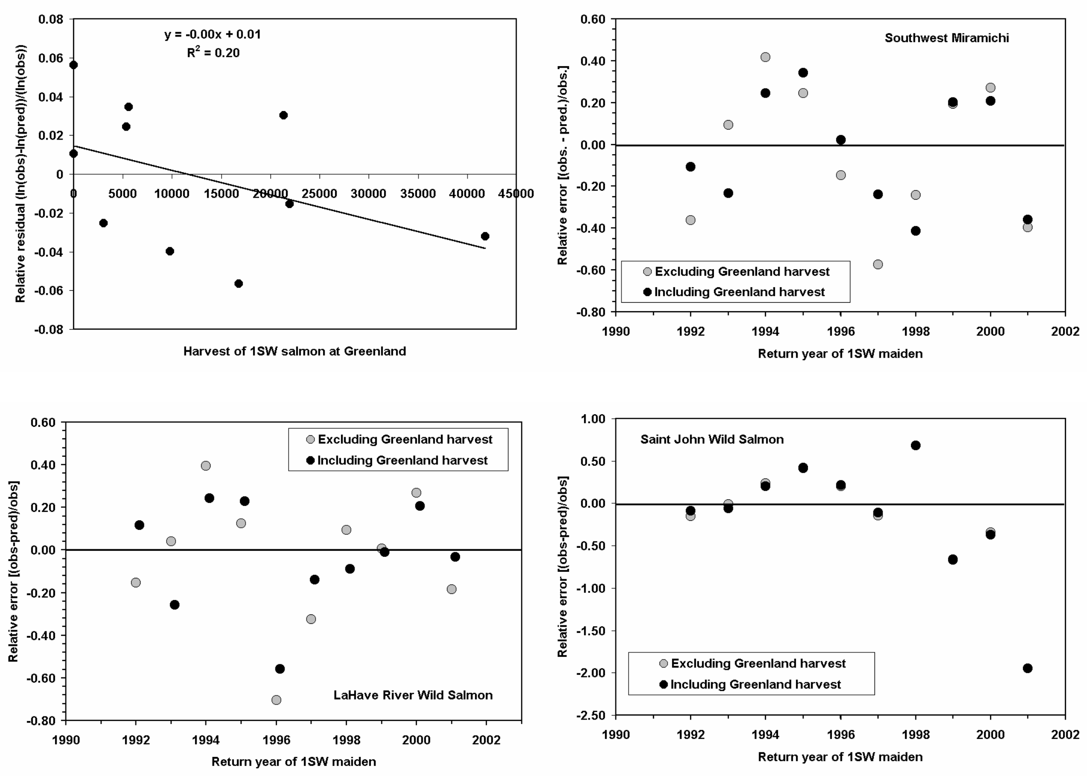

Figure 2.4.4.1. Postitions and numbers of large post-smolts and salmon captured in surface trawl hauls for DST tagging in a Nordic project. During the Norwegian survey, 21 June – 5 July 2002 west of the Vøring plateau, in addition to a few salmon large numbers of post-smolts were caught. These were too small for tagging. Hence, in that area, the stars (see legend in figure) may mark both "no salmon" and small post-smolts. Late autumn/ early winter the post-smolts captured north of the Faroes and east of Iceland were mostly sufficiently large to be tagged. The sites of release and recapture of one salmon, and its possible migration path are marked with open circles and dashed line. The boundaries of the various EEZs are marked with dotted lines.

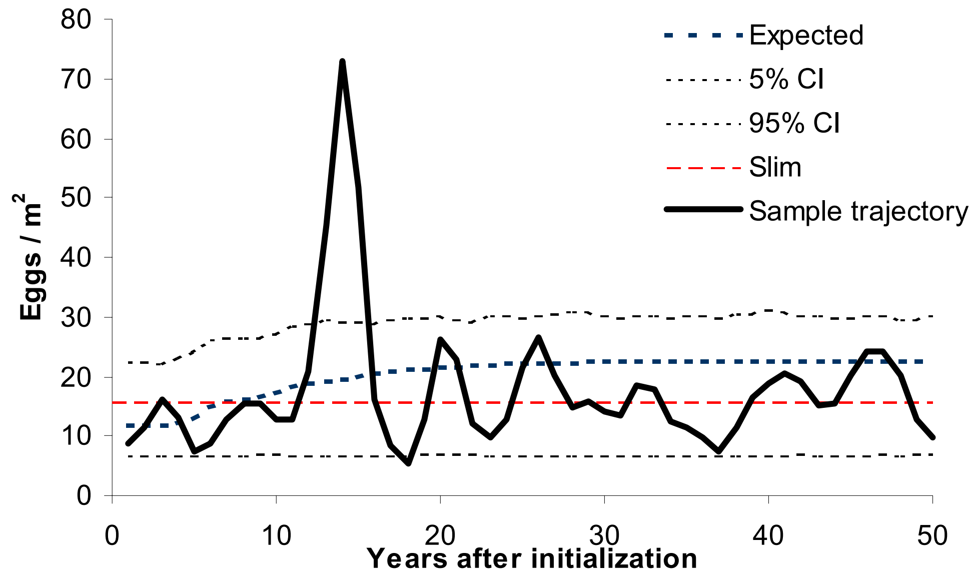

Figure 2.5.1.2. Number of years to attain S_{lim} in 50 years for High (14.93), Medium (2.13) and Low (1.85) alpha values in a Ricker stock and recruitment function over 10,000 simulations with uncertain parameters.

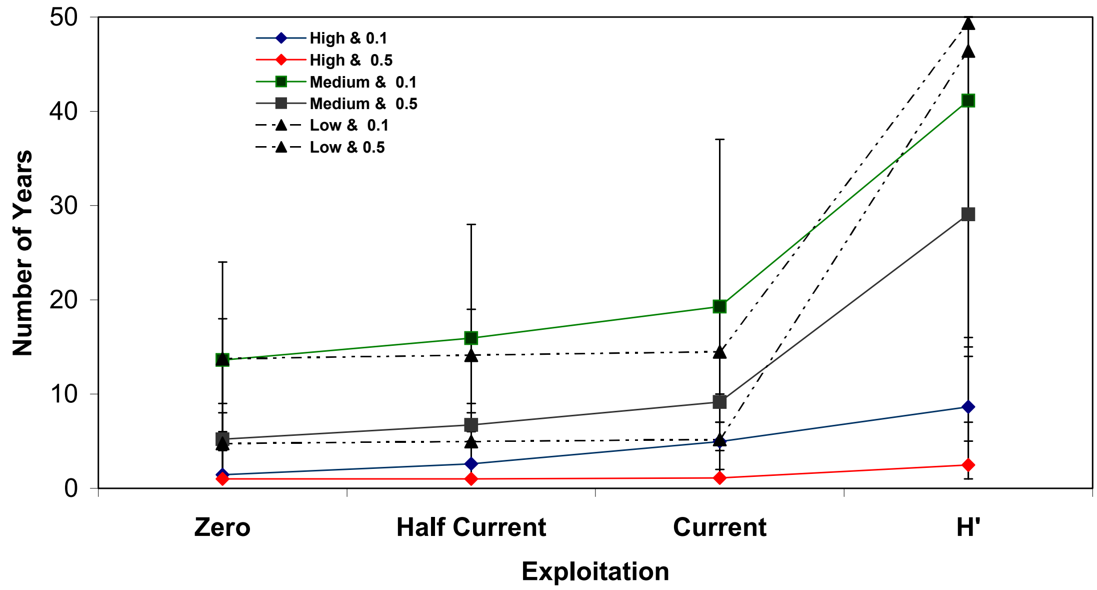

Figure 2.5.3.1. Estimated wild smolt run of the Rivers Tornionjoki (upper panel) and Simojoki (lower panel) in the northernmost Baltic Sea Region (Gulf of Bothnia). The error bar is presented as an example of the 95% confidence limits of the estimates. The probabilistic estimation methods used are presented in Mäntyniemi & Romakkaniemi (2002).

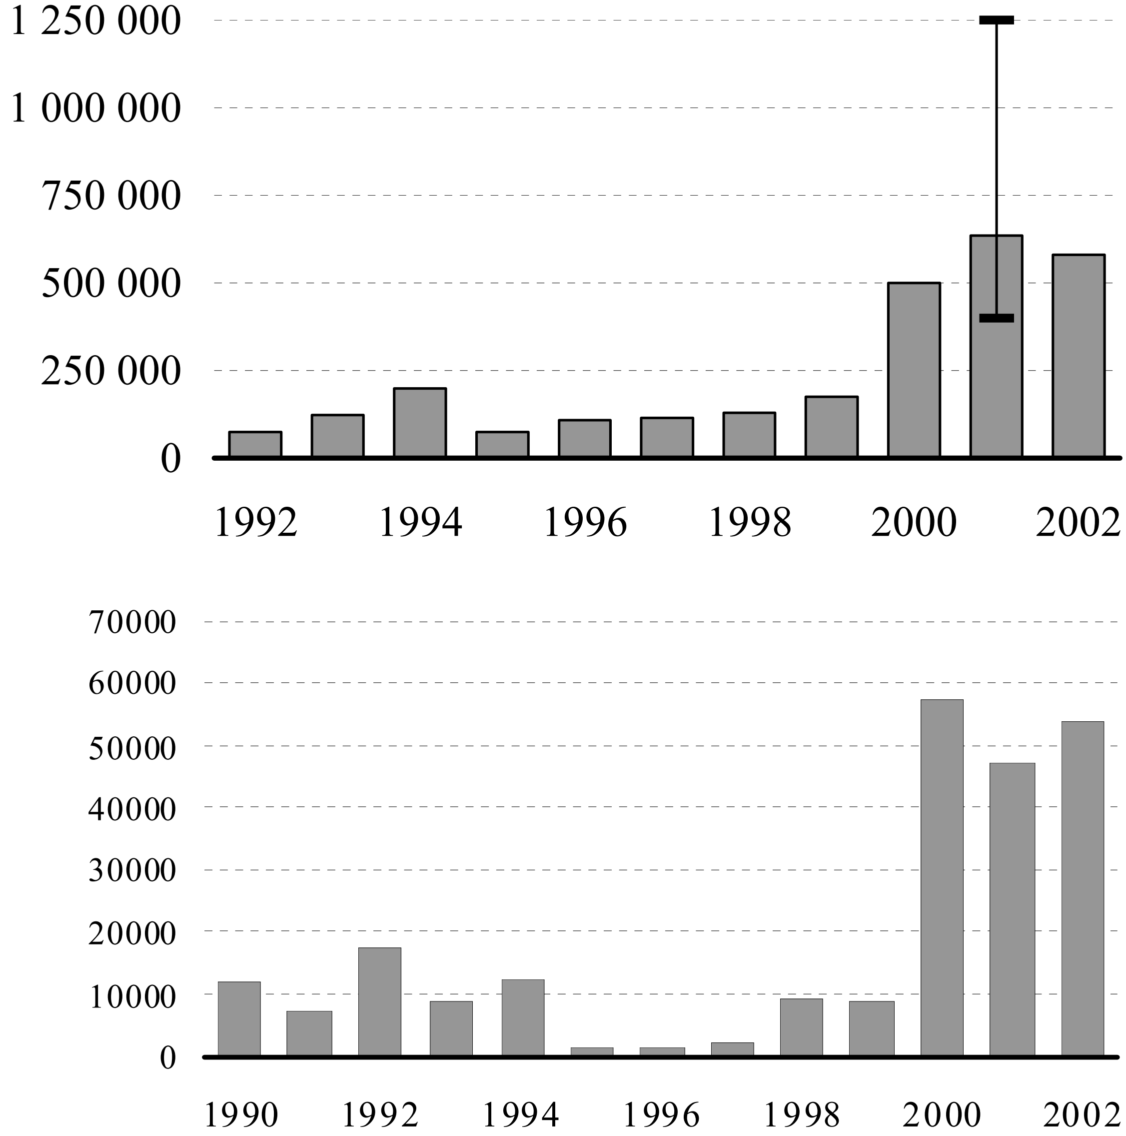

3 FISHERIES AND STOCKS IN THE NORTH-EAST ATLANTIC COMMISSION AREA

3.1 Fishing at Faroes in 2001/2002

No fishery for salmon was carried out in 2001/2002 or, to date, in 2002/2003. Consequently, no sample data is available from the Faroese area for this season. No buyout arrangement has been arranged since 1999. Although no research fishery was carried out some biological information is available from a DST tagging programme as detailed in section 2.4.4.

3.2 Homewater fisheries in the NEAC area

3.2.1 Significant events in NEAC homewater fisheries in 2002

Measures in Russia led to a considerable reduction in unreported catch and exploitation rate in some areas (see section 3.2.2). Gill nets that had been used for commercial in-river fisheries, in the Archangel Region of Russia, were prohibited in 2002. The only permitted gears remaining are those designed to trap salmon. For example, this measure led to a considerable reduction in unreported catch in the fishery conducted in the downstream section of the Severnaya Dvina River.

In Iceland, the Institute for Freshwater Fisheries, The Federation of River Owners and Association of Icelandic Angling Clubs formed a coalition to spare 2SW salmon by all means. This was done by voluntary catch and release of caught 2SW salmon and by various restrictions on fishing. The 2SW salmon in Icelandic salmon rivers have been declining in numbers and catch since 1985 and are currently at low numbers in many rivers. No such decline is evident for the 1SW salmon.

Sweden introduced new fishing regulations in 2002 by establishing fifteen new protected areas outside small sea trout rivers. In addition a number of existing protected areas outside individual salmon rivers were merged into larger units. For some of these larger protected areas, greater responsibility was given to county administrations to manage fisheries. Towards the end of year 2002 decisions were taken to have the salmon fishery in rivers closed in the period from 1 October to 31 March (previously 1 October- end of February). This regulation has been implemented from 1 January 2003.

In Ireland all fishermen (commercial and rod) are now obliged to tag their catch with locking coded strap tags (carcass tags) indicating the region, year and method of capture and to record details of the catch in a logbook. These logbooks must be returned to the Central and Regional Fisheries Boards who collate the information and report the catch statistics. In 2002, a TAC of 219,619 fish was imposed on the commercial fishery as a method of limiting catches and it is now illegal to sell rod caught fish.

A carcass tagging and logbook scheme for all salmon fishing was introduced into both fishery areas of UK (N. Ireland) for the first time during 2001, and had its first full year of operation in 2002. In the Fisheries Conservancy Board (FCB) area significant management changes came into effect in 2002, aimed at conservation of wild salmon stocks. For the 2001 season there was a voluntary agreement with licensed net operators that no net shall fish until the 1st June (season was previously 17th March to 15th September), with around 8 nets agreeing not to fish at all. Holders of drift net licenses agreed to operate for only eight weeks during the period 1 June to 15 September, broken down into two four-week periods. These voluntary agreements preceded a public:private sponsored voluntary buyout, which came into effect for the 2002 season, with funds being made available to purchase netting rights from a significant proportion of operators in the FCB area. Accompanying measures to regulate angling, introduced into the FCB area on a voluntary code-of-practice basis in 2001, operated again in 2002, pending introduction of appropriate bylaws.

In UK (Scotland) a ban on the sale of rod caught salmon came into effect on the 1st of October 2002.

A number of measures aimed at reducing exploitation were implemented or strengthened in UK (England & Wales) in 2002. A number of net fisheries are being (or have been) phased out because they exploit migratory salmonids returning to several rivers (i.e. mixed stock fisheries). A further phase out was introduced in 2002 for one fishery in South West England, as a result of a new net limitation order. This will reduce the number of nets permitted to zero; a byelaw was also introduced for this fishery to limit the fishing season to June and July only. Arrangements were also made to reduce netting effort in a number of other fisheries by compensating netsmen not to fish for particular periods.

3.2.2 Gear

Gill nets that had been used for commercial in-river fisheries, in the Archangel Region of Russia, were prohibited in 2002. The only permitted gears remaining are those designed to trap salmon. No changes in the type of gear used were reported by other countries

3.2.3 Effort

The number of gear units licensed or authorised in several of the NEAC area countries provides a partial measure of effort, but does not take into account other restrictions, for example, closed seasons (Table 3.2.3.1). In addition, there is no indication from these data of the actual number or licences utilised of the time each licence fished.

Trends in effort are shown in Figures 3.2.3.1 and 3.2.3.2 for the Northern and Southern NEAC countries respectively. In the Northern NEAC area, drift net effort in Norway accounted for the majority of the effort expended, in the early part of the time-series. However, this fishery closed in 1989, reducing the overall effort substantially. The liftnet fishery, which made a minor contribution to overall effort, showed a decreasing trend until it ceased to operate in 1993. The two remaining methods, bagnets and bendnets, show contrasting patterns of effort until the early 1990s when both show downward trends until the end of the time-series. In the Archangel region of Russia, the effort in the coastal fisheries in 2002 remained at the 5-year average while effort in in-river fisheries shows a decline and is at the lowest number for the period reported. In the Southern NEAC countries, net effort data show a downward trend of various degrees for UK (England & Wales), UK (N. Ireland), Ireland, France and UK (Scotland).

Rod effort, where available, show both upward and downward trends for the period reported. In the Northern NEAC area the catch and release rod fishery in Russia and the rod fishery in Finland showed an increase in 2002 from the previous year and were at the highest level for the period reported. In the Southen NEAC area rod fishing effort show decreasing trend in UK (England & Wales) over the period presented. In Ireland rod fishing effort has shown increase for the past 11 years.

3.2.4 Catches

NEAC area catches are presented in Table 3.2.4.1. The total catch in the NEAC area was 2,464 tonnes**,** down 14% on the 2001 catch, but representing 94% of the total North Atlantic nominal catch in 2002. Both Southern and Northern areas reported catches significantly below those in 2001. However catches for the Southern region were below the 5-year mean (by 1%) but catches were 7% above the 5-year mean in the Northern region.

Figure 3.2.4.1 shows the trends of nominal catches of salmon in the Southern and Northern NEAC areas, from 1971 until 2002. Catches in Southern countries were near to 4,500 t in 1972-1975 but in the latter part of the time series, average catches were between 1,000 and 1,500 t. The overall pattern is characterised by two steep declines, one in 1976 and the other over the years 1987-1991. Catches in Northern countries varied from 1,850 to 2,700 t from 1971 to 1986 and have undergone a slower decline since then to levels of 1,000 to 1,600 t during the 1995-2001 period. Thus, catches in the Southern countries, which were predominant in the NEAC area before 1990, are now slightly lower than those reported in the Northern countries.

3.2.5 Catch per unit effort (CPUE)

CPUE is a measure that can be influenced by various factors, and it is assumed that the CPUE of net fisheries is a more stable indicator of the general status of salmon stocks than rod CPUE; the latter may be more affected by varying local factors, e.g. weather conditions, management measures, angler experience and the degree to which catch and release is practised. Both may also be affected by many measures taken to reduce fishing effort, for example, changes in regulations affecting gear. If large changes occur for one or more factors a common pattern may not be evident over larger areas. It is, however, expected that for a relatively stable effort CPUE can reflect changes in the status of stocks and stock size.

An overview of the CPUE data for the NEAC area is presented in Figure 3.2.5.1. The CPUE values presented are standardized indices relative to the averages of the time series. The original, more detailed CPUE data are presented in Tables 3.2.5.1 - 3.2.5.5. The CPUE for rod fisheries have been collected by relating the catch to rod days or angler season, and that of net fisheries was calculated as catch per licence-day, trap-month or crew-month.

In the Southern NEAC area, CPUE shows a general increase in UK (N-Ireland) net fisheries, a decrease in UK(Scotland) net fisheries, whereas no trend was observed in UK(England & Wales) net fisheries and in French rod fisheries (Figure 3.2.5.1). In UK (England & Wales) CPUE for the net fishery decreased in most regions compared to 2001 and the previous 5-year averages (Table 3.2.5.3). The CPUE for the Scottish fixed engine fisheries were lower, whereas that of the net and coble fisheries was higher than in 2001 and the previous 5-year averages (Table 3.2.5.4). In UK (N-Ireland), the river Bush rod fishery CPUE showed a clear decrease compared to recent indices (Table 3.2.5.1).

In most of the Northern NEAC area, there has been an increasing trend in the CPUE figures for various fisheries, especially in recent years in Norway (net) and Finland (rod) (Figure 3.2.5.1). However, the figures for 2002 in Norway and Finland generally decreased from the previous year and were below the previous 5-year average (Tables 3.2.5.1 & 3.2.5.5). In comparison with the previous year, half of the CPUE values for the rod fisheries in Russian rivers were down and the other half was up. The same pattern was true in comparison with the previous five-year means (Table 3.2.5.2). No long-term trend can be detected either on the White Sea rivers or the Barents Sea rivers (Figure 3.2.5.1).

3.2.6 Age composition of catches

The percentage of 1SW salmon in catches is presented in Table 3.2.6.1 and Figures 3.2.6.1 and 3.2.6.2 for five Northern countries and four Southern countries of the NEAC area that have a time series of data. Several NEAC countries also report nominal catches partitioned according to sea-age category (Table 2.1.1.3.).

The percentage of 1SW fish in the catches of the Northern countries was 54 % in 2002, the lowest value since 1987 (Figure 3.2.6.1). It is below the 5-year mean (65%) and the 10-year mean (65%). Since 1987, this value has varied from 54 to 72 %. The five countries show similar percentages in 1987-1994, but have undergone substantial divergence since then. In most years Finland, Iceland, Russia are above the average of the Northern countries and have been in excess of 70% during the eight last years, whereas Norway and Sweden remain below the average of Northern countries.

For the Southern European countries (Figure 3.2.6.2), the overall percentage of 1SW fish varied from 49 to 65% since 1987 and was 64% in 2002, above the 5-year (62%) and the 10-year means (61%). (England & Wales) show high values (65 – 83% since 1990, 10-year mean = 75%), compared to UK (Scotland) (10-year mean = 54%). France shows quite variable values (27 to 74%) and Spain has the lowest percentages (10-year mean = 36%).

3.2.7 Farmed and ranched salmon in catches

The contribution of farmed and ranched salmon to national catches in the NEAC area in 2002 is again generally low (<2% in most countries) and is similar to the values that have been reported in previous reports (ICES 2000/ACFM:13, ICES 2001/ACFM:15, ICES 2002/ACFM:14). Consequently, the occurrence of such fish is ignored in assessments of the status of national stocks (Section 3.3.3). The exception to this is Norway, where farmed salmon continue to form a large proportion of the catch in coastal, fjordic and rod fisheries. An assessment of the likely effect of these fish on the output data from the PFA model was included in ICES 2001/ACFM:15.

3.2.8 National origin of catches

In 2002, a number of tags originating from fish released from other countries (UK (N. Ireland), UK (England & Wales), UK (Scotland) and Spain) were recovered in the Irish fisheries.

An update of the adult recovery information derived from tagged smolts released in Norway was made available to the Working Group. Between 1996 and 2001 a total of 532,742 smolts, mainly hatchery reared, were tagged and released. A total of 5,065 adult recoveries were reported from Norway and 24 from other countries (0.5% of the total number of salmon recovered). This is consistent with previous observations that very few Norwegian salmon are intercepted in other countries.

3.2.9 Summary of homewater fisheries in the NEAC Area

In the NEAC area, there has been a general reduction in catches since the 1980s. This reflects a decline in fishing effort, as a consequence of management measures and the reduced value of commercially caught salmon, as well as a reduction in the size of stocks. The overall nominal catch in the NEAC area in 2002 (2,464 t) represented a 14% decrease on the catch for 2001, but a 3% increase on the average 1997-2001 catch. Catches in both Southern and Northern areas decreased substantially compared to 2001 (-11% and -17% respectively), whereas compared to the 1997-2001 mean catches decreased in the Southern area (1%) while they increased in the Northern area (7%).

While there have been no major changes in the types of commercial fishing gear used, both northern and southern Europe have experienced general reductions in the number of licensed gear units. In contrast, there are no consistent trends for the rod fishing effort in NEAC countries.

CPUE data for various net and rod fisheries indicate a general increase in northern Europe while patterns in southern Europe are less consistent. The Working Group noted that reduction in the number of fisheries operating can benefit those fisheries still in operation and that the lack of consistent trends in CPUE may reflect the imprecise nature of these indices.

The proportion of 1SW salmon in 2002 was the lowest (54%) since 1987 in the catches of the Northern countries of the NEAC areas and has decreased sharply since 2000. This proportion has been more stable in Southern Europe for the last years, and the 2002 figure (64%) is very near to the previous five -year average (62%) and the previous 10-year average (61%).

Despite the continued high levels of production in the salmon farming industry, the incidence of farmed salmon in NEAC homewater fisheries was generally low (<2%) and similar to recent years. The exception to this is Norway, where farmed salmon still comprise a large proportion of the catch in several of the coastal, fjordic and rod fisheries.

3.3 Status of stocks in the NEAC Area

3.3.1 Survival indices

An overview of the estimates of marine survival for wild and hatchery-reared smolts returning to homewaters (i.e. before homewater exploitation) for the 2001 and 2000 smolt year classes (returning 1SW and 2SW salmon, respectively) is presented in Figure 3.3.1.1. The survival values presented are standardized (Z-score) indices relative to the averages of the time series. The original survival indices for different rivers and experimental facilities are presented in Tables 3.3.1.1 and 3.3.1.2.

With the exception of the Northern NEAC hatchery indices, Northern and Southern NEAC areas show a general decline in marine survival over the past 10-20 years (Figure 3.3.1.1). The steepest decline appears to be for the wild smolts in the Southern NEAC area.

In general, a majority of the survival indices for the latest smolt year classes for both wild and hatchery-reared smolts were below those of the previous year and the 5- and 10-year averages (Tables 3.3.1.1 & 3.3.1.2). Return rates of hatchery released fish, however, may not always be a reliable indicator of marine survival of wild fish.

Results from these analyses are consistent with the information on estimated returns and spawners as derived from the PFA model (section 3.3.4), and suggest that returns are strongly influenced by factors in the marine environment.

3.3.2 The NEAC – PFA model

Description of model

The Working Group has previously developed a model to estimate the pre-fishery abundance (PFA) of salmon from countries in the NEAC area. PFA in the NEAC area is defined as the number of 1SW recruits on January 1st in the first sea winter. The method employs a basic run-reconstruction approach similar to that described by Rago *et al.* (1993) and Potter and Dunkley (1993). The model estimates the PFA from the catch in numbers of 1SW and MSW salmon in each country. These are raised to take account of minimum and maximum estimates of non-reported catches and exploitation rates of these two sea-age groups. Finally these values are raised to take account of the natural mortality between January 1st in the first sea winter and the mid-point of the respective national fisheries. As reported last year (ICES 2002/ACFM:14), the Working Group has determined an ‘m’ value of 0.03 per month to be appropriate. A Monte Carlo simulation (1000 runs) using ‘Crystal Ball’ in Excel (Decisioneering, 1996) is used to estimate confidence limits on the PFA values. Potter et al. (1998) provides full details of the model.

3.3.3 Sensitivity analysis of the PFA model

A sensitivity analysis for the spreadsheet model which generates PFA estimates in the NEAC area was described in ICES 2002/ACFM:14.

The sensitivity of the overall assessment of PFA for the NEAC Area, and for the Northern and Southern European stock complexes, depends on the values of the various parameters provided for different countries, and these will also be weighted by the national catches. The analysis provided an evaluation of the effects (% change) on the assessment of PFA of maturing and non-maturing 1SW salmon from Northern and Southern Europe of making changes to the non-reporting rate (‘R’), the exploitation rate (‘U’) and the time of return to homewaters (‘t’).

Changes to the parameter values listed in the text table below had a greater than 5% effect on the respective (ie. Northern or Southern European) PFA estimates indicating that particular attention should be paid to ensuring that these parameter values are accurate:

Country (Region)	Sea-age	Parameter
Norway (mid)	1SW	Non-reporting rate
Norway (North)	MSW	Non-reporting rate
Ireland	1SW	Non-reporting rate
Ireland	1SW	Exploitation rate
Scotland (East)	1SW	Exploitation rate
Scotland (East & West)	MSW	Exploitation rate
Scotland (East)	MSW	Non-reporting rate

No changes were made to any of these variables prior to running the NEAC PFA model for the 2003 assessment.

3.3.4 Grouping of national stocks

National outputs of the NEAC PFA model are combined in the following groups to provide NASCO with catch advice or alternative management advice for the distant water fisheries at West Greenland and Faroes.

Southern European countries:	Northern European countries:
Ireland	Finland
France	Norway
UK(England & Wales)	Russia
UK(Northern Ireland)	Sweden
UK(Scotland)	Iceland

The groups were deemed appropriate by the Working Group as they fulfilled an agreed set of criteria for defining stock groups for the provision of management advice that were considered in detail at the 2002 meeting (ICES 2002/ACFM:14). Consideration of the level of exploitation of national stocks at both the distant water fisheries resulted in the proposal that that advice for the Faroes fishery (both 1SW and MSW) should be based upon all NEAC area stocks, but that advice for the West Greenland fishery should be based upon Southern European MSW salmon stocks only (comprising UK, Ireland, and France).

3.3.5 National input to the NEAC PFA model

To run the NEAC PFA model most countries are required to input the following time-series information (beginning in 1971) for 1SW and MSW salmon:

- Catch in numbers
- Unreported catch levels (min and max)
- Exploitation levels (min and max)

In some instances, the above information has been supplied in two or more regional blocks per country. In these instances, the model output is combined to provide one set of output variables per country. Descriptions of how the model input has been derived were presented in detail at the Working Group meeting in 2002 (ICES 2002/ACFM:14). Where there have been modifications to these derivation methods an explanation is given below. The input values for the required variables are provided in Table 3.3.3.1a-u.

Changes were made to the exploitation and unreported inputs for the Swedish data based on re-consideration of information available for wild salmon. In the case of UK (England & Wales) minor modifications were made to the values of unreported catch for the earlier part of the time series.

Changes were made to the Russian Kola Peninsula: Barents Sea Basin input data for 2003. In previous years, catches taken in the recently developed recreational rod fishery were not included, as the numbers were insignificant. Account was taken of these recreational catches in the "unreported catch" term in the model. As recreational catches are now substantial, they are now included in the 2003 catch input and the exploitation rate is adjusted accordingly.

3.3.6 Status of national stocks as derived from the PFA model

The Working Group has previously noted that the NEAC PFA model provides our best interpretation of available information on national salmon stocks. There remains considerable uncertainty around the derived estimates, and national representatives are continuing to improve the data inputs each year on the basis of new data, improved sampling and further analysis.

The National Conservation limits model has been designed as a means to provide a preliminary S_{lim} reference point for countries where river-specific reference points have not been developed. These figures should also be regarded as uncertain and should only be used with caution in developing management options. A drawback with an overall national status of stocks analysis is that it does not capture variations in status in different fishery areas or stock complexes; something that has been addressed, at least in part, by the area splits in some countries.

The model output for each country has been displayed as a summary sheet (Figures 3.3.4.1(a to j)) comprising the following:

- Estimated total returns and spawners (±SD) (derived from the National Conservation Limit model).

- Estimated total catch (including non-reported) of 1SW and MSW salmon.

- Estimated pre-fishery abundance (PFA) of maturing 1SW and non-maturing 1SW salmon (labelled as 1SW and MSW).

- Total exploitation rate of 1SW and MSW salmon estimated from the total returns and total catches derived from the model.

- National stock-recruitment relationship (PFA against lagged egg deposition), with S_{lim} fitted by the method presented in ICES 2001/ACCESS:14.

A brief description is given below summarising the outputs from the model.

Finland: Finnish salmon essentially comprise a single river stock, the River Teno (Tana). The data inputs include both Finnish and Norwegian catches for this river. The assessment suggests that the numbers of returns and spawners have fluctuated widely since 1971. The early part of the time-series (1971 to 1975) is characterised by a steep rise, followed by a sharp decline. Numbers of returns and spawners remained low until 1982, but have shown a steady increase since this time, reaching a peak in 2000. In the last two years both returns and spawners have shown a steep decline.

France: Returns and spawners are estimated to have declined over the past 20 years, although there have been large annual fluctuations. Numbers have been particularly low in recent years, with the last eight years being the lowest in the time-series. There has also been a decline in the proportion of MSW salmon in the catch over the time-series. The current status of the stocks must therefore be considered to be low with no indication of a recovery.

Iceland: The assessment suggests that there has been an overall decline in total returns of salmon to Iceland, from around 120,000 in the 1970s to about 60,000 in 2002. However the 2002 values for both returns and spawners are greater than observed in the two previous years. Estimated returns showed an upward trend in the early part of the time-series (1971-78), followed by a sharp decline (1979-84) and a brief recovery to early levels in the late 1980s. There has been a clear downward trend since 1988. There has also been a marked decline in MSW salmon relative to 1SW fish.

Ireland: Estimates of PFA and spawning stocks for Ireland show significant fluctuations over time and three distinct periods are indicated with highest abundance in the 1970’s, lower abundance in the 1980’s, and the lowest abundance occurring in the 1990’s. The early part of the time-series (1971 to 1981) is characterised by a steep rise to the maximum value in the entire time-series, followed by a sharp and prolonged decline. A subsequent recovery period is noted from 1981 to 1989, although the values did not rise to the levels observed in the earlier part of the time-series. A period of steep decline occurred over the period 1989 to 1992 with stock levels fluctuating around a new, lower, level for the remainder of the time series. The status of the stocks must therefore be considered to be low with no significant recovery in the last decade.

Norway: Before 1983 the catch data were considered to be unreliable. Therefore, only catch information after this date were used for the development of the national PFA estimates. The data for the Norwegian part of the River Tana (Teno) are included in the Finnish PFA estimates. There was a decline until the late 1990s thereafter, a sustained increase in returns was observed over the period 1998-2001 but a decline was observed in 2002. The spawning stock has remained relatively constant throughout the period due to a reduced exploitation rate in the second half of the time period.

Russia: Total returns to Russia are estimated to have been generally greater in the early part of the time series. From 1987 onwards there has been a slight upward trend in the number of returns although the estimates in the last two years counter this general trend. Estimates of spawners follow a similar pattern to that described for returns. There has been a marked reduction in the exploitation rate in the last decade. It should be noted that, for Russia in particular, year on year trends in estimated PFA may not be closely reflected in the subsequent year on year trend in the number of spawners. To account for biological reality, the model assigns a fixed proportion of potential spawners returning in a given year to the spawning numbers for the following year.

Sweden: Stocks in Sweden have fluctuated widely throughout the time-series and following a substantial decline in the mid-1990s, there has been a rapid recovery followed by successive and moderate declines in the last two years. A feature of the latter half of the time-series is the increasing proportion of the stock that is comprised of MSW salmon. The exploitation rate has remained high over the last 30 years although there has been a decline from 1990 onwards.

UK (England & Wales): Stocks are estimated to have declined over the past 30 years, although there have been large annual fluctuations. The estimated PFA has declined more rapidly for MSW than 1SW salmon. There has been a slight up-turn in overall PFA since 1997, the lowest in the time-series. The decline in spawner numbers is less marked than that for the returns, reflecting a reduction in the homewater exploitation rate in the last decade.

UK (Northern Ireland): Stocks are estimated to have declined slowly during the 1970's and early 1980's, increasing again in the 1990's. However, estimates of PFA2 for the last four years being among the lowest over the period. The catch is dominated by 1SW fish, but there are uncertainties in the relative status of 1SW and MSW fish, as the data on catch composition by sea age are uncertain for most of the historical time-series.

UK (Scotland): The assessment indicates that stocks have fallen markedly since the early 1970s, although the decline in total spawner numbers has been less marked than those of homewater returns, reflecting the reduction in homewater exploitation rates. The estimated return rates for the last seven years are the lowest in the time series.

3.3.7 Summary of status of stocks

The marine survivals of wild and hatchery-reared smolts in both Northern and Southern NEAC areas show an overall decline over the past 20 years. The steepest decline is that in the wild smolts in Southern NEAC area (Figure 3.3.1.1). Survival of both wild and hatchery fish in the Northern NEAC area, however, have generally increased since 1997.

In general, the total returns of salmon and spawning stocks in the Northern NEAC area, as derived from the NEAC PFA model, have fluctuated for past 30 years but have undergone a relative increase since 1998, followed by a new decrease in the very last years for 1SW salmon. In contrast, salmon stocks in Iceland show a slow but constant decline since 1985 for both 1SW and MSW salmon.

Salmon stocks in the Southern NEAC area show a consistent declining trend over the past 30 years. This relates especially to the MSW component of the salmon stocks.

The consistent trends in marine survival of smolts and the estimated returns and spawners as derived from the PFA model underline the effect of factors in the marine environment on the number of returns.

3.4 Development of Age-Specific Conservation Limits

3.4.1 Progress with setting river-specific Conservation Limits

Information on progress with setting and use of CLs in individual countries and on a European project addressing this issue was reported to the Working group, as follows:

UK (England &Wales): In UK (England & Wales) the river-specific assessment procedures have been modified by addition of a Management Target (MT) for each river. The MT is a spawning stock level for managers to aim at, to ensure that the objective of exceeding the conservation limit (CL) is met in four years out of five (i.e. 80% of the time). It provides an additional mechanism to assist managers in safeguarding stocks. The value for the MT has been estimated using the standard deviation (SD) of egg deposition estimates for the last 10-years, where: MT = CL + 0.842*SD. The constant 0.842 is taken from probability tables for the standard normal distribution, such that the CL forms the 20 percentile of a distribution whose average (or 50 percentile) equates to the MT.

Management decisions in UK (England & Wales) are never based simply on a compliance result alone. Because stocks are naturally variable, the fact that a stock is exceeding its CL does not mean that there will be no need for any management action. Similarly, the fact that a stock may fall below its CL for a small proportion of the time may not mean there is a problem. Thus, a range of other factors are taken into account, particularly the structure of the stock and any evidence concerning the status of particular stock components, such as tributary populations or age groups, based for example on patterns of run timing and the production of juveniles in the river sub-catchments. A programme of river catchment monitoring provides these data.

The Environment Agency in UK (England & Wales) continues to review and revise its assessment procedures with the aim of incorporating more extensive statistical descriptions of the risks and uncertainties in reference points and assessments. An improved procedure for estimating angling exploitation is being developed which will take account of annual changes in fishing effort, as well as partitioning effort between salmon and sea trout (no distinction is currently made between these species when reporting effort). This new procedure is expected to be available shortly and will be applied retrospectively to the 2002 data set and earlier years. In addition, the Environment Agency is also considering the influence that recent changes in the marine survival of salmon might have in calculating CLs for all monitored rivers.

UK (N. Ireland): The most comprehensively developed conservation limit for N. Ireland at present is that for the R. Bush, derived from a whole river stock/recruitment relationship. Work is in progress to extend CL setting to all salmon producing rivers in the Fisheries Conservancy Board (FCB) area of N. Ireland, and to install fish counters to enable compliance to be assessed in key indicator rivers. Provisional CLs for all other rivers in the FCB area have been set by transporting the Bush CL on the basis of catchment area (ICES 1998/ACFM:13). These CLs are indicative only and not presently used for management. However, further work to refine these CLs by using available river-specific habitat data is in progress, with revised CLs being set for the Blackwater, Maine and Glendun rivers in 2002. Counters installed on these rivers to assess compliance with the CLs were operated for the first full year in 2002.

A spawning target based management system has been operating in the Foyle fishery area for many years, based on a scientific study of stock and recruitment relationships in the system (Elson & Tuomi, 1975). Associated management targets are operated on the basis that, if, at certain dates during the season, certain target numbers of fish have not been counted upstream at Sion Mills Weir (R. Mourne), and at two other rivers (R. Faughan & R. Roe) then specified closures of the angling and/or commercial fisheries take place. Conversely, if the seasonal management targets have been met by the normal end of the commercial netting season, an extension is granted. The Loughs Agency is in the process of setting conservation limits for the other rivers with counter sites within the catchment.

The SALMODEL project: The rate of development of river-specific conservation limits reflects *inter alia* the availability and representativeness of stock and recruitment (SR) data, together with the logistical difficulty of accurately surveying large numbers of rivers, often in remote locations. As a result, less than 25% of NEAC rivers have river-specific conservation limits at present, with many of those at interim/developmental stages.

These and related issues were considered by the EU funded SALMODEL Concerted Action *"A co-ordinated approach towards the development of a scientific basis for management of wild Atlantic salmon in the North-East Atlantic"* (Contract No**:** QLK5-CT1999-01546; www.salmodel.net). Reports on progress in SALMODEL have been presented to the Working Group in 2001and 2002 via a number of working papers. A brief summary of progress taken from the draft final report of the project is given below:

Setting and transporting biological reference points for Atlantic salmon

The analysis of SR data is the most widely used approach for deriving BRPs (Biological Reference Points) for Atlantic salmon. There are several hundreds of salmon stocks across the NEAC area, each having its own characteristics with regards to the SR relationship. Suitable SR series (both in terms of length and reliability of observations) are available for only a few monitored rivers. Extrapolation of knowledge gained from monitored rivers to rivers for which SR data are not available is therefore required.

Bayesian meta-analysis using hierarchical SR modelling provides a probabilistic framework for organising the transfer of information from the monitored rivers towards rivers with no SR data, while incorporating the nested structure of the uncertainty.

A Bayesian Hierarchical SR Analysis (BHSRA) was developed by SALMODEL. Merits and limits of this approach were assessed by applying it to a set of 15 existing SR series from NEAC monitored rivers. Riverine wetted area accessible to salmon and latitude were introduced as covariates explaining variations in the SR related parameters between rivers. The output of the analysis is the posterior probability distributions of the model parameters and related quantities of interest. Special attention was given to the prediction of conservation limits both at the river level and at an aggregated regional level.

The treatment of SR series from monitored rivers using BHSRA allows the derivation of a probability distribution of the NASCO standard CL (S_{lim}) for any river with no SR data. These distributions are very wide, mostly because, even within a narrow geographical range, CLs can vary widely between rivers. This indicates that over-reliance on local monitored rivers can lead to a major underestimation of the uncertainty of the management parameters for rivers without SR data and this practice is not advised.

Regional CLs are widely used at ICES for fisheries management advice to NASCO. In recent years, CLs for some countries have been set by means of non-parametric methods applied to 'pseudo' SR relationships (i.e. the national conservation limit model; Section 3.4.2,). One of the major shortcomings of this approach is that it does not allow for an assessment of the uncertainty in the CL estimates. SALMODEL developed an approach to provide a more objective estimate of CLs from the national SR relationships with confidence limits, which therefore take account of some of the uncertainty in the value. Nevertheless, the model is still recognised as providing only a crude measure of the conservation requirements of stocks, and SALMODEL has recommended that it should only be employed to provide preliminary estimates of CLs. The BHSRA offers an alternative approach that makes better use of biological information on stocks.

Such probability distributions are the natural complement of forecasted PFA probability distributions for the provision of management advice in a risk/decision analysis framework. This framework would account for the uncertainty in both the PFA and the CL. PFA and CL distributions can be easily combined to evaluate the probability of reaching a regional CL under various options of exploitation.

Transport of CLs between rivers

Salmon SR studies are resource-intensive and relatively scarce; hence for the foreseeable future we will need to find means of transporting CLs from data-rich rivers to data-poor rivers. Digital techniques combining database and mapping technologies (GIS) represent important and necessary tools in facilitating transportation.

SALMODEL reviewed different methodologies, revealing differing levels in detail and complexity. River habitat assessment approaches in the NEAC area vary with a definite bias (in number of rivers surveyed) towards measurements of catchment area, stream length, and stream order and wetted area. In most countries, only a minority of rivers had in-stream or remote-sensing measurements of physical habitat carried out. SALMODEL identified clear potential to improve and harmonise methodologies.

An intermediate habitat variable, such as wetted area, is identified as the only viable approach in the short to medium term for quantifying production areas for transport of BRPs. It can be obtained relatively easily without field based survey and in a standardized manner across countries, but it is also demonstrated that this alone does not reflect the actual proportions of various habitat types in this range of rivers. The choice to concentrate on wetted area, is therefore driven by necessity and it is important to assess the consequences of not making better use of other approaches reflecting the variation in quality of the habitat between rivers.

Use of Geographic Information System (GIS) derived measurements of wetted area is recommended to be used together with data from existing SR data sets in a Bayesian hierarchical framework for the transport of BRPs across NEAC rivers. It is also important to develop verification standards to ensure a highest possible level of consistency for these measurements, as well as indicator systems for habitat quality, based on GIS techniques. SALMODEL has provided a comprehensive explanation of methodology for GIS supported measurements of wetted fluvial areas.

CLs and underlying genetic structure

Genetic and ecological analyses of Atlantic salmon populations suggest that they are sufficiently isolated to allow the development of local adaptations through natural selection. This suggests that fitness and productivity may be compromised if important genetic units of Atlantic salmon are not recognised, and that management may benefit by considering the genetic structure of the species. However, estimates of gene flow between populations show that anadromous populations do not exist in isolation. A focus for SALMODEL was therefore to look at how genetic variation is lost from a group of Atlantic salmon populations that are harvested together in the ocean, but may be managed separately in fresh water. The scientific problem was formulated so as to combine the goals of optimal harvesting (maximum sustainable yield) and effective population size in a group of populations interconnected by migration. A second objective was to review knowledge about the fitness consequences of loss of genetic variation.

Effective population size is a key concept in population genetics. It is defined as the size of an ideal population that is losing genetic variation at the same rate as the actual population. It determines the rate of inbreeding in a population, and its rate of loss of heterozygosity and genetic variance in quantitative traits. Knowledge about local population sizes and migration patterns, or alternatively, studies of the genetic structure of the species, can be used to assess the relationship between local effective population sizes and the effective size of the total population.

By developing a model that maximises harvesting yield of a group of populations, subject to constraints set by maintaining the total effective size, SALMODEL has shown that:

- considerable gain can be made in total effective size in a group of populations through harvesting based on knowledge about population structure,
- in source-sink population systems, the total effective size can be increased without reducing total harvesting yield by first reducing the harvest in the smallest population(s), while maintaining the harvest in the largest population,

- when populations differ in their degree of isolation, it pays to harvest relatively less in isolated populations because these contribute more to the total effective size, and
- in cases with moderate or strong directionality in the migration pattern, the total effective size can become less than the sum of the subpopulation sizes.

SALMODEL discussed these results in the light of conservation genetic theory and empirical results on the fitness consequences of loss of genetic variation, and concluded that the genetic consequences of harvesting need to be assessed both at the level of local subpopulations and at the level of the total population.

The effects of dynamic change on the establishment of CLs

Using several statistical techniques, dynamic change (non-stationarity) was detected in all of the NEAC rivers where SR data were available. The two main periods identified were from 1970 to the mid 1980s and from the mid 1980s to the end of the 1990s. These changes result in large differences in the magnitude of BRPs derived from these relationships and make the choice of appropriate CLs more difficult. Selection of a CL that is too high relative to the prevailing stock capability would result in over-restrictive fishery measures. Similarly, selection of a low CL relative to the productive capacity of the system in question would result in a degradation of that productive capacity if insufficient spawners were allowed to seed the habitat effectively.

Transport of CLs to management situations under different scenarios of stock productivity in distinct periods was examined and it is suggested that transported targets from donor stocks must also represent the stock situation of the recipient river as closely as possible, rather than a pristine state. However, the establishment of a “benchmark” CL representing pristine conditions was also felt to be useful as these could be accepted or rejected depending on local conditions, and they represented a more likely limit to achieve in the event that factors limiting production were mitigated or overcome.

The implications of sympatric trout for the setting and use of Atlantic salmon CLs

Sea trout, the anadromous form of the brown trout (*Salmo trutta* L.), live sympatrically with salmon in many salmon rivers in the NEAC area. Because the two species have similar habitat requirements and a broadly similar life cycle, there is a *prima facie* case that interspecific interaction may be important for the setting of salmon CLs.

A review of relative abundance, based on rod catches from 192 rivers, showed that sea trout were generally more prevalent than salmon in smaller catchments. A few rivers supported very large sea trout stocks from which egg deposition was up to twice that of salmon. However, in the NEAC sample as a whole, 95% of salmon rod catch came from rivers in which salmon contributed the major part of migratory salmonid egg deposition. Electro-fishing data showed that trout was, on average, the dominant salmonid in small channels (<6 m wide). Such streams represented, however, only a small proportion of total catchment wetted area, so that in most of the wetted area where salmon occur they are the numerically dominant salmonid species.

Habitat overlap of juveniles gives rise to competitive interactions in which trout are normally dominant and, although local niche separation operates, there are several reported examples of trout limiting salmon abundance at macro-habitat (10 m) or smaller scale. However, at catchment scale segregating processes (e.g. spawning times and gravel size selection) operate, so the potential interaction presented by salmon and trout sympatry tend to be reduced by the details of their behaviour and ecology.

Analysis of data from Swedish and UK streams showed that trout summer 0+ abundance exerted only minor impact on salmon 0+ to 1+ loss rates, which were more strongly influenced by habitat and salmon 0+ density. However, an analysis of interactions during the early post-emergent phase when density-dependence is strongest was not possible due to lack of suitable data and this remains a key topic to investigate. Predation by mature trout (non-migratory) on salmon juveniles in freshwater was thought to be very important on some rivers and possibly was the most likely mechanism by which trout affect salmon, but this remains to be tested. This effect probably falls into the same category as other forms of predation and should be considered as part of the random annual variation on survival.

Overall, SALMODEL concluded that, trout egg deposition on catchment scale cannot be simply taken into account in setting salmon CLs. Combined SR relationships are currently not feasible and probably not appropriate for whole rivers. However, the possibility remains of important interspecific, early life stage density-dependent effects in smaller sub-catchments or in the comparatively few whole catchments where sea trout are particularly abundant.

Risk in setting CLs

The probability of achieving the spawning requirement objective in a specific year is defined by the stochastic properties of small numbers and factors such as the size of the stock, the proportion female in the stock, and annual variation in the biological characteristics. The uncertainty in achieving the spawning escapement objective is greater for small stocks than large ones, such that measures of annual performance are more variable for small stocks. Straying among rivers increases the uncertainty of achieving spawning requirements simultaneously in the rivers within the complex. Variations in productivity among rivers, when not accounted for, result in under-escapement in the lower productivity rivers.

Two case studies of aggregating rivers within a regional requirement were examined by SALMODEL. In the first case, 17 rivers within the Welsh region of UK (England & Wales) were combined and the probability profiles of achieving requirements in all rivers simultaneously were described. In order to achieve a probability greater than 50% of simultaneously achieving the required escapement in these 17 rivers, the regional spawner requirement must be increased by at least 10%. In the second case study, 15 monitored rivers across the NEAC area were aggregated into a NEAC complex. Even when releases from the fishery are double the regional spawning requirement, there is a less than 50% probability of meeting the spawning requirements simultaneously in all 15 rivers. This is a consequence of one of these being a small low productivity river, which produces proportionally fewer recruits than the other stocks and therefore has a lower probability of meeting spawning requirements compared to other more productive rivers when managed together in the same aggregation.

Each mixed stock fishery situation can and should be evaluated on a case-by-case basis. This can be done using the Monte Carlo techniques described. The impact of mixed stock fisheries can be most important on the small stocks and especially if these are of low relative productivity. Increasing the regional spawner requirement in an attempt to compensate for lower productivity may alleviate the problem somewhat but is not a guaranteed solution to the challenge of protecting low productivity stocks.

3.4.2 Description of the national Conservation limits model

As indicated above, relatively few river-specific conservation limits have been developed for salmon stocks in the NEAC area. An interim approach has therefore been developed for estimating national conservation limits for countries that cannot provide one based upon river-specific estimates. The approach is based on establishing quasi-stock-recruitment relationships for national salmon stocks in the North East Atlantic Commission (NEAC) area (Potter *et al*., 1998).

As described in last years report (ICES 2002/ACFM:14), the model provides a means for relating estimates of the numbers of spawners and recruits derived from the PFA model. This is achieved by converting the numbers of 1SW and MSW spawners into numbers of eggs deposited, using the proportion of female fish in each age class and the average number of eggs produced per female. The egg deposition in year ‘n’ is assumed to contribute to the recruitment in years ‘n+3’ to ‘n+8’ in proportion to the numbers of smolts produced of ages 1 to 6 years. These proportions are then used to estimate the ‘lagged egg deposition’ contributing to the recruitment of maturing and non-maturing 1SW fish in the appropriate years. The plots of lagged eggs (stock) against the 1SW adults in the sea (recruits) have been presented as ‘pseudo-stock-recruitment’ relationships.

ICES and NASCO currently define the conservation limit for salmon as the stock size that will result in the maximum sustainable yield in the long term (i.e. S_{lim}). However, it is not straightforward to estimate this point on the national stock-recruitment relationships because the replacement line (ie the line on which ‘stock’ equals ‘recruits’) is not known for the pseudo-stock-recruitment relationships established by the national model because the stock is expressed as eggs, while the recruits are expressed as adult salmon. In 2001 the Working Group adopted a method for setting biological reference points from “noisy” (uncertain) stock-recruitment relationships, such as provided by the national pseudo-stock-recruitment datasets (ICES CM2001/ACFM:15). This model assumes that there is a critical stock level below which recruitment decreases linearly towards zero stock and recruitment, and above which recruitment is constant. The position of the critical stock level is determined by searching for the value that minimises the residual sum of squares. This point is a proxy for S_{lim} and is therefore defined as the conservation limit for salmon stocks. A modified version of this method, which updates the approach first used by ICES in 2001, by allowing uncertainty around these estimates to be described was outlined in last years report (ICES 2002/ACFM:14). This approach was again applied to the 2002 national stock-recruitment relationship assessment for countries where no river-specific conservation limits have been determined.

3.4.3 National Conservation Limits

The national model has been run for the countries for which no river-specific conservation limits have been developed (i.e. all countries except France, UK (England & Wales), and Sweden). The outputs are illustrated in Figures 3.3.4.1. For Iceland, Russia, Norway, UK (Northern Ireland), and UK(Scotland) the input data for the PFA analysis (1971-2002) have been provided separately for more than one region; the lagged spawner analysis has therefore been conducted for each region separately and the estimated conservation limits summed for the country. The conservation limits derived from the national model and river-specific estimates are shown in Table 3.4.3.1. The Working Group has previously noted that outputs from the national model are only designed to provide a provisional guide to the status of stocks in the NEAC area. It will also be noted that the conservation limit estimates may alter from year to year as the input of new data affects the 'pseudo-stock-recruitment relationship'. This further emphasises the fact that this approach only provides a basis for qualitative catch advice.

The estimated national conservation limits have been summed for Northern and Southern Europe (Table 3.4.3.1) and are given on Figures 3.5.1.4 and 3.5.1.6 for comparison with the estimated spawning escapement. The conservation limits have also been used to estimate the spawner escapement reserves (SERs) (i.e. the CL increased to take account of natural mortality between the recruitment date (1st Jan) and return to home waters) for maturing and non-maturing 1SW salmon from the Northern and Southern Europe stock complexes. The SERs are shown as horizontal lines in Figures 3.5.1.3 and 3.5.1.5. The Working Group also considers the current SER levels may be less appropriate for evaluating the historic status of stocks (e.g. pre-1985), that in many cases have been estimated with less precision.

3.5 Catch Options or Alternative Management Advice

3.5.1 Trends in the PFA for NEAC stocks

Tables 3.5.1.1 to 3.5.1.6 show combined results from the PFA assessment for the Northern and Southern European groups and the whole NEAC area. The PFA of maturing and non-maturing 1SW salmon and the numbers of 1SW and MSW spawners for these areas are shown in Figures 3.5.1.1 to 3.5.1.6.

The 95% confidence limits (dotted lines for PFA and vertical bars for the spawning escapement) shown in Figures 3.5.1.1 to 3.5.1.6 indicate the high level of uncertainty in this assessment procedure. However, the Working Group recognised that the model provided an interpretation of our current understanding of national fisheries and stocks based upon simple parameters. Errors or inconsistencies in the output largely reflect uncertainties in our best estimates of these parameters. Furthermore, there are risks that progressive errors could occur if, for example, the rate that exploitation has been reduced over a period of years is underestimated. The results therefore need to be treated with caution.

Figure 3.5.1.1 shows that there has been a general decline in recruitment among 1SW and MSW salmon in the whole NEAC area over the past 30 years, and both age groups are currently the lowest levels observed. Numbers of 1SW and MSW spawners have also declined (Figure 3.5.1.2) over the past 30 years, although the decline has been less severe, indicating that reductions in exploitation have, to some extent, compensated for the decline in stocks. The general trends depicted are similar to those derived from the model run last year.

Figure 3.5.1.3 shows that recruitment of maturing 1SW salmon (potential grilse) in Northern Europe was generally high (around 1.1 million) in the 1970s and 1980s, although the numbers have fluctuated quite widely, but there was a steady decline in these stocks from the mid-1980s to the mid-1990s. Following an upturn over the years 1998-2001 there has bee a steep downturn in 2002 to approximately 727,000. In contrast, there is an increasing trend in the number of 1SW spawners (Figure 3.5.1.4) throughout the time-series, with escapement in 1987 to 2001 being above the conservation limit. This is consistent with a decline in exploitation. However, in 2002, there has been a marked drop in the number of 1SW spawners.

Numbers of non-maturing 1SW recruits (potential MSW returns) for Northern Europe (Figure 3.5.1.3) are also estimated to have fluctuated around 1.1 million between 1970 and 1985, but subsequently fell to about half this level in the late 1990s; there has been an upturn in the past five years. The numbers of MSW spawners, however, show no trend over the time-series although numbers appear to have increased in the last four years. It therefore appears that the decline in recruitment has been balanced by the reductions in exploitation both in homewater fisheries and at Faroes. These trends in recruitment for the Northern European stocks are broadly consistent with the limited data available on the marine survival of monitored stocks in the Northern area (Section 3.3.1).

In the Southern European stock complex (Figure 3.5.1.5), the numbers of maturing 1SW recruits are estimated to have fallen substantially since the 1970s, with values in the last four years being among the lowest in the time-series. This pattern is consistent with the data obtained from a number of monitored stocks. Survival of wild smolts to return as 1SW fish fell to very low levels in the Southern European area for which data were available (Section 3.3.1). This suggests that the marked reduction in 1SW returns in 1999 is likely to have been due in large part to a widespread decline in marine survival.

The PFA estimates suggest that the number of non-maturing 1SW recruits in Southern Europe has declined fairly steadily over the past 30 years (Figure 3.5.1.5); these stocks have also reached their lowest levels at the end of the time-series. This is broadly consistent with the general pattern of decline in marine survival of 2SW returns in most monitored stocks in the area (Section 3.3.1). In more recent years, reductions in exploitation do not appear to have kept pace with the stock declines, and the spawning escapement has thus also fallen over the period (Figure 3.5.1.6).

3.5.2 Forecasting the PFA for NEAC stocks

The Working Group has previously considered the development of a model to forecast the pre-fishery abundance of PFA *non-m* (PFA of non-maturing potential MSW) salmon from the Southern European stock group (comprising Ireland, France, and all parts of UK) (ICES 2002/ACFM:14). Stocks in this group are the main European contributors to the West Greenland fishery (See Section 3.3.2). The model took the form:

$$PFA\ non\text{-}m = Spawners^{\lambda} \times e^{B_0 + B_1 Habitat + B_2 Year + Noise} \qquad (Model\ 1)$$

where the habitat term is the same as that used in the North American model (section 4).

Both the year and spawner term were found to be significant predictors but the habitat variable had no significant effect. Therefore, this year, the Working Group considered an alternative model that used only the year and spawner terms to predict PFA. This model took the following form:

$$PFA\ non\text{-}m = Spawners^{-0.127} \times e^{20.14 - 0.04984(Year - 1990)} \qquad (Model\ 2)$$

This year the model was fitted to data from 1977-2001 (Table 3.5.2.1) to predict PFA in the subsequent years 2002-2003.

The predictions using this model and the bootstrapped 95% confidence intervals are given in Table 3.5.2.2 and the trend in PFA *non-m* is shown in Figure 3.5.2.1. It should be noted that the confidence intervals are wide and this reflects the uncertainty around the point estimate. These predictions have been used as an input to the provision of quantitative catch advice for this stock complex for 2003.

Alternative model inputs

The Working Group also considered a further predictive model that used the PFA *m* (PFA of maturing 1SW salmon), in addition to the spawner term, as a predictor variable for the PFA *non-m* salmon in the Southern NEAC area the following year. The advantage of such a model is that the inclusion of the PFA *m* utilises a further biological variable and thus should capture, to some degree, the effects of biological influences on the stock. However, as predictions are required two years in advance to provide catch advice for the West Greenland fishery, the final value for the PFA of maturing 1SW salmon has to be estimated. Therefore the Working Group agreed not to include this variable in the 2003 assessment.

However, in the Northern NEAC area, predicting PFA *non-m* based on the PFA *m* might be more appropriate. In this case, the final input value of a PFA of maturing 1SW salmon predictor might be obtained in time (eg. from homewater fisheries) to provide catch advice to the Faroes fishery that, to the best of our knowledge, exploits salmon mainly from the northern NEAC area. The Working Group therefore considered the following model:

$$PFA\ non\text{-}m = Spawners \times e^{-7.603 + 0.638 \log(PFA\ m) - 0.277 Habitat} \qquad (Model\ 3)$$

This analysis is exploratory and is restricted to the input variables available prior to the 2003 assessments. The habitat term (mean sea surface temperature (SST) in the month of February for the period 1982-2001 in the area 58-64ºN 10ºW – 10ºE) although available was not extracted for 2002. Thus, it was estimated as the mean of the previous three years. The data used to fit the model are shown in Table 3.5.2.3. The predictions using this model and the bootstrapped 95% confidence intervals are given in Table 3.5.2.4 and the trend in *PFA non-m* is shown in Figure 3.5.2.2. The Working Group recommended that such a model should be developed further.

3.5.3 Management Advice

The Working Group has been asked to provide catch options or alternative management advice, if possible based on a forecast of PFA, with an assessment of risks relative to the objective of exceeding stock conservation limits in the NEAC area. The Working Group reiterated its concerns about harvesting salmon in mixed stock fisheries, particularly for fisheries exploiting individual river stocks and sub-river populations that are at unsatisfactorily low levels. Annual adjustments in quotas or effort regulations based on changes in the mean status of the stocks is unlikely to provide adequate protection to the individual river stocks that are most heavily exploited by the fishery or are in the weakest condition.

The Working Group also emphasised that the national stock conservation limits discussed above are not appropriate for the management of homewater fisheries, particularly where these exploit separate river stocks. This is because of the relative imprecision of the national conservation limits and because they will not take account of differences in the status of different river stocks or sub-river populations. Nevertheless, the Working Group agreed that the combined conservation limits for the main stock groups (national stocks) exploited by the distant water fisheries could be used to provide general management advice to the distant water fisheries.

Due to the preliminary nature of the conservation limit estimates, the Working Group is unable to provide quantitative catch options for most stock complexes at this stage. Furthermore, to do so requires predictive estimates of PFA which have not yet been developed for all stock complexes. However, for the second time, a quantitative prediction of PFA for Southern European MSW stocks is provided. The Working Group also notes that progress has been made in the development of an approach to derive predictive estimates of PFA for the Northern European PFA stocks (Section 3.5.2). The Working Group considers that the following qualitative catch advice is appropriate based upon the PFA data and estimated SERs shown in Figures 3.5.1.3 and 3.5.1.5.

Based on recent work on resolving the most appropriate stock groupings for management advice for the distant water fisheries (ICES 2002/ACFM 14) the Working Group agreed that advice for the Faroes fishery (both 1SW and MSW) should be based upon all NEAC stocks. Advice for the West Greenland fishery should be based upon southern European MSW salmon stocks only (comprising UK, Ireland and France).

For all fisheries, the Working Group considers that management of single stock fisheries should be based upon local assessments of the status of stocks. Conservation would be best achieved by fisheries in estuaries and rivers targeting stocks which have been shown to be above biologically-based escapement requirements.

[NB In the evaluation of the status of stocks, PFA or recruitment values should be assessed against the spawner escapement reserve values while the spawner numbers should be compared with the conservation limits.]

Northern European 1SW stocks: The PFA of 1SW salmon from the Northern European stock complex has been above the spawning escapement reserve throughout the time series (Figure 3.5.1.3a). However, the spawning escapement was at or below the conservation limit until 1997 (Figure 3.5.1.4a). There has been an upward trend throughout the time series until 2002 when there was a sharp decline taking the stock complex below the conservation limit again. The Working Group considers that the overall exploitation of the stock complex should decrease so that the conservation limit can be exceeded. It should be noted, however, that the inclusion of farmed fish in the Norwegian data will result in the exploitable surplus being overestimated. Since very few of these salmon have been caught outside homewater fisheries in Europe, even when fisheries were operating in the Norwegian Sea, management of maturing 1SW salmon should be based upon local assessments of the status of river or sub-river stocks.

Northern European MSW stocks: The PFA of non-maturing 1SW salmon from Northern Europe has been declining since the mid 1980s and the exploitable surplus has fallen from around 1 million recruits in the 1970s to about half this level in recent years (Figure 3.5.1.3b). The Working Group considers the Northern European MSW stock complex to be within safe biological limits, as spawners are above CL and trending in a positive direction (Figure 3.5.1.4b). However, it should be noted that the status of individual stocks may vary considerably. In addition, the inclusion of farmed fish in the Norwegian data will result in the exploitable surplus being overestimated. The Working Group therefore considers that caution should still be exercised in the management of these stocks particularly in mixed stock fisheries and exploitation should not be permitted to increase, until a clear pattern of status above SER is established.

Southern European 1SW stocks: Recruitment of maturing 1SW salmon in the Southern European stock complex has shown a strong decreasing trend throughout most of the time series (Figure 3.5.1.5a). Moreover the spawning escapement for the whole stock complex has fallen below the conservation limit in three of the past five years, although a small improvement was noted in 2002 (Figure 3.5.1.6a). Despite a small surplus above SER of around 300,000 fish during the last three years, exploitation in these years was clearly high enough to prevent conservation limits being consistently met. The Working Group therefore considers that mixed stock fisheries present particular threats to conservation and that reductions in exploitation rates are required for as many stocks as possible.

Southern European MSW stocks: The PFA of non-maturing 1SW salmon from Southern Europe has been declining steadily since the 1970s (Figure 3.5.1.5b) and the preliminary quantitative prediction of PFA for this stock complex indicates that PFA will remain close to present low levels for each of the next two years (537,000 and 524,000) (Figure 3.5.2.1). There is evidence from the prediction that PFA will decrease in the near future and the spawning escapement has not been significantly above conservation limit for the last seven years (Figure 3.5.1.6b). The stock group is therefore very close to safe biological limits, and the Working Group considers that precautionary reductions in exploitation rates are required for as many stocks as possible, in order to ensure that conservation requirements are met for each river stock with high probability.

With catch advice for three of the four stock groupings above still being provided on the basis of extrapolation from historical PFA data, the Working Group recommends that further progress be made with establishing PFA forecast methodologies. Catch advice would also be significantly enhanced if conservation limits were more certain for national stocks. The Working Group noted progress with both of these areas in the EU SALMODEL Concerted Action.

3.6 Evaluation of the effects on stocks and homewater fisheries of significant management measures introduced in the last 5 years

The Working Group noted the ongoing reductions in the number of gear units deployed in most countries in the NEAC area since 1997 (Table 3.6.1). This is thought to reflect both management measures aimed at reducing levels of exploitation and the declining commercial viability of some fisheries. A number of other measures have also been introduced, or continued, in NEAC countries over this period. These include: restrictions on fishing seasons and gear, buy-out arrangements, voluntary restrictions, and increasing use of catch and release. Given the widely divergent measures introduced, variability in the timing of their introduction and duration, and the nature of the fisheries themselves, the Working Group recognised that it was not possible to quantify the effects of management measures on stocks and fisheries across the NEAC area in a consistent manner.

The effect of specific management measures on stocks and fisheries has been evaluated in a number of NEAC countries.

NEAC northern area

In Russia, commercial catches have been declining steadily as a result of various management changes, including the prohibition of some important in-river fisheries, aimed at reducing the fishing effort and enhancing the development of recreational catch-and-release fisheries. The mean commercial catch in the last five years (1998-2002) is 15% below that of the previous five years (1993-1997). A large decline in the fishing effort by bend nets along part of the Norwegian coast was implemented in 1997 and the start of the fishing season for bag nets was delayed by 2 weeks from 1998. These measures have resulted in a substantial decline in fishing effort, and although it has not been possible to quantify this, exploitation is believed to have fallen markedly.

NEAC southern area

In Ireland, the introduction of measures in the commercial fishery in 1997 effectively reduced effort in the commercial fishery by about 20% (5 to 4 days). Further restrictions on night-time fishing further reduced the effort by up to 50% in some areas where all day fishing was previously carried out. Fishing effort on spring salmon stocks was also reduced with the later opening of the season for some gears. A more detailed appraisal of these methods on Irish stocks and fisheries was presented in ICES 2001/ACFM:15. This had concluded that the measures contributed to a reduction in both the overall catch and the exploitation rate on Irish stocks.

In UK (N. Ireland), significant management changes came into effect in the Fisheries Conservancy Board area in 2002, aimed at conservation of wild salmon stocks. For the 2001 season there was a voluntary agreement with licensed net operators that no net should operate until 1st June (season was previously 17th March to 15th September), with around 8 nets agreeing not to fish at all. Holders of drift net licenses agreed to operate for only eight weeks during the period 1st June to 15th September, split into two four-week periods. These voluntary agreements preceded a public:private sponsored voluntary buyout, which came into effect for the 2002 season, with funds being made available to purchase netting rights from a significant proportion of operators in the FCB area. This scheme has resulted in the buyout of some 18 commercial licence holders. The number of commercial licences issued in the FCB area fell to 14 for the 2002 season, in comparison to 23 in 2001 and 27 in 2000. Accompanying measures to regulate angling, introduced into the FCB area on a voluntary code-of-practice basis in 2001, operated again in 2002, pending introduction of appropriate byelaws. These included catch and release from the start of the season up to the end of May; a daily bag limit of two fish from 1st June to the end of the season, and a ban on the sale of rod caught salmon. While the effects of these measures on stock status will require some years to fully evaluate, it is noted that the voluntary net buyout scheme probably contributed to the reduction in net catch in the FCB area from 23.4 t in 2001 to 9.4 t in 2002.

National measures were introduced in UK (England & Wales) in 1999 to protect spring salmon. In 2002, these are estimated to have saved around 2,800 salmon from capture by net fisheries and around 1,300 by rod fisheries before June 1. These estimates are based on the catch and the average proportion of fish taken in this period in the 5 years prior to the measures being introduced; the latter estimate has been adjusted for catch and release.

Since 1993, there has also been a policy to phase out coastal mixed stock salmon fisheries in UK (England & Wales). The largest of these fisheries is on the north east coast, where the number of drift net licences issued has now been reduced by 51%. Nine other small coastal mixed stock fisheries have also been identified in recent years, seven of which are no longer operating, while the remaining two are in the process of been phased out. In some cases, these phase-outs have been accelerated where fishermen have agreed to accept compensation payments to give up their licences early. Although there have been large annual fluctuations in the declared catches, the overall effect of these measures has been to reduce the catches in these coastal fisheries from an average of about 39,000 fish for the period 1993-97 to a little under 32,000 for the period 1998-2002. These measures have had more of an impact at the local level. For example, prior to the buy-off of the nets and fixed engines on the River Usk in 2000, this fishery took, on average, about 1,000 fish each year (~40% of the total net catch in Wales). The partial phase out of the Taw/Torridge fishery in 2002 resulted in a drop in the catch from a five-year mean (1997-2001) of 665 fish to just 103 in 2002.

In Scotland, members of the Salmon Net Fishing Association, to which the majority of active netsmen are affiliated, continued a voluntary agreement, introduced in 2000, to delay fishing until the beginning of April in order to protect early running MSW salmon. This has resulted in about an 80% reduction in the catch of MSW salmon by nets and fixed engines in the months of February and March, compared with the five years previous.

In northern France, TACs have been operated in several regions for some years. In Brittany (which accounts for more than 60% of the total rod catch) a MSW-specific TAC was introduced in 2000. This continued to apply in 2002. One and two month delays to the start of the angling season were introduced in 2001 and continued in 2002 on three other rivers in an effort to reduce exploitation of spring salmon. However, catch data suggest that this resulted in catches well above average when the season commenced, suggesting that the measures merely delayed exploitation in these small rivers. In addition, the net fishery in the Adour estuary was subject to closed periods throughout the season, where previously this had been concentrated on June and July only. This resulted in a higher proportion of 1SW salmon in the catch (58%) than in 2001 (16%), but did not reduce the estimated level of exploitation on 2SW salmon (the objective of the measure), which remained at around 50%.

The above estimates and the overall reduction in gear units suggest that management measures introduced in the last 5 years have continued to reduce levels of exploitation on NEAC stocks.

3.7 Estimate of by-catches of Post-Smolts in mackerel and other pelagic fisheries

3.7.1 Research surveys and distribution of salmon

In the Norwegian research surveys a total of 4,164 post-smolts and 171 older salmon have been captured in 2,438 surface trawl hauls carried out since 1990 during cruises for surveying pelagic fish and during dedicated salmon surveys (Table 3.7.1.1). A specially designed “salmon trawl” with extra flotation on the head line and bridles was used together with a device for live fish capture (modified from Fish Lifter, Holst and McDonald, 2000) attached to the cod end of the trawl. The rope end of the trawl consisted of a segment of approximately 3,000 mm meshes, followed by mesh segments with diminishing mesh size. A 20 mm blinder net is used in the cod end. The horizontal opening of the trawl is 40 m and it covers 0 – 14 m vertically. The average towing speed with this trawl was 4.8 kt (SD ±0.4) and the wire length was 290 – 340 m depending on the condition of the waves. The trawl was towed in large arcs to avoid the wake of the ship.

Geographical distribution of all post-smolts and salmon captured in 2002 in the salmon surveys carried out by several countries is presented in Figure 3.7.1.1, and Norwegian captures in the period 1990-2001 is shown in Figure 3.7.1.2. Since the start of the dedicated salmon cruises in the Norwegian Sea in 1999, the CPUE values for post-smolts (number of fish caught per trawl hour) have been relatively high reaching a peak of 28 in 2001. However, this value was partly explained by the input from one very large catch. The values in 2002 of individual tows are lower (Table 3.7.1.1, cruise 4 ; Table 3.7.1.2) but more evenly distributed over the area than the values recorded in 2001 (0 – 93), indicating that the timing of the cruise must have been favourable in relation to the density of post-smolt cohorts passing through that particular area. However, the largest densities of post-smolts were recorded from June 21 to 24 around 68°N, earlier and further north than previously recorded (Figure 3.7.1.3). Smolt age distribution for these fish indicate a southern origin, as does the fact that 9 out of 10 microtags retrieved were Irish.

The surface trawls have previously been thought to catch predominantly post-smolts as it has been anticipated that the trawling speed is too low (3.2 – 3.8 kt) for capturing larger salmon and video recordings performed in the trawl in 2000-2002 seem to support this (M. Holm, pers obs.). Consequently, no efforts have been made to calculate CPUE for larger salmon. However, in a Nordic DST tag and release experiment where the new experimental salmon trawl was used in October - January, substantial numbers of pre-adult and adult salmon were captured raising concern about the potential risk of larger salmon also being intercepted by pelagic fisheries.

Several investigations indicate that while migrating through areas with intensive fish farming activity Atlantic salmon post-smolts may be heavily infested by sea lice, which may cause a considerable mortality. The number of potential hosts for sea lice along the coast of Norway has increased dramatically recently because of the increasing farming industry. A programme to study the sea lice infestations in fjords with different infestation potentials has been carried on since 1998. In 2002 the monitoring of seaward migrating wild salmon smolts has been continued by trawling and by lice counting on smolts in sentinel pens along fjordic and coastal migration routes. Highest intensities of infestation have been recorded in intensive farming areas in fjords at the southwestern coast of Norway. However, results show large variations in louse prevalence and mean intensity between years and between fjords (Figure 3.7.1.4) possibly as a result of a combination of timing of de-lousing activities at the farms and hydrographical conditions in the fjords at the time of migration.

One of the objectives of a Russian pelagic fish survey conducted by the research vessel "F. Nansen" in the Norwegian Sea from 29 May to 26 July 2002 was to map the distribution of post-smolts in the Norwegian Sea. This survey is a part of an international research programme to study commercial species in the Norwegian and Barents Seas and is conducted on a yearly basis in May-July. Its target species are herring, blue whiting and mackerel. According to standard methods used in the international assessment of pelagic fisheries, hauls were taken by pelagic research trawl with an opening of 45 x 40 m and 24 mm mesh blinder. The trawl was not rigged with additional floats. Towing speed was from 3.2 to 5.1 kt, with a standard duration of hauls of 30-60 min. The whole catch was screened and each fish was handled and identified to species. In surface hauls the headline moved at depths from 0 to 5 m, and 65 of 85 hauls taken in the Norwegian Sea in June-July were such surface hauls. Of the 20 non-surface hauls, three were towed at depths of 190-290 m while another 17 varied in depth from 5 to 40 m. Figure 3.7.1.5 shows a map of the area covered during surveys in the Norwegian Sea. In June hauls were taken mainly in the southern part of the sea, while in July the middle part up to the island of Jan Mayen was covered. In June 30 hauls were taken (in 22 the headline was at depth 0-5 m), of which 14 contained mackerel. In July mackerel was found in 26 of 52 hauls (43 at depth 0-5 m). Mackerel catch varied from 1 to 600 kg, the average being 136 kg, and was mainly taken in hauls with the headline towed at depth 0-5 m. In one haul taken at a depth of 40 m a catch of 500 kg of mackerel was taken. The total catch of mackerel was 5.45 t. No by-catch of post-smolts was recorded in June, however one adult salmon was caught in the international waters (Figure 3.7.1.6). In July another two adult salmon were found in two hauls. One was caught in the Norwegian Economic Zone at the latitude of Jan Mayen at 14°E, another was a previous spawner caught in the international waters of the Norwegian Sea (Figure 3.7.1.6). July, when the research was conducted to the north of 66°N, was the most productive in terms of post-smolt by-catch: in four hauls on 8, 9 and 15 July 32 post-smolts were found (Figure 3.7.1.6). In the two most northern hauls (2 and 17 post-smolts) no mackerel were caught, while in the other two (2 and 11 post-smolts) the catch of mackerel was 3 and 28 kg, respectively.

3.7.2 By-catches of post-smolts and salmon

A Norwegian research cruise was dedicated to salmon and mackerel investigations both in the international area west and north of the Voeringplateau and the Norwegian EEZ (cruise 4; table 3.7.1.1.) in the Norwegian Sea (66°N – 69.7°N and 1°W – 17.4° E). During the by-catch investigations, 44 tows were carried out between 21st June and 1st July, yielding catches of 590 post-smolts, 8 salmon and 19,125 kg mackerel. Starting from the north and moving southwards, the post-smolt catches were medium to large at the beginning of the cruise and became smaller when approaching the 66°N. The captures in single tows were smaller in the Norwegian EEZ than in the international zone, but every haul contained post-smolts, while 56 % of the hauls in the international zone contained post-smolts (Table 3.7.1.2, Figure 3.7.2.1). Large catches of mackerel were made in the same tows. The mackerel sometimes filled up the cod end and the Fish-Lifter completely, and the post-smolts were badly damaged when found. The average CPUE was 10 post-smolts per trawl hour in the international zone and 11.9 in the Norwegian EEZ. 10 micro tagged, but no Carlin- tagged post-smolts were found (Section 3.7.1).

The mean CPUE (catch per trawl hour) for mackerel was 589 kg in the international zone while it was 224 kg in the Norwegian EEZ (Table 3.7.1.2). Calculation of the ratio of total number of post-smolts per kg mackerel in the international zone gave an estimate 0.026 post-smolts per kg captured in the Norwegian research fishery in 2002. This area was not surveyed in 2001. In the Norwegian EEZ the ratio in 2002 was 0.057 compared with 0.025 post-smolts per kg mackerel in 2001 (cf. Table 3.7.2.1.). The degree of spatial and temporal overlap between the mackerel distribution and the northward migration routes for the post-smolts from the Southern NEAC area and south- Norway were discussed in ICES (2002/ACFM:14), and the 2002 investigations confirm the earlier observations, although both mackerel and post-smolts had an earlier and more northerly to north westerly distribution than previously recorded at these cruises.

In 2002 the Russian Federation carried out a comprehensive programme to study potential by-catch of Atlantic salmon and post-smolts in the Russian mackerel fishery in the Norwegian Sea. In June-August 16 scientific observers and fisheries inspectors worked onboard Russian fishing vessels. Their tasks included, *inter alia*, screening of the mackerel catch for potential by-catch of Atlantic salmon. Catches by 20 of the nearly 50 Russian fishing vessels, which fished mackerel in the Faroese fishing zone and international waters in 2002, were scanned immediately on board during the discharging of the trawl catch into bins and at a ship factory during grading. The vessel's crew assisted in this work.

Catch from screened hauls varied from a few hundreds of kilos to 87 t. Average catch of mackerel per haul for inspected vessels was 17.5 t and varied from 2 t to 42 t among vessels. For catches of more than 10 t one to three samples of 3000 kg each were taken for screening. Catches from a total of 1070 hauls, or 25% of all hauls taken by the Russian vessels during the fishing season, were screened (Figure 3.7.2.2). The details of the screening are given in Table 3.7.2.2. As a result of considerable effort invested by the Russian Federation into screening of commercial catches of mackerel, 15 adult salmon (one of them carried a Swedish Carlin tag) and 12 post-smolts were recorded. The highest occurrence of post-smolts (0.065 per haul) was recorded in June, while in July this index was 0.015, and in August no post-smolts were found in the commercial catch. All by-catches of post-smolts, except one, and by-catches of salmon were taken along the 200-mile limit of Norway in the area with coordinates 65°30' - 66°30'N and 01°00'-03°00E (Figure 3.7.2.3 & 3.7.2.4).

The Working Group received information from Iceland on a by-catch of almost 200 salmon (1 – 2 kg) in a herring catch of 800 metric tonnes from the Spitsbergen area in August 2002. The fish were taken by a multi-gear-vessel in a mid-water trawl. One of the salmon caught was tagged as a smolt in the River Drammen, Norway. Historical information from the 1960s on by-catches of up to 30 salmon per haul in the herring fishery from Iceland was also presented to the Working Group. To date no assessment on by-catch rates in the herring fishery is available. The Working Group recommended that further research should be carried out on the potential of salmon being taken in the herring fisheries.

No specific land based sampling or screening for salmon post-smolts has been initiated in recent years in the Faroes. However, routine samples of catches of herring, blue whiting and mackerel from the purse-seiners landed to a fish-meal factory in the Faroes have not revealed any salmon by-catch. No post-smolts have been reported taken as by-catch in the herring fisheries north of the Faroes in 2002, based on reports from captains and crew on board Faroese purse-seiners.

Assessment of by-catch survey results

The discrepancy between the large numbers of post-smolts caught along with mackerel in the Norwegian research fishery (13.25 and 13.47 post-smolts per haul in late June in the Norwegian EEZ and international waters respectively) and the low by-catch levels observed in the commercial mackerel fishery (0.065, 0.015 and 0 post-smolts per haul in June, July and August respectively) may have a number of possible explanations:

- Detection rates may decrease with increasing sample size. Therefore the rate of non-detection may be higher in the Russian survey as larger numbers of fish were sampled in the catches. However, Russian samplers considered it unlikely that any considerable portion of adult salmon or post-smolts were overlooked during sampling.

- The Working Group noted that the research fishery, due to its directed nature (post-smolts predominantly) and the trawl methods used, may lead to over-estimation of the salmon by-catch in commercial pelagic fisheries.

- The major component of the post-smolts migrating with the western branch of the Norwegian current may have passed international waters before a large-scale mackerel fishery starts there. In contrast, the research fishery specifically tries to sample the peak post-smolt migration in these areas.

- There are substantial differences between the Norwegian research trawl and the gear used in the commercial mackerel fishery. In particular, the research trawl is much smaller, is fished closer to the surface and is towed more slowly than the commercial gear. It has been speculated that post-smolts migrate very close to the surface and may thus avoid the commercial gear. However, the behaviour of post-smolts in relation to these different gears is not known. The extent to which post-smolts may be lost through the larger mesh in the cod end of commercial trawls (40mm as opposed to 20mm) is also not clear.

Research requirements

Given the large differences between the results from the Norwegian by-catch studies in 2001-02 and the Russian research trawling and screening of commercial catches, the Working Group agreed it was necessary to continue to collect data on the biology and distribution of post-smolts and older Atlantic salmon in the sea. In particular, scientific surveys of pelagic fish species in the Barents and Norwegian Seas were needed to collect data on by-catches of salmon from commercial vessels. The Working Group recommended that:

- Efforts should be made to inter-calibrate the CPUE for different trawling methods, in particular research gears against commercial trawls, to provide a better basis for assessing levels of by-catch.

- Studies on post-smolts and older salmon should be extended to elucidate behaviour patterns at sea and to investigate their behaviour in relation to different commercial gear types (e.g. pelagic trawls, purse seines).

- The Planning Group on Surveys on Pelagic Fish in the Norwegian Sea (PGSPFN) should consider intensive screenings of pelagic research hauls for the presence of post-smolts (small salmon in their 1st year at sea, generally < 45cm) and older salmon.

- Surveys should be extended to provide better temporal and spatial information on the distribution of post-smolts in relation to pelagic fisheries.

- Experimental trawling surveys should be conducted to evaluate the vertical distribution of post-smolts and older salmon in the sea, if possible in combination with tagging of post-smolt and salmon with depth and temperature recording tags (DSTs).

- The Working Group requests that ICES should make available the commercial catches of mackerel and herring in the Norwegian Sea (ICES Divisions IIa and Vb), Northern North Sea (Division IVa), and the west of Ireland and Scotland (Divisions VI a & b; VII b,c,j & k) by ICES Division and standard week.

- The Working Group requests that ICES should make available the number of boats and gear types used in the commercial fishery of mackerel, herring and horse mackerel and blue whiting in the Norwegian Sea (ICES Divisions IIa and Vb), Northern North Sea (Division IVa), and the west of Ireland and Scotland (Divisions VI a & b; VII b,c,j & k) by ICES Division and standard week.

3.7.3 Description of mackerel and other commercial pelagic fisheries

A detailed description of the mackerel fishery was provided by the Russian Federation and is presented in this section. No other details of fisheries were provided to the Working Group, and the descriptions below are taken from the reports of the Working Group on Mackerel, Horse Mackerel, Sardine and Anchovy (WGMHSA 2003/ACFM:07) and Working Group on Northern Pelagics and Blue Whiting (WGNPBW 2002/ACFM:19).

Russian mackerel fishery: Over the period of 1977 – 2001 the Russian fishery for mackerel in the Norwegian Sea starts in the south-eastern part of the Faroese fishing zone in May-June, and follows the migrations of fish northward and north-eastward into the international waters of the Norwegian Sea. In July-August, when most of the catch is taken, the fishery is conducted in the north-eastern part of the Faroese fishing zone and international waters of the Norwegian Sea (Figure 3.7.3.1). Recently a total catch limit for mackerel includes a quota for the Faroese fishing zone allocated to Russia within the Russian-Faroese Fisheries Commission, a quota for the international waters allocated to Russia within NEAFC and allowed level of by-catch in the blue whiting fishery in the Norwegian economic zone.

In 2002 the Russian fishery for mackerel in the Faroese fishing zone started in the end of June in the area between 62°30 and 64°00N and from 4°30 to 9°00W. In July the fishery moved towards the 200-mile limit of Norway and took place in the area between 62°40 and 63°30N and from 4°30W to the 200-mile limit of Norway. In August a small group of vessels continued fishing in the same area until the middle of that month (Figure 3.7.3.2). In the international waters the fishery also began in the end of June and was prosecuted along the economic zone of Norway in the area between 65°30 and 66°30N. In June only 94 hauls were done in the international waters. In July the vessels were operating, mostly, near the 200-mile limit of Norway from the border between the zones to 67°N and 2-3°W in the west. In August fishery of mackerel mostly took place in the first half of the month along the 200-mile limit of Norway between 64°30 and 68°00N. In the south the vessels were operating along the northern boundary of the Faroese fishing zone (Figure 3.7.3.2).

The largest catches of mackerel were taken in the south-eastern section of the international waters, along the boundary of the Norwegian economic zone, south of 67°N. 5.5% of the total catch was fished in June (937 t or 2.4% in the international waters), and most of the catch (75.5%) was taken in July. Such a distribution of catch by month and area is typical of the history of the Russian mackerel fishery since 1977 (Figure 3.7.3.1).

Presently, in the fishery of mackerel in the Norwegian Sea the Russian fishing vessels use a midwater rope trawl, where ropes in mesh in the front part of the trawl can be as long as 3 to 25 meters. The length of the rope part in trawl used in the mackerel fishery can vary from 100 to 200 m. With the length of the rope part of the trawl of 100 m a small mesh retaining part is 14 m deeper (depth of net with the mesh size less than 800-400 mm) than the headline, and with the increase of the length of the rope part to 200 m, its depth increases to 28 m. The highest efficiency is achieved when the trawl has a horizontal opening of 50 to 120 m and a vertical opening of 40-70 m. Trawls are towed at a speed of 4.8 to 6.5 kt. A minimal mesh size in the blinder is 40 mm. Figure 3.7.3.3 shows a drawing of the midwater trawl used by Russian vessels in the mackerel fishery.

There are many pelagic fisheries going on in the Atlantic, and the Working Group has included only those few possibly relevant for by-catch of salmon in the descriptions.

Mackerel: The total estimated mackerel catch in 2001 was about 678,000 t (ICES CM 2003/ACFM:07). The catches per quarter are shown per statistical rectangle in Figure 3.7.3.4. 38% of the total catch was taken during the 1st quarter as the shoals migrate from Div. IVa through Sub-area VI to the main spawning areas in Sub-area VII. The proportion of the total catch taken in Quarter 2 increased slightly to 7%. 25% of the total catch was taken during Quarter 3 this is a similar pattern as in 2000. The main catches in the second quarter were taken from the summer feeding areas in Division IIa and IVa. During Quarter 4, 30% of the total catch was taken mainly from Division IVa. The main catches of southern mackerel are taken in VIIIc (83%) and these are mainly taken in the first quarter. Catches from IXa, which comprise 17% of southern mackerel catches, are mainly taken in the first and third quarters. Both purse-seiners and trawlers are used in the fishery.

Norwegian spring spawning herring: The catches of Norwegian spring-spawning herring by all countries in 2001 by ICES rectangles are shown in Figure 3.7.3.5 (per quarter). In 2001 the catch provided as catch by rectangle represented approximately 756,845 tonnes or 98.3% of the total catch. In general the development of the international fishery shown by these figures follows the known migration pattern for Norwegian spring-spawning herring (ICES CM 2002/ACFM:19). Both purse-seiners and trawlers are used in the fishery.

Blue-Whiting: Estimates of the total landings of blue whiting in 2001 by various fisheries of 1 780 000 were the highest ever and were 368,000 t more than the total landings of 1,412,000 t in 2000 (ICES CM 2002/ACFM:19). Total landings for 1999 were 1,256,000 tonnes. As in previous years, nearly 60% of blue whiting catches were taken in the spawning area. The catch there was 1,044,000 t in 2001 compared to 997,000 t in 2000, representing a slight increase of 5% from 2000 to 2001. Blue whiting is caught by different gears and mesh sizes and can be grouped in two types of fisheries: a directed fishery, where by-catches of other species are insignificant; a mixed fishery, where varying proportions of blue whiting are caught together with Norway pout or other species. As in previous years, the predominant part (1,676,000 t or 94%) of the total landings in 2001 was taken in the directed fishery and 104 000 t taken as by-catch in other fisheries, such as the Norway pout fishery. Most (74,000 t) of the by-catch of blue whiting is taken in the North Sea. The fishery in 2001 took place mainly in the second and third quarter (Figure 3.7.3.6). In the first quarter the fishery occurred on the spawning grounds from the Porcupine Bank to Rockall. The fishery continued in the area west of Rockall and in the shelf area off the Hebrides. In the second quarter the fishery was conducted mainly in Division VIa and in Division Vb and southeast of Iceland. During summer and autumn a significant fishery also took place in the southern part of the Norwegian Sea. The landings from the Norwegian Sea (Divisions I and II) and the area southeast of Iceland between Iceland and the Faroe Islands increased from 277,000 t in 2000 to 592,000 t in 2001.

Horse mackerel fishery: The total catch from all areas in 2001 was 283,300 tons, which is 11,000 tons more than in 2000 which was the lowest catch since 1988 t (ICES CM 2003/ACFM:07). Some countries have a directed trawl fishery and some a directed purse seine fishery for horse mackerel. Some nations conduct both trawl and purse seine fishery. The quarterly distributions of the fisheries are given in Figure 3.7.3.7.

Icelandic summer-spawning herring fishery: In 2001 the fishery started in September and terminated in January (ICES CM 2002/ACFM:19). The catch in September-January was 95,278 t. The catch was taken with traditional purse-seines and pelagic trawls. The main purse-seine fishery took place off the east coast of Iceland in September-November and only minor quantities were taken west of Iceland in October-January. The pelagic trawl fishery started in September, which is unusually early, but only 2,500 t were taken east of Iceland throughout the month. In October-January the pelagic trawl fishery took place both in the east and the west of Iceland.

Capelin fishery in the Iceland-East Greenland-Jan Mayen area: Over the years, fishing has not been permitted during April-June and the season has been opened in July/August or later, depending on the state of the stock (ICES CM 2002/ACFM:19). 2001 the fishery opened on 20 June and began in deep waters north of the shelf edge northeast and north of Iceland. As usual the fishery gradually shifted to the northwest and north in July. By the end of July, the total catch was 276,000 t. After July the capelin remained scattered and few catches were made for the rest of the year, except for 18,000 t taken in December. In January 2002, large fishable concentrations of adult capelin were located in deep waters off the shelf east of Iceland and resulted immediately in a successful fishery. The total catch during the 2002 winter season was 955,000 t, the highest on record.

3.8 Data deficiencies and research needs in the NEAC area

Data deficiencies and research needs for the NEAC area are presented in section 6.

[1] Common licence for salmon and seatrout introduced in 1986 leading to a short-term increase in the number of licences issued.

[2] Since 1987 fishermen have been obliged to declare their catches.

[3] This figure is an estimate from a sample of anglers, the sea trout and salmon angling licenses being common since 2000

[4] The number of licences, 1999 included, indicates only the number of fishermen or boats allowed to fish for salmon. It overestimates the actual number of fishermen fishing for salmon up to 2 or 3 times.

[5] Adour estuary only southwest of France.

[6] (2002/mean - 1) * 100

[7] Estimated from from licences sold to migratory salmonid fisheries.

[1] Microtags.
[2] Carlin tags, not corrected for tagging mortality.
[3] Microtags, corrected for tagging mortality.
[4] Assumes 50% exploitation in rod fishery.
[5] Minimum estimates.
[6] From 0+ stage in autumn.
[7] Incomplete returns.
[8] Assumes 30% exploitation in trap fishery.

4 NORTH AMERICAN COMMISSION

4.1 Description of Fisheries

4.1.1 Gear and effort

Canada

The 23 areas for which the Department of Fisheries and Oceans (DFO) manages the salmon fisheries are called Salmon Fishing Areas (SFAs); for Québec, the management is delegated to the Société de la Faune et des Parcs du Québec and the fishing areas are designated by Q1 through Q11 (Figure 4.1.1.1). Harvest (fish which are killed and retained) and catches (including harvests and fish caught-and-released in recreational fisheries) are categorized in two size groups: small and large. Small salmon, generally 1SW, in the recreational fisheries refer to salmon less than 63 cm fork length, whereas in commercial fisheries, it refers to salmon less than 2.7 kg whole weight. Large salmon, generally MSW, in recreational fisheries are greater than or equal to 63 cm fork length and in commercial fisheries refer to salmon greater than or equal to 2.7 kg whole weight.

Three user groups exploited salmon in Canada in 2002: Aboriginal peoples, residents fishing for food in Labrador, and recreational fishers. Commercial quotas normally fished by Aboriginal peoples in Ungava Bay (zone Q11) remained closed. Hence there were no commercial fisheries in Canada in 2002.

The following management measures were in effect in 2002:

Aboriginal peoples' food fisheries:

In Québec, Aboriginal peoples' food fisheries took place subject to agreements or through permits issued to the bands. There are 10 bands with subsistence fisheries in addition to the fishing activities of the Inuit in Ungava (Q11), who fished in estuaries or within rivers. The permits generally stipulate gear, season, and catch limits. Catches for subsistence fisheries have to be reported collectively by each Aboriginal user group. However, if reports are not available, the catches are estimated. In the Maritimes and Newfoundland (SFAs 1 to 23), food fishery harvest agreements were signed with several Aboriginal peoples groups (mostly First Nations) in 2002. The signed agreements often included allocations of small and large salmon and the area of fishing was usually in-river or estuaries, except in Labrador. Harvests which occurred both within and outside agreements were obtained directly from the Aboriginal peoples. In Labrador (SFAs 1 and 2), food fishery arrangements with the Labrador Inuit Association and the Innu resulted in fisheries in estuaries and coastal areas. There were no food fisheries on the island of Newfoundland in 2002. Under agreements reached in 2002, several Aboriginal communities in Nova Scotia agreed to retain only "adipose clipped" 1SW salmon from five Atlantic coast rivers (Musquodoboit, Sackville, Mushamush, LaHave, and Tusket) in SFA's 20 and 21, using methods that allowed live release of wild fish. Harvest by Aboriginal peoples with recreational licenses are reported under the recreational harvest categories.

Residents food fisheries in Labrador:

In the Lake Melville (SFA 1) and the coastal southern Labrador (SFA 2) areas, DFO allowed a food fishery for local residents. Residents who requested a license were permitted to retain a maximum of four salmon of any size while fishing for trout and charr; four salmon tags accompanied each license. All licensees were to complete logbooks.

Recreational fisheries:

Unless otherwise determined by management authorities, licenses are required for all persons fishing recreationally for Atlantic salmon, gear is generally restricted to fly fishing and there are restrictive daily/seasonal bag limits. Recreational fisheries management in 2002 varied by area (Figure 4.1.1.2). Except in Québec and Labrador (SFA 1 and some rivers of SFA 2), only small salmon could be retained in the recreational fisheries.

The seasonal bag limits in the recreational fishery remained at eight small salmon in New Brunswick and in Nova Scotia. In SFA 16 and in Nepisiquit River (SFA 15) of New Brunswick, the small salmon daily retention limit remained at one fish. In the remainder of SFA 15 and in Nova Scotia (SFA 18), the daily retention limits were two small salmon. The maximum daily catch limit was four fish daily. In SFA 17 (PEI), the season and daily bag limits were seven and one respectively. Catch-and-release fishing only for all sizes of Atlantic salmon was in effect in SFA 19 of Nova Scotia. In SFAs 20-23 of Nova Scotia and New Brunswick, most rivers were closed to all salmon angling, except for four acid-impacted rivers on the Atlantic coast of Nova Scotia, where retention of small salmon was allowed. As well, eight Atlantic coast rivers of Nova Scotia were opened for a hook and release fishery from June 1 to July 15 in 2002.

A five-year (2002-2006) management plan was introduced in Newfoundland and Labrador in 2002, based upon the river classification system utilized for SFAs 3-14B in 1999-2001. For insular Newfoundland (SFAs 3 to 14A) and the Strait of Belle Isle of Labrador (SFA 14B), retention limits ranged from a seasonal limit of six fish on Class I rivers, to no retention and catch-and-release only on Class IV rivers . Some rivers were closed to all angling and were not assigned a class number. In SFA 1 and some rivers of SFA 2 of Labrador, there was a seasonal limit of four fish, only one of which could be a large salmon, except in those rivers (now Class II) of SFA 2 crossed by the new Trans Labrador Highway, where a seasonal retention limit of two small salmon and no large salmon was imposed.

In Québec, three different fishing permits are sold. The first allows a landing total of seven salmon for the season. The second is a one day permit and allows a landing total of two salmon. The third type of permit is for catch and release only. In the northern zones, the management regimes for Q8,Q9 and Q11 (44 rivers) were applied uniformly to rivers within each zone. Retention of both small and large salmon was generally allowed throughout these northern zones. However fishing was not permitted on the Matamec River and only small salmon could be retained in the sport fishery on the Mingan River. The daily limit was two fish in Q8 and Q9, and one fish in zone Q11. Release of large salmon occurred mainly on a voluntary basis in these zones. The 74 rivers of the southern zones were managed river by river. Fishing was not allowed on 29 rivers, retention of small salmon only was in force on 22 rivers, and retention of small and large salmon was allowed on 23 rivers at the start of the season. However, on these 23 rivers, 16 were further restricted to retention of small salmon only after mid-season reviews.

USA

There was no fishery for sea-run Atlantic salmon in the USA as a result of angling closures in 1999. Therefore effort measured by license sales was zero.

France (Islands of Saint-Pierre and Miquelon)

For the Saint-Pierre and Miquelon fisheries in 2002, there were 12 professional and 42 recreational gillnet licenses issued. Since 1997, the number of professional fishermen has doubled from six to 12 and the number of recreational licenses has increased by six to 42.

Year	Number of Professional Licenses	Number of Recreational Licenses
1995	12	42
1996	12	42
1997	6	36
1998	9	42
1999	7	40
2000	8	35
2001	10	42
2002	12	42

There is no legal limit on the number of professional and recreational licences. However, local authorities have restricted these numbers to 12 (professional) and 42 (recreational) so far, based on the maxima observed since the beginning of the statistics recording on salmon fishing at SPM in 1990.

Due to a sharp decline in other fish resources exploited by the professional fishermen (lumpfish, snow crab and cod), more of them have expressed interest in having salmon licenses and have asked for an increase in the number of licences that could be compensated by a reduction in the number of recreational licences.

4.1.2 Catch and catch per unit effort (CPUE)

Canada

The provisional harvest of salmon in 2002 by all users was 148 t, the same as the 2001 harvest (Table 2.1.1.1; Figure 4.1.2.1). The 2002 harvest was 53,832 small salmon and 8,401 large salmon, 5% more small salmon and 27% fewer large salmon, compared to 2001 (Table 4.1.2.1). The dramatic decline in harvested tonnage since 1988 is in large part the result of the reductions in commercial fisheries effort, the closure of the insular Newfoundland commercial fishery in 1992, the closure of the Labrador commercial fishery in 1998, and the closure of the Québec commercial fishery in 2000 (Figure 4.1.2.1). These reductions were introduced as a result of declining abundance of salmon.

The 2002 harvest of small and large salmon, by number, was divided among the three user groups in different proportions depending on the province and the fish-size group exploited (Table 4.1.2.1). Newfoundland reported the largest proportion of the total harvest of small salmon and Québec reported the greatest share of the large salmon harvest. Recreational fisheries exploited the greatest number of small salmon in each province, accounting for 83% of the total small salmon harvests in eastern Canada. Unlike years previous to 1999 when commercial fisheries took the largest share of large salmon, food fisheries (including the Labrador resident food fishery) accounted for the largest share in 2002 (69% by number).

Aboriginal peoples' food fisheries:

Harvests in 2002 (by weight) were up 9 % from 2001 and 3 % above the previous 5-year average harvest.

Aboriginal peoples' food fisheries			
		% large	
Year	**Harvest (t)**	**by weight**	**by number**
1990	31.9	78	
1991	29.1	87	
1992	34.2	83	
1993	42.6	83	
1994	41.7	83	58
1995	32.8	82	56
1996	47.9	87	65
1997	39.4	91	74
1998	47.9	83	63
1999	45.9	73	49
2000	45.7	68	41
2001	42.1	72	47
2002	45.9	68	43

Residents fishing for food in Labrador:

The estimated catch for the entire fishery in 2002 was 5.9 t, about 2,700 fish (83% small salmon by number).

Recreational fisheries:

Harvest in recreational fisheries in 2002 totalled 47,140 small and large salmon, 5 % below the previous 5-year average and 4 % below the 2001 harvest level and the lowest total harvest reported (Figure 4.1.2.2). The small salmon harvest of 44,518 fish was about the same as the previous 5-year mean. The large salmon harvest of 2,622 fish was a 51 % decline from the previous five-year mean. Small and large salmon harvests were up 3 % and down 53 % from 2001, respectively. The small salmon size group has contributed 87% on average of the total harvests since the imposition of catch-and-release recreational fisheries in the Maritimes and insular Newfoundland (SFA 3 to 14B, 15 to 23) in 1984 (Figure 4.1.2.2).

In 1984, anglers were required to release all large salmon in the Maritime provinces and insular Newfoundland. Changes in the management of the recreational fisheries since 1984 have compromised the use of angling catches as indices of abundance. Therefore, the interpretation of trends in abundance relies mostly on rivers where returns have been estimated or completely enumerated. Caught-and-released fish are not considered equivalent to retained fish and their inclusion in catch statistics further compromises the reliability of interpretation of trends. In more recent years, anglers have been required to release all salmon on some rivers for conservation reasons and, on others, they are voluntarily releasing angled fish. In addition, numerous areas in the Maritimes Region in 2002 were closed to retention of all sizes of salmon (Figure 4.1.1.2).

Hook-and-release salmon fisheries:

In 2002, about 54,400 salmon (about 18,700 large and 35,700 small) were caught and released (Table 4.1.2.2), representing about 54% of the total number caught, including retained fish. This was a 7 % decrease from the number released in 2001. Most of the fish released were in Newfoundland (53 %), followed by New Brunswick (33%), Québec (10%), Nova Scotia (4%), and Prince Edward Island (0.4%). Expressed as a proportion of the fish caught, that is, the sum of the retained and released fish, Nova Scotia released the highest percentage (87%), followed by Prince Edward Island (67%), New Brunswick (57%), Newfoundland (55%), and Québec (37%). As has been mentioned in Section

2.1.2, there is some mortality on these released fish, which is accounted for when individual rivers are assessed for their attainment of conservation limits.

Commercial fisheries:

All commercial fisheries for Atlantic salmon were closed in Canada in 2002 and the catch therefore was zero. Catches have decreased from a peak in 1980 of almost 2,500 t to zero currently as a result of effort reductions, low abundance of stocks, and closures of fisheries.

Unreported catches:

Canada's unreported catch estimate for 2002 was about 83 t. Estimates were included for four of five provinces as no estimates were available for New Brunswick. Estimates provided for Newfoundland and Labrador were the same as those estimated in 2001 and estimates were available for only three of five SFAs in Nova Scotia. Estimates were provided mainly by enforcement staff. In all areas, most unreported catch arises from illegal fishing or illegal retention of bycatch of salmon.

By stock groupings used for Canadian stocks throughout the report, the unreported catch estimates for 2002 were:

Stock Area	Unreported Catch (t)
Labrador	4
Newfoundland	45
Gulf	< 1
Scotia-Fundy	< 1
Québec	34
Total	83

USA

All fisheries (commercial and recreational) for sea-run Atlantic salmon within the USA are now closed, including rivers previously open to catch-and-release fishing. Thus, there was no harvest of sea-run Atlantic salmon in the USA in 2002. Unreported catches in the USA were estimated to be zero t.

France (Islands of Saint-Pierre and Miquelon)

The harvest in 2002 was reported to be 3.6 t from professional and recreational fishermen, 67% higher than in 2001 and the largest catch recorded since before 1960 (Table 2.1.1.1). Professional and recreational fishermen reported catching 2,437 kg and 1,153 kg of salmon, respectively. There was no estimate available of unreported catch for 2002.

Year	Catch by Professional Licenses (kg)	Catch by Recreational Licenses (kg)	Total (kg)
1990	1,146	734	1,880
1991	632	530	1,162
1992	1,295	1,024	2,319
1993	1,902	1,041	2,943
1994	2,633	790	3,423
1995	392	445	837
1996	951	617	1,568
1997	762	729	1,491
1998	1,039	1,268	2,307
1999	1,182	1,140	2,322
2000	1,134	1,133	2,267
2001	1,544	611	2,155
2002	2,437	1,153	3,590

4.1.3 Origin and composition of catches

In the past, salmon from both Canada and the USA have been taken in the commercial fisheries of eastern Canada. These fisheries have been closed. The Aboriginal Peoples' and resident food fisheries that exist in Labrador may intercept some salmon from other areas of North America although there are no reports of tagged fish being captured there in 2002. The fisheries of Saint-Pierre and Miquelon catch salmon of both Canadian and US origin (section 4.6). Little if any sampling occurs in these remaining fisheries.

Fish designated as being of wild origin are defined as the progeny of fish where mate selection occurred naturally (eggs not stripped and fertilized artificially) and whose life cycle is completed in the natural environment (ICES 1997/Assess:10). Hatchery-origin fish, designated as fish introduced into the rivers at any life stage, were identified on the basis of the presence of marks or an adipose clip, from fin deformations, and/or from scale characteristics. Not all hatchery fish could be identified as such in the returns because of stocking in the early life stages. Commercial fish-farm escapees were differentiated from hatchery fish on the basis of scale characteristics and fin erosion (especially of the tail).

The returns in 2002 to the majority of the rivers in Newfoundland and to most rivers of the Gulf of St. Lawrence and Québec were comprised exclusively of wild salmon (Figure 4.1.3.1). Hatchery-origin salmon made up varying proportions of the total returns and were most abundant in the rivers of the Bay of Fundy, the Atlantic coast of Nova Scotia and the USA. Aquaculture escapees were noted in the returns to five rivers of the Bay of Fundy and the coast of USA (Saint John, Magaguadavic, St. Croix, Dennys, Union).

Aquaculture production of Atlantic salmon in eastern Canada has increased annually, exceeding 10,000 t in 1992 and rising to over 34,000 t in 2002 (Table 2.2.1.1). Escapes of Atlantic salmon have occurred annually. Reports of these escapes have not been made available to the Working Group.

In the Magaguadavic River (SFA 23; Table 4.1.3.1), which is located in close proximity to the center of both the Canadian and USA east coast salmon farming areas, the proportion of the adult run composed of fish farm escapees has been high (greater than 50%) since 1994. Escaped fish were not observed between 1983 and 1988. Since 1992, escaped fish have comprised between 33% and 90% of adult salmon counts. However, while fish farm escapees have dominated the run in terms of percentages, in absolute terms, their numbers have been trending downwards, with the exception of 2000 (Table 4.1.3.1). Fish farm escapees were also monitored in the St. Croix River (Canada/USA border), and Maine's Dennys, Narraguagus and Union rivers. The St. Croix and Dennys rivers are also in close proximity to the principal USA and Canadian salmon farming areas, whereas the Narraguagus and Union are more to the south, but have a few farm sites located in their vicinity. Percentages of returns that were fish farm escapees in the returns to the St. Croix and Dennys rivers in 2002 were 66% and 20% respectively. In the Union and Narraguagus rivers, fish farm escapees in 2002 made up 55% and 0% of the runs, respectively.

4.1.4 Exploitation rates in Canadian and USA fisheries

Canada

There is no exploitation by commercial fisheries and the only remaining fisheries are for recreation and food.

In the Newfoundland recreational fishery, exploitation rates were available for 12 rivers in 2002. For those rivers with retention of small salmon, exploitation rates ranged from 7% to 41% with a mean value of 14%. All values were about the same as those from 2001.

In the Québec recreational fishery, exploitation rates were available for 38 rivers. Exploitation rates of small salmon ranged from 3% to 69% with a mean value of 38%. Retention of large salmon was permitted on 20 of those rivers; exploitation rate for large salmon ranged from 1% to 25% with a mean value of 12%. Overall exploitation rates by the Québec recreational fishery, using mid-point estimates of total returns and recreational landings, were 23% for small salmon and 8% for large salmon.

In previous years, overall Canadian exploitation rates were calculated as the harvest of salmon divided by the estimated returns to North America. No estimates of returns to Labrador are possible for 1998 - 2002, as there was no commercial fishery and there was insufficient information collected on freshwater escapements to extrapolate to other Labrador rivers. For this reason, exploitation rates cannot be calculated for 1998 - 2002. Harvests of 53,832 small and 8,401 large salmon in 2002 were less than those of 1997, substantially in the case of large salmon. Exploitation rates in 1997 were estimated to be between 14% and 26% for small and between 15% and 25% for large salmon.

USA

There was no exploitation of USA salmon in homewaters, and no salmon of USA origin were reported in Canadian fisheries in 2002.

4.2 Status of Stocks in the North American Commission Area

There are approximately 550 Atlantic salmon rivers in eastern Canada and 21 rivers in eastern USA each of which could contain at least one population of salmon. Assessments are prepared for a limited number of specific rivers, because they compose significant fractions of the salmon resource or are indicators of patterns within a region, or because of the demands by user groups, or as a result of requests for biological advice from fisheries management. The status is evaluated by examining trends in returns and escapement relative to the conservation requirements.

4.2.1 Measures of abundance in monitored rivers

Canada

1985-2002 patterns of adult returns:

The returns represent the size of the population before any in-river and estuarine removals (Figure 4.2.1.1). These returns can include returns from hatchery stocking but do not account for commercial fisheries removals in Newfoundland, Labrador, Québec, and Greenland. A gradual moratorium closed the Newfoundland, Labrador and Québec commercial salmon fisheries in Canada between 1992 and 2000.

Annual returns of salmon by size group are available for 22 rivers in eastern Canada since 1985. Peak return years differed for regions within eastern Canada (Figure 4.2.1.1). For rivers in Scotia-Fundy, Gulf, and Québec regions, the returns have been generally decreasing since the closures of the Newfoundland and Québec commercial fisheries, showing that factors other than fisheries are influencing marine mortality. Alternatively, the returns to seven rivers in Newfoundland have generally increased since the commercial fisheries closures there in 1992. These Newfoundland stocks mainly mature at 1SW age and seem to have been more heavily affected by the local commercial fisheries. The large salmon are mostly repeat-spawning 1SW fish. The total returns of these seven Newfoundland rivers doubled during 1993 to 2001 from the low levels observed during 1989 to 1991 period (Figure 4.2.1.1).

The returns for 2002 of large salmon in Scotia-Fundy, Gulf, and Québec regions were down by 68, 48, and 31% respectively from 2001, down 66, 43, and 24% respectively from the recent five year average and are at their lowest levels observed during the last 15 years. Large salmon decreased (24%) also in Newfoundland to the lowest value since 1998 and were 39% lower than the recent five year average (Figure 4.2.1.1). Returns of small salmon in 2002 relative to 2001 for the rivers of Newfoundland were approximately the same as 2001 and 27% lower than the recent five year average. In Scotia-Fundy,Gulf, and Québec regions, the returns in 2002 of small salmon increased by 68, 39 and 63 %, respectively from 2001. In Scotia-Fundy the 2002 small salmon return was about equal to the recent five year average, whereas in Gulf and Québec, the small salmon returns were 34 and 41%, respectively, higher than the five year average.

Smolt and juvenile abundance:

Counts of smolts provide direct measurements of the outputs from the freshwater habitat. Previous reports have documented the high annual variability in the annual smolt output. In tributaries, smolt output can vary by five times but in the counts for entire rivers, annual smolt output has generally varied by a factor of three. Wild smolt production was estimated in 10 rivers of eastern Canada in 2002. Of these, nine rivers have several years of data (Figure 4.2.1.2). In numerous other rivers, juvenile abundance surveys have been conducted.

In 2002, smolt production improved from the previous year in only two of five monitored rivers in Newfoundland, decreased in both rivers of Québec, and improved in two of three rivers in the Maritimes Provinces (Figure 4.2.1.2). In only three of these monitored rivers was smolt production in 2002 above the previous five-year mean (or the maximum number of years available in that period). These three rivers were all located in Newfoundland.

Juvenile salmon abundance has been monitored annually since 1971 in the Miramichi (SFA 16) and Restigouche (SFA 15) rivers and for shorter and variable time periods in other rivers (Figure 4.2.1.3). In the rivers of the southern Gulf, densities of young-of-the-year (fry) and parr (juveniles of one or more years old) have increased since 1985 in response to increased spawning escapements (Figure 4.2.1.3). Densities of parr in 2002 remained at high values in the both the Southwest and Northwest Miramichi. In the Restigouche River, both fry and parr densities increased and remained higher than average values since 1986. Rivers of SFAs 20 and 21 along the Atlantic coast of Nova Scotia are generally organic stained, of lower productivity, and, when combined with acid precipitation, can result in acidic conditions lethal to salmon. Prognoses for salmon populations in 47 of 65 of these rivers indicate that 40 populations are likely to be extirpated if the trend in low annual marine survival of salmon persists. In the low-acidified St. Mary's River, fry (age 0+) density was at its lowest and older parr (age-1+ and 2+) densities remain low (Figure 4.2.1.3). Trends in densities of age-1+ and older parr in the outer Bay of Fundy (SFA 23) have varied since 1980. Parr densities in the Nashwaak River and Saint John River above Mactaquac Dam have generally declined in accordance with reduced spawning escapements. Although densities increased in 2001, they declined again in 2002 to either average and low values (Nashwaak) or to record lows (Saint John above Mactatquac). During the same period, densities in the Hammond River that have periodically increased since 1984, have now decreased in 2002 to among the lowest values recorded during the past 10 years.

The salmon stock in 33 rivers of the inner Bay of Fundy (SFA22 and a portion of SFA 23) was listed as Endangered by the Committee on the Status of Endangered Wildlife in Canada in 2000 (Section 4.2.6). Juvenile densities remained critically low in 2002.

USA

2002 Adult Returns

Total estimated return to USA rivers was 985. These are the sum of documented returns to traps and returns estimated using redd counts on selected Maine rivers. However, the documented return of Atlantic salmon as determined strictly from returns to traps and weirs in New England was 962. Returns of 1SW salmon were 436, a 64% increase from the 266 in 2001. Returns of MSW salmon were 526, a 32% decrease from the 797 in 2001. Total salmon returns to the rivers of New England continued the downward trend that began in the mid-1980s, and were lower than the previous 5-year and 10-year averages (Figure 4.2.1.4). These are minimal estimates, since many rivers in Maine do not contain fish counting facilities, and where counting facilities exist, they do not count 100% of the returns.

For five of the eight rivers that comprise the Endangered Gulf of Maine Distinct Population Segment (DPS), redd counts were used to estimate returns because traps or weirs were not present. The total estimated returns in 2002 for the entire DPS was 33 (95% CI = 23-46) originated either from natural spawning or hatchery fry, with two rivers having an estimate of zero. These numbers are down from the 2001 estimates of 98 (95% CI = 81-122) with two rivers having an estimate of zero.

The majority of the returns were recorded in the rivers of Maine, with the Penobscot River accounting for nearly 79% of the total New England returns. The Connecticut River returns accounted for 4.6% of the total and 44% of the adult returns outside Maine. Overall, 46% of the adult returns were 1SW salmon and 54% were MSW salmon. Most returns (88%) originated from hatchery smolts and the balance (12%) originated from either natural spawning or hatchery fry.

4.2.2 Estimates of total abundance by geographic area

For assessment purposes, the following regions were considered: Labrador (SFA 1, 2, & 14B), Newfoundland (SFA 3−14A), Québec (Q1-Q11), Gulf of St. Lawrence (SFA 15-18), Scotia-Fundy (SFA 19-23), and USA. Returns of 1SW and 2SW salmon to each region (Tables 4.2.2.1 and 4.2.2.2; Figures 4.2.2.1 and 4.2.2.2; and Appendix 5) were estimated by updating the methods and variables used by Rago *et al.* (1993b) and reported in ICES 1993/Assess:10. The returns for both sea-age groups were derived by applying a variety of methods to data available for individual river systems and management areas. These methods included counts of salmon at monitoring facilities, population estimates from mark-recapture studies, and the application of angling and commercial catch statistics, angling exploitation rates, and measurements of freshwater habitat (Appendix 5). The 2SW component of the MSW returns was determined using the sea-age composition of one or more indicator stocks.

In the context used here "returns" are the number of salmon that returned to the geographic region, including homewater commercial fisheries, except in the case of the Newfoundland and Labrador regions where returns do not include commercial fisheries. This was done to avoid double counting of fish when commercial catches in Newfoundland and Labrador are added to returns of all geographic areas in North America to create the PFA of North American salmon.

Canada:

Labrador:

The basis for estimates of 2SW and 1SW salmon returns and spawners for Labrador (SFAs 1, 2 & 14B) prior to 1998 are catch data from angling and commercial fisheries. In 1998-2002, there was no commercial fishery in Labrador and although counting projects took place in 2002 on four Labrador rivers, out of about 100 salmon rivers that exist, it is not possible to extrapolate from these rivers to unsurveyed ones. For Labrador, returns were previously estimated from commercial catches and exploitation rates. As there was no commercial fishery since 1998, it was not possible to estimate the returns or spawners to Labrador for these years.

Newfoundland:

The estimates of 1SW and 2SW returns and spawners for insular Newfoundland (SFAs 3−12 & 14A) are updated for the entire time-series. Prior to 1999, they were derived from exploitation rates estimated from rivers with counting facilities which were subsequently applied to angling catches of small salmon, adjusted for the proportions of large:small salmon at counting facilities, and finally the proportion of large salmon that were 2SW. Beginning in 1999, the method used in previous years was modified to take into consideration the changes implemented in the 1999-2002 Salmon Management Plan. The Management Plan introduced, for the first time, a river classification scheme with different season limits for each of classes I-IV and, in addition, some other rivers were placed in a special class with a different management plan for each river. Returns and spawners were estimated as documented previously (ICES 2002/ ACFM:14). Catches in 2001 and the calculated exploitation rates were updated and catches in 2002 and exploitation rates were calculated.

The mid-point of the estimated returns (156,400) of 1SW salmon to Newfoundland rivers in 2002 is 6% lower than in 2001 and 26% lower than the average 1SW returns (210,700) for the period 1992–95 (Figure 4.2.2.1, Appendix 5). The 1992–95 1SW returns are higher than the returns in 1989-91, but similar to the returns to the rivers between 1971 and 1988. The mid-point (6,100) of the estimated 2SW returns to Newfoundland rivers in 2002 was 9% lower than in 2001 and 25% lower than the recent 5-year average of 8,100 (Figure 4.2.2.2, Appendix 5).

Québec:

The mid-point (34,200) of the estimated returns of 1SW salmon to Québec in 2002 is 65% higher than that observed in 2001 and is 22% higher than the previous five-year mean (Figure 4.2.2.1, Appendix 5).The mid-point (22,400) of the estimated returns of 2SW salmon in Québec in 2002 is 26% lower than that observed for 2001 (Figure 4.2.2.2). Within the 1971-2002 time-series, the 2002 value is the lowest estimated and a substantial decline from the high of 98,000 2SW salmon in 1980.

Gulf of St. Lawrence, SFAs 15−18:

The mid-point (58,900) of the estimated returns in 2002 of 1SW salmon returning to the Gulf of St. Lawrence was a 31% increase from 2001 and it is the highest value since 1996. The low values noted in 1997 through 2002 are low relative to the high value of about 189,000 in 1992 (Figure 4.2.2.1, Appendix 5).
The mid-point (12,000) of the estimate of 2SW returns in 2002 is 47% lower than the estimate for 2001 and the second lowest of the time-series (Figure 4.2.2.2, Appendix 5), the lowest being 1979 at 11,500. Returns of 2SW salmon have declined since 1995 with only slight improvement shown in 2001, relative to the years prior to 1995.

Scotia-Fundy, SFAs 19-23:

The mid-point (12,500) of the estimate of the 1SW returns in 2002 to the Scotia-Fundy Region was a 36% increase from the 2001 estimate, however, it was the third lowest value in the time-series, 1971-2002. Returns have generally been low since 1990 (Figure 4.2.2.1, Appendix 5). The mid-point (1,800) of the 2SW returns in 2002 is 65% lower than the returns in 2001 and the lowest value in the time-series, 1971–2002 (Figure 4.2.2.2, Appendix 5). A declining trend in returns has been observed from 1985 to 2002.

USA:

Total salmon returns for USA rivers in 2002 were based on trap and weir catches (documented returns). Because many of the Maine rivers do not have fish counting facilities, total abundance continues to be underestimated. The 1SW returns to USA rivers in 2002 were 436 fish. This was an increase from the 2001 estimate and larger than both the previous 5-year and 10-year averages. The 2SW returns in 2001 to USA rivers were 504 fish. There were 22 3SW and repeat spawners compared to only 9 in 2001.

4.2.3 Pre-fishery abundance estimates of non-maturing and maturing 1SW North American salmon

North American run-reconstruction model

The Working Group has used the North American run-reconstruction model to estimate pre-fishery abundance, which serves as the basis of abundance forecasts used in the provision of catch advice. The catch statistics used to derive returns and spawner estimates have been updated from those used in ICES 2002/ACFM:14 (Table 4.2.3.1). The North American run-reconstruction model has also been used to estimate the fishery exploitation rates for West Greenland and in homewaters.

Non-maturing 1SW salmon

The non-maturing component of 1SW fish, destined to be 2SW returns (excludes 3SW and previous spawners) is represented by the pre-fishery abundance estimator for year i designated as [NN1(i)]. Definitions of the variables are given in Table 4.2.3.2. It is constructed by summing 2SW returns in year i+1 [NR2(i+1)], 2SW salmon catches in commercial and Aboriginal peoples' food fisheries in Canada [NC2(i+1)], and catches in year i from fisheries on non-maturing 1SW salmon in Canada [NC1(i)] and Greenland [NG1(i)]. In Labrador, Aboriginal peoples' food harvests of small (AH_s) and large salmon (AH_l) were included in the reported catches for 1999-2002. Because harvests occurred in both Lake Melville and coastal areas of northern Labrador, the fraction of these catches that are immature was labeled as af_imm. This was necessary because non-maturing salmon do not occur in Lake Melville where approximately half the catch originated. However, non-maturing salmon may occur in coastal marine areas in the remainder of northern Labrador. Consequently, af_imm for the fraction of Aboriginal peoples' harvests that was non-maturing was set at 0.05 to 0.1 which is half of f_imm from commercial fishery samples. The equations used to calculate NC1 and NC2 are as follows:

Eq. 4.2.3.1 $$NC1(i) = [(H\_s(i)_{\{1\text{-}7,14b\}} + H\_l(i)_{\{1\text{-}7,14b\}} * q) * f\_imm] + [(AH\_s(i) + AH\_l(i) * q) * af\_imm]$$, and

Eq. 4.2.3.2 $$NC2(i+1) = [H\_l(i+1)_{\{1\text{-}7,14b\}} * (1-q)] + [AH\_l(i+1) * (1-q)]$$

As in 1998-2001, the commercial fishery in Labrador remained closed in 2002. In past reports, salmon returns and spawners for Labrador, which make up one of the six geographical areas contributing to NR2 for Canada, were based on commercial fishery data. Since the commercial fishery was closed in Labrador beginning in 1998, the time-series also ended. However, in order to estimate pre-fishery abundance it was still necessary to include Labrador returns for 1998-2002. Consequently, a raising factor was developed by dividing pre-fishery abundance without Labrador into pre-fishery abundance with Labrador based on the time-series of Labrador recruit estimates and pre-fishery abundance data from 1971-97. The raising factor (RFL2) to estimate returns to Labrador for 1998-2002 for 2SW salmon was set to the low and high range of values in the time-series which was 1.05 to 1.27. An assumed natural mortality rate [M] of 0.03 per month (Section 2.3) is used to adjust the numbers between the salmon fisheries on the 1SW and 2SW salmon (10 months) and between the fishery on 2SW salmon and returns to the rivers (1 month) as shown below:

Eq. 4.2.3.3 $$NN1(i) = RFL2*[(NR2(i+1) / S1 + NC2(i+1))/S2 + NC1(i)] + NG1(i)$$

where the parameters S1 and S2 are defined as exp(-M *1) and exp(-M *10), respectively. A detailed explanation of the model used to determine pre-fishery abundance is given in Rago *et al*. (1993a).

This estimated pre-fishery abundance represents the extant population and does not account for the fraction of the population present in a given fishery area. The model does not take into account non-catch fishing mortality in any of the fisheries. This is because rates for non-catch fishing mortality are not available on an annual basis and are not well described for some of the fisheries harvesting potential or actual 2SW salmon. Commercial catches were not included in the run-reconstruction model for the West Greenland fishery (1993 and 1994), Newfoundland fishery (1992–2001), and Labrador fishery (1998-2001), as these fisheries were closed.

As the pre-fishery abundance estimates for potential 2SW salmon requires estimates of returns to rivers, the most recent year for which an estimate is available is 2001. This is because pre-fishery abundance estimates for 2002 require 2SW returns to rivers in North America in the year 2003, which of course are as of yet unavailable. The minimum and maximum values of the catches and returns for the 2SW cohort are summarized in Table 4.2.3.3. The 2001 abundance estimates ranged between 54,615 and 111,372 salmon. The mid-point of this range (82,993) is 29% lower than the 2001 value (117,084) and is the lowest in the 30-year time-series (Figure 4.2.3.1). The most recent five years are shown with hollow symbols as no Labrador values were estimated for these years and the raising factor described previously was used. The results indicate the general decline in recent years is still continuing and current year values are still much lower than the 917,282 in 1975. The Working Group expressed concern over the dramatic decline in the 2001 value and that pre-fishery abundance still remains considerably lower than the conservation limits.

Maturing 1SW salmon

Estimation of an aggregate measure of abundance has utility for identifying trends, evaluating management measures, and investigating the influence of the marine environment on survival, distribution, and abundance of salmon. Maturing 1SW salmon are in some areas a major component of salmon stocks, and measuring their abundance is thought to be important to provide measures of abundance of the entire cohort from a specific smolt class.

For the commercial catches in Newfoundland and Labrador, all small salmon are assumed to be 1SW fish based on catch samples, which show the percentage of 1SW salmon to be in excess of 95%. Large salmon are primarily MSW salmon, but some maturing and non-maturing 1SW are also present in commercial catches in SFAs 1–7, 14B. Estimates of fractions of non-maturing salmon present in the Newfoundland and Labrador catch were presented in ICES 1991/Assess:12. The large category in SFAs 1–7 and 14B consists of 0.1–0.3 1SW salmon (Rago *et al*. 1993a; ICES 1993/Assess:10). Salmon catches in SFAs 8–14A are mainly maturing salmon (Idler *et al*. 1981). These values were assumed to apply to the Aboriginal food fishery catches in marine coastal areas of northern Labrador.

Similar to calculations to determine non-maturing 1SW salmon, a raising factor was also required to include Labrador returns in the maturing component of pre-fishery abundance necessitated by the closure of the commercial fishery in Labrador in 1998. Consequently, a raising factor was developed by dividing pre-fishery abundance without Labrador into pre-fishery abundance with Labrador based on the time-series of Labrador recruit estimates and pre-fishery abundance data from 1971-97. The raising factor (RFL1) to estimate returns to Labrador for 1998-2002 for 1SW salmon was set to the low and high range of values in the time-series, which were 1.04 to 1.59.

The maturing 1SW component is represented by the pre-fishery abundance estimator for year i [MN1(i)]. It is constructed by summing maturing 1SW returns in year i [MR1(i)] in Canada and the USA and catches in year i from commercial and food fisheries on maturing 1SW salmon in Newfoundland and Labrador [MC1(i)]. An assumed natural mortality rate [M] of 0.03 per month is used to adjust the numbers between the fishery on 1SW salmon and returns to the rivers (1 month) as shown below:

Eq. 4.2.3.4 $$MN1(i) = [MR1(i) / S1 + MC1(i)] * RFL1$$

where the parameter S1 is defined as exp(-M * 1).

Eq. 4.2.3.5 $$MC1(i) = [(1-f\_imm)(H\_s(i)_{\{1\text{-}7,14b\}} + q*H\_l(i)_{\{1\text{-}7,14b\}})] + H\_s(i)_{\{8\text{–}14a\}} + [(1-af\_imm)(AH\_s(i) + q*AH\_l(i))]$$

This estimated pre-fishery abundance represents the extant population and does not account for the fraction of the population present in a given fishery area. The model does not take into account non-catch fishing mortality in any of the fisheries. This is because rates for non-catch fishing mortality are not available on an annual basis and are not well described for the fisheries harvesting 1SW salmon. Thus, catches used in the run-reconstruction model for the Newfoundland commercial fishery were set to zero for 1992–2002 and for Labrador for 1998-2002 to remain consistent with catches used in other years in these areas (Section 4.1.1).

The minimum and maximum values of the catches and returns for the 1SW cohort are summarized in Table 4.2.3.4 and the mid-point values are shown in Figure 4.2.3.1. The most recent four years are shown with hollow symbols as no Labrador values were estimated for these years and the raising factor described previously was used. The mid-point of the range of pre-fishery abundance estimates for 2002 (376,296) is 9% higher than in 2001 (345,308) which had increased considerably from the low 1997 value of 331,762, which was the lowest, estimated in the time-series 1971-2002. The reduced values observed in 1978 and 1983–84 and 1994 were followed by large increases in pre-fishery abundance.

Total 1SW recruits (maturing and non-maturing)

Figure 4.2.3.1 shows the pre-fishery abundance of 1SW maturing for the 1971-2002 and 1SW non-maturing salmon from North America for 1971-2001. Figure 4.2.3.2 shows these data combined to give the total 1SW recruits. While maturing 1SW salmon in 1998-2002 have increased over the lowest value achieved in 1997, the non-maturing portion of these cohorts remained unchanged since 1997. As the prefishery abundance of the non-maturing portion (potential 2SW salmon) has been consistently well below the Spawning Escapement Reserve (derived from S_{lim}) since 1993, this situation is considered to be very serious. The decline in recruits in the time-series is alarming. Although the declining trend appears common to both maturing and non-maturing portions of the cohort, non-maturing 1SW salmon have declined further. The Working Group expressed concerns about these stock trends and recommended further investigation into their causes.

4.2.4 Spawning escapement and egg deposition

4.2.4.1 Egg depositions in rivers

Egg depositions in 2002 exceeded or equaled the river specific conservation limits in 23 of the 85 assessed rivers (27%) and were less than 50% of conservation limits in 40 other rivers (47%) (Figure 4.2.4.1). Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where 10 of the 11 rivers assessed (91%) had egg depositions that were less than 50% of conservation limits. Proportionally fewer rivers in Gulf (0%) and Québec (38%) had egg depositions less than 50% of conservation limits. Only 40% of the Gulf rivers and 33% of the

Québec rivers had egg depositions that equaled or exceeded conservation limits (Figure 4.2.4.1). In Newfoundland, 30% of the rivers assessed met or exceeded the conservation limits and 35% had egg depositions that were less than 50% of limits. Most of the deficits occurred in the east and southwest rivers of Newfoundland (SFA 13). All USA rivers had egg depositions less than 5% of conservation limits (Figure 4.2.4.1).

On assessed rivers, escapements over time relative to conservation limits (S_{lim}) in 2002 in Bay of Fundy/Atlantic coast of Nova Scotia and the Gulf areas and Newfoundland were mostly stable whereas Québec regions decreased in 2002 (Figure 4.2.4.2). The proportion of the conservation limits achieved on three Bay of Fundy/Atlantic coast of Nova Scotia rivers has severely declined, especially since 1989. However, 2002 was the highest of the time series in this area since 1992. For the Québec rivers, spawning escapements declined continually from a peak median value in 1988 with two slight recoveries in 1995 and 1999. In almost all years in Québec, the median proportion of conservation requirements achieved has exceeded the requirements. However, in 2002, the median proportion was the lowest value of the time series at 64% of the conservation limit. This reflects the poor returns of the 2SW salmon observed for all of the Québec areas in 2002. Although high returns of 1SW salmon were noted in Québec, they are almost all males and do not contribute to egg depositions. The rivers of the Gulf of St. Lawrence have also previously been quite consistent in equalling or exceeding the conservation limits. The median escapements were slightly below conservation limits in 2002. Newfoundland rivers in 2002 have shown a small increase to be just over the conservation limit. The exceeding of limits encountered in Newfoundland from 1992 to 2000 corresponded to the commercial salmon and groundfish moratoria initiated in 1992.

4.2.4.2 Run-reconstruction estimates of spawning escapement

Updated estimates for 2SW spawners were derived for the six geographic regions referenced in Section 4.2.2 (Table 4.2.4.1). Estimates of 1SW spawners, 1971-2001 are provided in Table 4.2.4.2. These estimates were derived by subtracting the in-river removals from the estimates of returns to rivers. A comparison between the numbers of spawners, returns, and conservation limits (S_{lim}) for 1SW and 2SW salmon are shown in Figures 4.2.2.1 and 4.2.2.2 respectively (there are no spawning requirements defined specifically for 1SW salmon).

Labrador:

As previously explained, it was not possible to estimate spawners in Labrador in 1998 - 2002 due to lack of assessment information.

Newfoundland:

The mid-point of the estimated numbers of 2SW spawners (5,800) in 2002 was 9% below that estimated in 2001 (6,400) and was 144% of the total 2SW conservation limit (S_{lim}) for all rivers. The 2SW spawner limit has been met or exceeded in ten years since 1984 (Figure 4.2.2.2). The 1SW spawners (132,800) in 2002 were 5% less than the 140,400 1SW spawners in 2001. The 1SW spawners since 1992 were higher than the spawners in 1989–91 and similar to levels in the late 1970s and 1980s (Figure 4.2.2.1), although in 1995-1996 they were unusually high. There had been a general increase in both 2SW and 1SW spawners during the period 1992–96 and 1998-2001, and this is consistent with the closure of the commercial fisheries in Newfoundland. For 1997, decreases occurred most strongly in the 1SW spawners.

Québec:

The mid-point of the estimated numbers of 2SW spawners (15,100) in 2002 was 26% lower than that observed for 2001 and was about 52% of the total 2SW conservation limit (S_{lim}) for all rivers (Figure 4.2.2.2). The spawning escapement in 2002 was the second lowest in the time-series (1971-2002), with 1971 having been the lowest. Estimates of the numbers of spawners approximated the spawner limit from 1971 to 1990; however, they have been below the limits since 1990. The mid-point of the estimated 1SW spawners in 2002 (21,600) was about 55% higher than in 2001 (Figure 4.2.2.1) and similar to the mean value of the previous ten years.

Gulf of St. Lawrence:

The mid-point of the estimated numbers of 2SW spawners (11,500) in 2002 was about 45% lower than estimated in 2001 (20,900) and was about 38% of the total 2SW conservation limits (S_{lim}) for all rivers in this region (Figure 4.2.2.2). This is the seventh time in ten years that these rivers have not exceeded their 2SW spawner limits. The mid-point of the estimated spawning escapement of 1SW salmon (42,100) increased by 42% from 2001 and was the fourth highest in the last ten years. The abundance remains low relative to the peak (154,000) observed in 1992 (Figure 4.2.2.1). Spawning escapement has on average been higher in the mid-1980s than it was before and after this period.

Scotia-Fundy:

The mid-point of the estimated numbers of 2SW spawners (1,500) in 2002 is a 68% decrease from 2001, the lowest in the time series, 1971-2002 and is about 6% of the total 2SW conservation limits (S_{lim}) for rivers in this region (Figure 4.2.2.2). Neither the spawner estimates nor the conservation limits include rivers of the inner Bay of Fundy (SFA 22 and part of SFA 23) as these rivers do not contribute to distant water fisheries and spawning escapements are extremely low. The 2SW spawning escapement in the rest of the area has been generally declining since 1985. The mid-point of the estimated 1SW spawners (12,300) in 2002 is a 37% increase from 2001 and is the eighth lowest in the time-series, 1971-2002. There has been a general downward trend in 1SW spawners since 1990 (Figure 4.2.2.1).

USA:

Spawning 2SW salmon were only 1.7% of their conservation limit (S_{lim}) for all USA rivers combined. Spawners of all age classes (1SW, 2SW, 3SW, and repeat) in 2002 (962 salmon) represented 3.3% of the 2SW conservation spawner limits (S_{lim}) for all USA rivers combined. On an individual river basis, the Penobscot River met 5.6% of its conservation limit while all the other USA rivers (Connecticut, Pawcatuck, Merrimack, Narraguagus, Pleasant, Dennys and all other Maine rivers combined) met less than 1% each.

4.2.4.2 Escapement variability in North America

The projected numbers of potential 2SW spawners that could have returned to North America in the absence of fisheries can be computed from estimates of the pre-fishery abundance taking into consideration the 11 months of natural mortality at 3% per month. These values, termed potential 2SW recruits, along with total North American 2SW returns, spawners, and conservation limits (S_{lim}) are shown in Figure 4.2.4.3 and indicate that the overall North American conservation limit could have been met, in the absence of all fisheries prior to, but not since 1994. The difference between the potential 2SW recruits and actual 2SW returns reflect the extent to which mixed stock fisheries at West Greenland and in SFAs 1–14 have reduced the populations.

Similarly, the impact of the Greenland fishery can be considered by subtracting the non-maturing 1SW salmon (accounting for natural mortality) harvested there from the total potential 2SW recruits. These values, termed 2SW recruits to North America, are also shown in Figure 4.2.4.3. The difference between the 2SW recruits to North America and the 2SW returns reflects the impact of removals by the commercial fisheries of Newfoundland and Labrador when they were open and the Labrador food fisheries since reports began in 1998. The 2SW recruits to North America indicate that, even if there had not been a West Greenland commercial fishery, conservation limits could not have been met since 1992. The difference between the actual 2SW returns and the spawner numbers reflects in-river removals throughout North America and coastal removals in Québec, Gulf, and Scotia Fundy regions.

Following on the technique outlined in previous reports (ICES 1994/Assess:16, ICES 1995/Assess:14), the spawners in each geographic area were allocated (weighted forward) to the year of the non-maturing 1SW component in the Northwest Atlantic using the weighted smolt age proportions from each area (Table 4.2.4.3). The total spawners for a given recruitment year in each area is the sum of the lagged spawners. Because the smolt age distributions in North America range from one to six years and the time-series of estimated 2SW spawners to North America begins in 1971, the first recruiting year for which the total spawning stock size can be estimated is 1979 (although a value for 1978 was obtained by leaving out the 6-year old smolt contribution which represents 4% of the Labrador stock complex (Table 4.2.4.3). Furthermore, for 1977, a value was obtained by estimating contributions from Québec and Newfoundland where five year old smolts exist, representing about 9% of the spawners from these two areas.

Except for Labrador, the 2SW spawners to North America have been estimated to 2005. In Labrador, the spawning stock is only known to 1997 and therefore lagged spawners contributing to the pre-fishery abundance can only be completely assembled to the 2002 pre-fishery abundance (Figure 4.2.4.4, Table 4.2.4.4). In Labrador, age-3 smolts contribute about 7% to 2SW returns six years later, or five years later to the pre-fishery abundance.
Spawning escapement of 2SW salmon to several stock complexes has been below S_{lim} (Labrador, Québec, Scotia-Fundy, USA) since at least the 1980s (Figure 4.2.4.4). In the last four years, lagged spawner abundance has been increasing in Labrador and Newfoundland, but decreasing in all other areas.

The relative contributions of the stocks from these six geographic areas to the total spawning escapement of 2SW salmon has varied over time (Figure 4.2.4.5). The reduced potential contribution of Scotia-Fundy stocks and the initial increased proportion of the spawning stock from the Gulf of St. Lawrence and, more recently, from Labrador rivers to future recruitment is most noticeable. Only the Newfoundland stock complex has received spawning escapements that have exceeded the area's requirements, all other complexes were below requirement, and most declined further in 2002.

4.2.5 Survival Indices

With the closure of most sea fisheries, counts of smolts and returning adult salmon can provide indices (% smolt survival) of natural survival at sea. These estimates are potentially influenced by annual variation in the size, age and sex composition of smolts leaving freshwater and possibly, annual variation in sea-age at maturity. Data available in 2002 on rivers with smolt counts and corresponding adult counts were from 11 wild and four hatchery populations distributed among Newfoundland (SFAs 4, 9, 11, 13, and 14a), Québec (Q2 and Q7), Nova Scotia (SFA 21), New Brunswick (SFA 16, 23) and Maine (USA).

Plots of percent returns of 1SW and 2SW adults over time (Figures 4.2.5.1 to 4.2.5.4) provide insight into the impact of changes in management measures and possible changes in marine survival of wild and hatchery 1SW and 2SW stocks. In general the plots suggest:

- Survival of North American stocks to home waters has not increased as expected after closure of the commercial fisheries in 1984 and 1992,
- 1SW survival greatly exceeded that of 2SW fish (except for Maine, where survival of 2SW fish generally exceeds that of 1SW fish),
- Survival of wild stocks exceeded that of hatchery stocks by roughly a factor of 10, and
- Survival of fish from many rivers in North America is low compared to historic levels, especially in the south.

In 2002, estimated return rates for 1SW fish improved somewhat for 10 stocks, declined in two, and was unchanged in two compared to 2001. By contrast, 2SW fish estimated return rates in 2002 improved in one stock, decreased in four, and was unchanged in two compared to 2001.

There have been no significant increasing trends ($p \leq 0.05$) in survival indices of any of the stock components since commercial closures in 1992.

		Number of stocks					
Sea-age		Relative to 2001			10-Year Trend		
& stock	Province/region	⇧	⇔	⇩	⇧	⇔	⇩
1SW Wild	West & North Nfld	1		1		2	
	South Nfld	2	1			3	
	Québec	1		1		2	
	NS/NB	3					
Hatchery	Québec			1		1	
	NS	1					1
	NB	1				1	
	Maine	1				1	
	Total	10	1	3	0	10	1
2SW Wild	West & North Nfld		1				
	Québec	1		1		1	1
Hatchery	Québec			1		1	
	NS			1			1
	NB			1		1	
	Maine			1			1
	Total	1	1	5	0	3	3

The return rates of 2SW adults from hatchery-reared smolts released in the Penobscot River drainage in 2000 was 0.06%. This was the second lowest rate observed in the time series (Figure 4.2.5.4). Marine survival for this cohort of Penobscot River hatchery-reared smolts continued the downward trend that began in the mid-1980s. However, the return rates of 1SW adults from hatchery-reared smolts released to the Penobscot River drainage in 2001 was 0.07%, which is the second highest survival documented for this adult return age class since 1991.

4.2.6 Atlantic Salmon Recovery and Restoration Actions

Recovery and Restoration Programs

Salmon populations in the southern portion of the range in North America and in isolated locations throughout the range have diminished to levels that require actions to prevent their extirpation. Programs have been initiated or have evolved from previous supplementary stocking programs and now seek to maintain numeric robustness and genetic integrity of affected populations. Programs operate on discrete populations identified through geographic separation, similar phenotypic and life history traits and through genetic typing (Table 4.2.6.1).

Two population segments in North America have been listed as Endangered by their respective national legislation, one listing consists of eight rivers in Maine, USA and the other consists of thirty-three rivers of the inner Bay of Fundy, Canada. Two of the eight listed rivers in the USA have not had returns for two consecutive years. At least two areas in Canada, the Atlantic coast of Nova Scotia and the outer Bay of Fundy have salmon populations that have been extirpated or are perilously close to extirpations. Because of the length of time required to obtain listings and because of uncertainty in the availability of discrete and specific data that are required to attain listings, limited actions have been taken to restore some of these populations before further extirpations occur. Assessed salmon populations of the Gulf of St. Lawrence and those further north persist at sustainable levels and therefore recovery actions in addition to standard fisheries management actions have not been deemed necessary.

In Canada, a legislated Recovery Program is being established for inner Bay of Fundy salmon and operational changes have taken place in supportive rearing programs operating on some of the remaining non-listed residual populations. In the USA formal Recovery Action Plans for the eight listed rivers have been initiated and similar changes have taken place in supportive rearing programs to restore some of the few remaining populations e.g. Penobscot.

Recovery programs for residual populations generally differ from programs that support fisheries in their source of broodstock and distribution of fish. Because sufficient numbers of adult fish with adequate genetic diversity cannot be captured, annual collections of parr are raised to maintain a captive brood population. Brood fish are genetically characterized prior to sexual maturity to guide hatchery-spawning operations and either insures siblings or closely related individuals are not mated or mated according to a designed pedigree. These measures are taken to reduce inbreeding and loss of genetic diversity and fitness. The captive broodstock serve multiple purposes:
(a) provide a reservoir of diverse genetic material to protect from catastrophic losses in the wild;
(b) increase the effective spawning population size (N_e) of each river population;
(c) minimize loss of genetic diversity (genetic bottlenecks) associated with very small populations;
(d) support river-specific stocking strategy to enhance juvenile population abundance; and
(e) provide fish for research.
Stocking into the natal rivers include fry, parr, limited numbers of smolts and redundant mature fish.

In larger rivers of the USA, adult fish are used as egg producers for one or more years, after which they too are returned to the rivers as kelts. River specific juvenile production for the Penobscot River is based on eggs taken annually from returning adults. On the Connecticut River, broodstock include sea run adults, rejuvenated kelts, and captive reared adults. Fry were the most numerous life stage of Atlantic salmon stocked into USA rivers, although other life stages are stocked (Table 4.2.6.1).

In the Saint John River, Canada, the focus of fish culture is changing from restoration to recovery. More juveniles are being grown to adult stages for release in the upper tributaries of the river. These actions have been necessary because of reduced adult returns (Table 4.2.6.1).

In addition to protecting populations, there are efforts underway to protect and restore freshwater habitat. These include: regulating water withdrawals for irrigation, reducing point and non-point source pollution, protecting riparian land, improving passage and habitat connectivity, reducing escapes from fish culture and aquaculture rearing facilities, instream habitat restoration. In addition, attempts are being made to use the link between Atlantic salmon survival and air quality to affect air and water quality policy.

Donor Stock Programs

In some rivers of the USA where stocks were extirpated and broodstock is being developed, donor stocks are based on adjacent rivers. In some of these cases, stocking has produced adult returns that are captured and used to complement the donor stock contributions. In others, at least a portion of riverine production will depend on stocking from the donor broodstock. The primary life stage stocked into these rivers is fry numerically, but smolts are a significant component of the programs (Table 4.2.6.1).

In Canada, the opportunity for donor stocking has diminished substantially due to low adult returns and the increased occurrence of the more space-demanding recovery programs.

4.2.7 Summary of status of stocks in the North American Commission Area

Estimates of pre-fishery abundance suggest a continuing decline of North American adult salmon over the last 10 years. The total population of 1SW and 2SW Atlantic salmon in the northwest Atlantic has oscillated around a generally declining trend since the 1970s, and the abundance recorded in 1993–2001 was the lowest in the time-series (Figure 4.2.3.2) with 2001 at 428,300 being the lowest point. During 1993 to 2000, the total population of 1SW and 2SW Atlantic salmon was about 600,000 fish, about half of the average abundance during 1972 to 1990. A further 50% decrease has occurred between 2000 and 2001, the most recent year for which it is possible to estimate the total population. The decline has been more severe for the 2SW salmon component than for the small salmon (maturing as 1SW salmon) age group.

In most regions the returns in 2002 of 2SW fish are at or near the lower end of the 32-year time-series (1971-2002). In Newfoundland, the 2 SW salmon are a minor age group component of the stocks in this area and even here, decreases of about 30% have occurred from peak levels of a few years ago. Returns of 1SW salmon generally increased from the extremely low values of 2001 in all areas except Newfoundland.

The rank of the estimated returns in 2002 in the 1971–2002 time-series for six regions in North America is shown below:

Region	Rank of 2002 returns in 1971-2002 (1=highest)		Rank of 2002 returns in 1993-2002 (1=highest)		Mid-point estimate of 2SW spawners as proportion of conservation limit (S_{lim})
	1SW	**2SW**	**1SW**	**2SW**	**(%)**
Labrador	Unknown	Unknown	Unknown	Unknown	Unknown
Newfoundland	25	11	8	8	144
Québec	13	32	4	10	52
Gulf	21	31	5	10	38
Scotia-Fundy	28	32	7	10	6
USA	12	31	2	9	2

Trends in abundance of small salmon and large salmon within the geographic areas show a general synchronicity among the rivers. Returns of large salmon in North America were generally decreased from 2001 often to record low values, while small salmon returns increased. Any increases however in small salmon returns were from often record low values in 2001. For the rivers of Newfoundland, large salmon returns decreased from 2001, but remained high relative to the years before the closure of the commercial fisheries. Large salmon in Newfoundland are predominantly repeat-spawning 1SW salmon, while in other areas of eastern Canada, 2SW and 3SW salmon make up varying proportions of the returns.

Egg depositions in 2002 exceeded or equaled the river-specific conservation limits (S_{lim} for eggs) in 23 of the 85 assessed rivers (27%) and were less than 50% of conservation in 40 other rivers (47%). Large deficiencies in egg depositions were noted in the Bay of Fundy and Atlantic coast of Nova Scotia where 10 of the 11 rivers assessed (91%) had egg depositions that were less than 50% of conservation limits. Proportionally fewer rivers in Gulf (0%) and Québec (38%) had egg depositions less than 50% of conservation. Only 40% of the Gulf rivers and 33% of the Québec rivers had egg depositions that equaled or exceeded conservation. In Newfoundland, 30% of the rivers assessed met or exceeded the conservation egg limits, and 35% had egg depositions that were less than 50% of limits. The deficits mostly occurred in the east and southwest rivers of Newfoundland (SFA 13) and in Labrador. All USA rivers had egg depositions less than 5% of conservation limits.

In 2002, the overall conservation limit (S_{lim}) for 2SW salmon was not met in any area except Newfoundland. The overall 2SW conservation limit for Canada could have been met or exceeded in only nine (1974-78, 1980-82 and 1986) of the past 31 years (considering the mid-points of the estimates) by reduction of terminal fisheries (Figures 4.2.2.2 and 4.2.4.3). In the remaining years, conservation limits could not have been met even if all terminal harvests had been eliminated. It is only within the last decade that Québec and the Gulf areas have failed to achieve their overall 2SW salmon conservation limits.

Measures of marine survival rates over time indicate that survival of North America stocks to home waters has not increased as expected as a result of fisheries changes**.** There have been no significant increasing trends in survival indices of any of the stock components since commercial closures in 1992.

Substantive increases in spawning escapements in recent years in northeast coast Newfoundland rivers and high smolt and juvenile production in many rivers, in conjunction with suitable ocean climate indices, were suggestive of the potential for improved adult salmon returns for 1998 through 2002. Colder oceanic conditions both nearshore and in the Labrador Sea in the early 1990s are thought to have contributed to lower survival of salmon stocks in eastern Canada during that period.

Based on the genera1ly increased 1SW returns in 2002, some modest improvement is expected for large salmon in 2003, however, this improvement will be from usually record low returns of large salmon in 2002. An additional concern is the low abundance levels of many salmon stocks in rivers in eastern Canada, particularly in the Bay of Fundy and Atlantic coast of Nova Scotia. USA salmon stocks exhibit these same downward trends. Most salmon rivers in the USA are hatchery-dependent and remain at low levels compared to conservation requirements. Despite major changes in fisheries management, returns have continued to decline in these areas and many populations are currently threatened with extirpation.

4.3 Evaluation of management measures

The management of Atlantic salmon in eastern North America has focused on the management of spawning escapement to meet or exceed conservation limits. Significant measures introduced in the last five years in order to meet this objective have included the closure of all commercial fisheries in eastern Canada as of 2000, the complete closure of numerous rivers to any fishing including Native and recreational fisheries, and the imposition of catch and release only access in others. The Working Group (ICES 1997/Assess:10, ICES CM 2002/ACFM:14) considered specifically the impact of the 1992 Newfoundland commercial fishery moratorium on the objective of reducing exploitation and meeting conservation limits. Within Newfoundland, the commercial fishery closure resulted in increased escapements of both small and large salmon, increased catches of large salmon increased escapements of both size groups. However in some areas, the increased escapements did not always result in increased smolt production nor were the increased escapements realized in all areas. The latter response indicates that factors other than fishing were impacting on survival of Atlantic salmon at sea.

Management measures may have impacts on Atlantic salmon stocks beyond changes in abundance of returning and spawning Atlantic salmon. The Working Group reviewed some examples of biological characteristics of stocks which may change as a consequence of changes in fishing exploitation (Section 2.4.3). These included changes in spawning escapement, juvenile abundance, age structure and composition, survival rates, size-at-age and run-timing. Of the changes resulting from reductions in fisheries, changes in spawning escapement and subsequently juvenile production are the most anticipated. Looking back three decades at the performance of some Maritime provinces stocks to changes in fisheries management, spawning escapements responded initially to the 1984 management plan (closure of commercial fisheries and mandatory catch and release of large salmon throughout the Maritimes) but the higher escapements were not sustained into the 1990s (Fig. 2.4.3.1). Juvenile abundance has generally increased in the Miramichi River but a statistically significant response in this abundance was not observed until six years after the increases in escapement (Fig. 2.4.3.1).

Reduced exploitation on large salmon in the in-river and estuarine fisheries of the Miramichi has resulted in an expanded age structure in which repeat spawners have comprised as much as 50% of the large salmon returns. Particularly notable is that since 1995, salmon with six previous spawnings have been observed in the returns to the Miramichi and salmon on the third to fifth spawnings are more abundant (Fig. 2.4.3.3; Table 2.4.3.1). That it took over 11 years after the management plan of 1984 to see these older salmon is consistent with the time required for the first maiden fish of 1984 to reach that sea age (9 sea years of age). Alternate repeat spawners undertake feeding migrations to West Greenland as evidenced from Carlin tag returns from that fishery of salmon tagged in the Miramichi on their spawning migrations the previous year.

There are fewer repeat spawner components in the Saint John River than in the Miramichi and there has not been any change in relative proportions over time as was seen in the Miramichi (Table 2.4.3.2). The post-spawner survival in the Saint John River is likely constrained by downstream fish passage through 2 to 3 hydro-generating facilities which cannot be managed like the fishing exploitation rates on the Miramichi stock. For the Saint John River, therefore, reduced fisheries exploitations have not resulted in improved post-spawner survivals.

The repeat spawning return rates of 1SW maiden salmon have not increased significantly over the past 30 years (Fig. 2.4.3.4). The returns rates are relative to maiden fish prior to in-river exploitation, and since there is exploitation of this age group by both the Native and recreational fisheries, survival of maiden fish to a second return was expected to be lower. In addition to being more abundant in recent years, repeat spawners from the Miramichi grow substantially between spawning events. These larger fish of proportionally greater abundance in the river are of interest to the recreational fishermen, produce more eggs per fish than maiden spawners, and provide a buffer to the annual spawning escapement when smolt to maiden spawner survivals are low.

Over the 1971 to 2002 period, the average length of 1SW and 2SW maiden salmon has increased. The 2SW salmon from the Miramichi River during 1999 to 2002 are the largest of the time series (Fig. 2.4.3.6) and the mean size increased in 1986, two years after the home water commercial fishery moratorium. The mean size of 1SW salmon of the last four years were also the largest of the time series (Fig. 2.4.3.6) and the change in size was also first observed in 1986. Moore et al. (1995) suggested that the stepped change in mean length-at-age of 1SW salmon which occurred post 1984 was evidence of a size-selective fishery on these fish. The change in size was also observed for the 2SW fish, however, it is not obvious how the fishing gear could have been selecting the larger 2SW salmon. Similar increases in mean size of 1SW salmon were observed in the Nashwaak River and the Saint John River, both Bay of Fundy stocks. The mean size in the last three years of both 1SW and 2SW salmon have been average to less than average for the 1986 to 2002 period (Fig. 2.4.3.6). Similar to the Miramichi, the change in mean size also first occurred in 1986. It is possible that exploitation with nets was still taking place on these stocks in 1984 and 1985.

Many historical commercial fisheries were prosecuted early in the season and frequently not in proportion to the timing of the fish entering the river. Evidence of the effect of fisheries exploitation in coastal waters on time of entry of salmon to rivers was evident in the time series of catches at the estuary trapnet in the Miramichi. The 50^{th} percentile count of large salmon at the trapnet in the 1950s and 1960s was post Sept. 1 but became progressively earlier in 1970 to 1972 following the closure of the directed commercial fisheries in the Maritimes and in the last part of the time series, the median date oscillated around mid-August (Fig. 2.4.3.7).

With management of salmon fisheries in eastern Canada now restricted mainly to home rivers, a number of stock characteristics were expected to have changed. Most notably, the mean size-at-age of salmon has increased in many rivers in which net fisheries of salmon historically occurred. Reduced exploitation in both the marine and freshwater environments has benefited the Miramichi River by providing repeat spawners as a buffer to the maiden salmon population when the latter is low.

4.4 Update of age-specific stock conservation limits

There are no changes recommended in the 2SW salmon conservation limits (S_{lim}) from those recommended previously. Conservation limits for 2SW salmon for Canada now total 123,349 and for the USA, 29,199 for a combined total of 152,548 (Table 4.4.1). The Working Group again recommends that these requirements be refined as additional information on sea-age composition of spawners becomes available and as further understanding of life history strategies is gained.

The Working Group has been providing advice on 2SW salmon stock conservation limits for over a decade, and changes from year to year have been documented in annual Working Group reports. Stock-recruitment curves that formed the basis of conservation requirements can be found in Prevost and Chaput (2001), Chaput (1997), and ICES 1994/M:6.

The conservation limits for USA rivers were reviewed in 1995 (ICES 1995/Assess:14). A review of the spawner limits for Canada was conducted in 1996 (ICES 1996/Assess:11), and were further refined by O'Connell *et al* 1997. This publication provided for the first time a comprehensive list of references documenting the methodologies and origins of the parameter values used to derive egg and spawner conservation limits throughout Atlantic Canada. Conservation limits so derived were adopted by the working group in 1998 (ICES CM 1998/ACFM:15). Limits were generally set on the basis of egg deposition densities which provided for MSY on a limited number of stocks where data was available, and such densities were used on the remainder of rivers where only habitat area and spawner demographics were available as documented in O'Connell *et al* 1997. The added production from lacustrine areas in Newfoundland and Labrador was also accommodated.

In 2000, a further refinement of the conservation limits was considered by the Working Group, specifically for stocks in Québec (ICES CM 2000/ACFM:13). Stock-recruitment analysis for six Québec rivers was used to define the conservation limit, defined as the S_{MSY} level at 75% probability level calculated by Bayesian analysis. A relationship between conservation limits and habitat production units was applied to all rivers after calculating production units for each river by means of aerial photography and habitat suitability indices specific to those Québec rivers. Overall, the conservation limit for 2SW salmon in Québec decreased by over 50% from that previously used by the Working Group and has resulted in the values currently used.

4.5 Catch options or alternative management advice and assessment of risks relative to the objective of exceeding stock conservation limits

Overview
Catch options are only provided for the non-maturing 1SW and maturing 2SW components as the maturing 1SW component is not fished outside of home waters, and in the absence of significant marine interceptory fisheries, is managed in homewaters by the producing nations.

Catch histories of salmon which could have been available to the Greenland fishery, 1972-2002, are provided in Tables 4.5.1 and 4.5.2. and expressed as 2SW salmon equivalents. The Newfoundland-Labrador commercial fisheries historically was a mixed stock fishery and harvested both maturing and non-maturing 1SW salmon as well as 2SW maturing salmon. The harvest in these fisheries of repeat spawners and older sea-ages was not considered in the run reconstructions. Harvests of 1SW non-maturing salmon in Newfoundland-Labrador commercial fisheries have been adjusted by natural mortalities of 3 % per month for 13 months, and 2SW harvests in these same fisheries have been adjusted by one month to express all harvests as 2SW equivalents in the year and time they would reach rivers of origin. Starting in 1998, the Labrador commercial fishery was closed. An Aboriginal Peoples' fishery occurred in 1998 - 2002 that may have harvested, to some degree, mixed stocks, and catches for this fishery have been included in Tables 4.5.1 and 4.5.2. As well, a resident's food fishery in Labrador which started in 2000 is included. Mortalities (principally in fisheries) in mixed stock and terminal fisheries areas in Canada are summed with those of USA to estimate total 2SW equivalent mortalities in North America (Table 4.5.1). The terminal fisheries areas included coastal and river catches of all areas, except Newfoundland and Labrador where only river catches were included. Mortalities within North America peaked at about 365,000 in 1976 and are now about 10,000 2SW salmon equivalents. In the most recent four years estimated (that is those since the closure of the Labrador commercial fishery), those taken as non-maturing fish in Labrador comprise 3%, or less, of the total in North America.

Of the North American fisheries on the cohort destined to be 2SW salmon, 86% of the catch comes from terminal fisheries in the most recent year. This value has ranged from as low as 20% in 1973, 1976 and 1987 to values of 77-91% in 1996-2002 fisheries (Table 4.5.1). The percentage increased significantly with the reduction and closures of the Newfoundland and Labrador commercial mixed stock fisheries, particularly since 1992.

Table 4.5.2 shows the mortalities expressed as 2SW equivalents in Canada, USA, and Greenland for 1972–2001, by applying a mortality of 3 % per month for 11 months to the estimates of harvests of 1SW non-maturing North American salmon in the Greenland fishery. Harvests within the USA of the total within North America approached 0.6% on a few occasions in the time-series and as recently as in 1990. As well as these harvests in the USA, USA-origin salmon were also harvested in Canada during the time period indicated. The percentage of the total 2SW equivalents that have been harvested in North American waters has ranged from 48-100%, with the most recent year estimated at 58%. The two years when 100% of the mortality occurred in North America were the years when the Greenland commercial fishery did not operate.

It is possible to provide catch advice for the North American Commission area for two years. The revised forecast for 2003 for 2SW maturing fish is based on a new forecast of the 2002 pre-fishery abundance and accounting for fish which were already removed from the cohort by fisheries in Greenland and Labrador in 2002 as 1SW non-maturing fish. The second is a new estimate for 2004 based on the pre-fishery abundance forecast for 2003 from Section 5.6. A consequence of these annual revisions is that the catch options for 2SW equivalents in North America may change compared to the options developed the year before.

4.5.1 Catch advice for 2003 fisheries on 2SW maturing salmon

A revised forecast of the pre-fishery abundance for 2002 is provided below.

Catch Options for 2002 North American Fisheries (Probability levels refer to probability density function estimates of pre-fishery abundance)		
Probability Level	**Pre-fishery Abundance Forecast**	**Catch Options in 2SW Salmon Equivalents (no.)**
25	91,807	0
30	99,352	0
35	107,418	0
40	115,459	0
45	123,662	0
50	133,087	0

This value of 133,087 at the 50% probability level is much lower than the value forecast last year at this time of 329,552 (See Section 5.5.2 for more detailed derivation of the models used). A pre-fishery abundance of 133,087 in 2002 can be expressed as 2SW equivalents by considering natural mortality of 3% per month for 11 months (a factor of 0.718924), resulting in 95,679 2SW salmon equivalents. There have already been harvests of this cohort as 1SW non-maturing salmon in 2002 for both the Labrador (299) and Greenland (1,499) fisheries (Tables 4.5.1 and 4.5.2) for a total of 1,798 2SW salmon equivalents already harvested, when the mortality factor is considered.

The table above uses the probability density projections for the revised pre-fishery abundance estimate of 133,087 (at 50% probability), converts them to 2SW salmon equivalents and subtracts the 2SW conservation limit (S_{lim}) of 152,548 and the harvests in Greenland and Labrador of 1SW non-maturing salmon that have been converted to 2SW salmon equivalents (from Tables 4.6.1 and 4.6.2). The calculation is as follows:

[(PFA_i – harvest in Greenland in 2002 of 1SW non-maturing fish) x exp - (0.03 *11 months)]
minus
[harvest in Labrador in 2002 of 1SW non-maturing fish x exp –(0.03*13 months)]
minus
the conservation limit
where PFA_i = values from 25–50%
conservation limit = 152,548

From the text table above, there are no harvest possibilities at forecasted levels considered risk-neutral or risk-averse, that is, at probability levels of 50% and below. The numbers provided for catch options refer to the composite North American fisheries. As the biological objective is to have all rivers reaching their conservation requirements, river-by-river management is necessary. On individual rivers, where spawning requirements are being achieved, there are no biological reasons to restrict the harvest.

Regional assessments in some areas of eastern North America provide a more detailed consideration of expectations for 2003, taking into consideration the contribution of all sea ages of salmon to the spawning population. By area, these are:

Labrador:

As there has been a lack of long-term monitoring facilities in Labrador, there is little information available to comment on expectations for 2003 and beyond.

Newfoundland:

There are no forecasts available for returns of small and large salmon in 2003. The majority of returns are small salmon and their return depends mainly on marine survival which has been quite variable. Exploitation in Newfoundland occurs primarily on maturing 1SW salmon.

Gulf:

In all rivers of the Gulf Region, large salmon returns and spawners in 2002 declined from 2001 and spawning escapement was below or at the conservation requirement. Small salmon abundance was above the previous five year average abundance and improved substantially from 2001. Exploitation on salmon in the Gulf region is restricted to retention of small salmon in the recreational fisheries and an allocation of large salmon to the native fisheries. Harvest rates on large salmon resulting from catch and release mortality and native fisheries has been rarely above 10% and usually less than 5%. The majority of the egg depositions come from large salmon which are predominantly females with some additional eggs from the small salmon which can be comprised of upwards of 25% female but are more often less than 10% female. The largest salmon producing river, the Miramichi, did not meet the conservation requirements in 2002, the fourth time in five years and the outlook for 2003 is for an improved return of large salmon greater than in 2002 and about 75% chance of meeting the conservation requirement in the Miramichi River overall. Because the majority of salmon returning to the Morell (91% in 2002) and to other PEI rivers (SFA 17) are of hatchery origin, current fisheries have little impact on future runs. In all areas of the Gulf, with the exception of the southeast New Brunswick rivers which are closed to salmon fishing, juvenile abundance in rivers are at historical high levels.

Scotia-Fundy:

Expectations that salmon returns in 2003 will meet or exceed conservation limits among 11 assessed rivers of the Atlantic coast of Nova Scotia range from zero to about 20%. Harvest in home waters is dependent on bi-weekly in-season assessments beginning June 15, at two monitoring facilities, Morgans Falls fishway on the LaHave River and at Mactaquac dam fishway on the Saint John River. Under the existing fisheries management strategy, harvest fisheries including aboriginal, hook and release recreational fishery or retention of small salmon in the recreational fishery would only be considered if the probability of achieving the conservation limit was greater than 75%. Supportive rearing programs are expected to move away from fisheries support objectives and toward population maintenance by rearing parr to mature adult spawners, pedigree breeding and earlier ages for stocking.

Québec:

There were 65% more 1SW returns in 2002 than in 2001, and the 2002 value was similar than the 1992-2001 mean. Returns of large salmon in 2002 are expected to increase by a range of 15% to 25% over 2001 and be similar to the previous 10 year mean. This level of increase should be sufficient for attainment of conservation limits on a majority of rivers, but not on all. Consequently, retention of large salmon is not expected to be permitted on 39 rivers.

USA: Salmon returns (both large and small) in 2003 are not expected to be sufficient to meet conservation limits in any river, including those receiving hatchery stocking.

4.5.2 Catch advice for 2004 fisheries on 2SW maturing salmon

Most catches (92%) in North America now take place in rivers or in estuaries. The commercial fisheries are now closed and the remaining coastal food fisheries in Labrador are mainly located close to river mouths and likely harvest few salmon from other than local rivers. Fisheries are principally managed on a river-by-river basis and in areas where retention of large salmon is allowed, it is closely controlled.

Catch options which could be derived from the prefishery abundance forecast for 2003 (111,042 at the 50% probability level) would apply principally to North American fisheries in 2004 and hence the level of fisheries in 2003 needs to be accounted for before providing these catch options. Assuming probability values at 50 % and below, accounting for mortality and the conservation limit and considering an allocation of 60% of the surplus to North America, would yield catch options in 2SW salmon equivalents of zero fish. This zero catch option refers to the composite North American fisheries. As the biological objective is to have all rivers reaching or exceeding their conservation limits, river-by-river management will be necessary. On individual rivers, where conservation limits are being achieved, there are no biological reasons to restrict the harvest.

4.6 Biological sampling program for the Islands of Saint-Pierre and Miquelon

A small Atlantic salmon fishery occurs off the coast of Saint-Pierre and Miquelon. A total of six tag returns of North American origin have been reported from this fishery since 1976.

Tag code	Country of origin	River of release	Year of release	Recovery date	Total length (cm)	Total weight (g)
BBS75332	CAN	Miramichi River, NB	1974	05/23/1976[1]	77	4,200
BBS84564	CAN	Miramichi River, NB	1973	5/28/1976	80	4,200
BBK78583	CAN	Morell River, PEI	1976	05/21/1977	76	3,975
BBX00427	CAN	Liscomb River, NS	1980	06/17/1981	51	1,200
AW14198	CAN	St John River, NB	1984	06/25/1985	85	3,966
A3458	USA	Penobscot River, ME	1980[2]	06/27/1981	80	3,600[3]

[1]capture response indicates that catch occurred in a research net
[2]fish was tagged as returning adult captured at the Veazie Trap
[3]estimated gutted weight

Fishery generated tag return data are not necessarily representative of the occurrence of tags within the catch. Not all countries/regions have large scale tagging operations, tagging operations are often not representative of countries/regions and internal tags, such as coded wire tags, would not have been detected as there was not a system set up to identify and recover these tags. As well, publicity concerning the existence of past tagging programs and instructions on the procedure to return tags from this fishery was not targeted on this area. Catch composition in terms of country/region of origin can therefore not be determined from these data. However, these types of data do confirm that North American fish from both Canada and USA have both been historically susceptible to capture in the Saint-Pierre and Miquelon fishery.

Given the increase in the number of licensed Saint-Pierre and Miquelon gillnet fishermen (section 4.1.1), the increase in reported catch (Table 2.1.1.1) and the historic tag return data, a biological sampling program is needed to investigate the composition and origin of the Saint-Pierre and Miquelon Atlantic salmon catches. These data are essential to characterize the effects that this fishery may have on the Atlantic salmon populations of North America and, in particular, on their “endangered” populations.

The following types of data are essential to gaining a better understanding of the composition of the Saint-Pierre and Miquelon Atlantic salmon fishery and for determining the effect that this fishery has on the Atlantic salmon resources of North America.

A biological sampling program for the Saint-Pierre and Miquelon gillnet fishery should be an international cooperative effort between USA, Canada, France and the local government of Saint-Pierre and Miquelon. At a minimum, an individual sampler will need to be coupled with a local contact and stationed in Saint-Pierre for a period of 2-3 weeks during the period when the fishery is expected to be prosecuted (June through August). The local contact would be essential for connecting the sampler with individuals who would likely be gillnetting during this period. The sampler would collect information related to fishing effort (description of gear, number of nets fished, soak time etc.) as well as catch (type and amount of species caught). In addition, detailed biological data needs to be collected for each individual Atlantic salmon sampled: including individual length and individual weight data plus a scale and genetic sample (o provide data on origin). The presence or absence of any external tags, clips or marks should also be noted for each individual as well as any abnormal physical features. Additional support from the countries involved could result in an increase of the number of sampling teams. This increase could be used to widen the sampling coverage in both time and space. Increased sampling may be valuable, depending on the spatial and temporal occurrence of the fishery, which is currently unknown.

4.7 Data deficiencies and research needs in the North American Commission Area

Data deficiencies and research needs for the NAC area are presented in Section 6.

Table 4.1.2.1. Percentages by user group and province of small and large salmon harvested (by number) in the Atlantic salmon fisheries of eastern Canada during 2002.

	% of provincial harvest			% of

Labrador : SFAs 1,2&14B
Newfoundland: SFAs 3-14A
Gulf of St. Lawrence: SFAs 15-18
Scotia-Fundy: SFAs 19-23 (SFA 22 is not included as it does not produce 2SW salmon)
Quebec: Q1-Q11

Table 4.2.3.1 Run reconstruction data inputs for harvests used to estimate pre-fishery abundance of maturing and non-maturing 1SW salmon of North American origin (terms defined in Table 4.2.3.2).

Table 4.2.3.2 Definitions of key variables used in continental run-reconstruction models for North American salmon.

i	Year of the fishery on 1SW salmon in Greenland and Canada
M	Natural mortality rate (0.03 per month)
t1	Time between the mid-point of the Canadian fishery and return to river = 1 months
S1	Survival of 1SW salmon between the homewater fishery and return to river {exp(-M t1)}
H_s(i)	Number of "Small" salmon caught in Canada in year i; fish <2.7 kg
H_l(i)	Number of "Large" salmon caught in Canada in year i; fish >=2.7 kg
AH_s	Aboriginal and resident food harvests of small salmon in northern Labrador
AH_l	Aboriginal and resident food harvest of large salmon in northern Labrador
f_imm	Fraction of 1SW salmon that are immature, i.e. non-maturing: range = 0.1 to 0.2
af_imm	Fraction of 1SW salmon that are immature in native and resident food fisheries in N Lab
q	Fraction of 1SW salmon present in the large size market category; range = 0.1 to 0.3
MC1(i)	Harvest of maturing 1SW salmon in Newfoundland and Labrador in year i
i+1	Year of fishery on 2SW salmon in Canada
MR1(i)	Return estimates of maturing 1SW salmon in Atlantic Canada in year i
NN1(i)	Pre-fishery abundance of non-maturing 1SW + maturing 2SW salmon in year i
NR(i)	Return estimates of non-maturing + maturing 2SW salmon in year i
NR2(i+1)	Return estimates of maturing 2SW salmon in Canada
NC1(i)	Harvest of non-maturing 1SW salmon in Nfld + Labrador in year i
NC2(i+1)	Harvest of maturing 2SW salmon in Canada
NG(i)	Catch of 1SW North American origin salmon at Greenland
S2	Survival of 2SW salmon between Greenland and homewater fisheries
MN1(i)	Pre-fishery abundance of maturing 1SW salmon in year i
RFL1	Labrador raising factor for 1SW used to adjust pre-fishery abundance
RFL2	Labrador raising factor for 2SW used to adjust pre-fishery abundance

Table 4.2.3.3 Run reconstruction data inputs used to estimate pre-fishery abundance of non-maturing (NN1) 1SW salmon of North American origin (terms defined in Table 4.2.3.2).

Labrador : SFAs 1,2&14B
Newfoundland: SFAs 3-14A
Gulf of St. Lawrence: SFAs 15-18
Scotia-Fundy: SFAs 19-23 (SFA 22 is not included as it does not produce 2SW salmon)
Quebec: Q1-Q11

Table 4.2.4.3. Smolt age distributions in six stock areas of North America used to weight forward the spawning escapement in the current year to the year of the non-maturing 1SW component in the Northwest Atlantic.

	Smolt age (years)					
Stock area	1	2	3	4	5	6
Labrador	0.0	0.0	0.077	0.542	0.341	0.040
Newfoundland	0.0	0.041	0.598	0.324	0.038	0.0
Québec	0.0	0.058	0.464	0.378	0.089	0.010
Gulf of St. Lawrence	0.0	0.398	0.573	0.029	0.0	0.0
Scotia-Fundy	0.0	0.600	0.394	0.006	0.0	0.0
USA	0.377	0.520	0.103	0.0	0.0	0.0

Table 4.2.4.4 The mid-point of 2SW spawners and lagged spawners for North America and to each of the geographic areas. Lagged refers to the allocation of spawners to the year in which they would have contributed to the year of prefishery abundance.

	North America		Prefishery	Recruits/	Labrador (L)		Newfoundland (N)		Quebec (Q)		Gulf of St. Lawrence (G)		Scotia-Fundy (S)		USA (US)	
	Total 2SW	Lagged 2SW	abundance	2SW lagged												
Year	spawners	spawners	recruits	spawner	Total	Lagged	Total	Lagged	Total	Lagged	Total	Lagged	Total	Lagged	Total	Lagged

NF-Lab comm as 1SW = NC1(mid-pt) * 0.677057 (M of 0.03 per month for 13 months to July for Canadian terminal fisheries)
NF-Lab comm as 2SW = NC2 (mid-pt) * 0.970446 (M of 0.03 per month for 1 month to July of Canadian terminal fisheries)
Terminal fisheries = 2SW returns (mid-pt) - 2SW spawners (mid-pt)
a - starting in 1993, includes estimated mortality of 10% on hook and released fish
b - starting in 1998, there was no commercial fishery in Labrador; numbers reflect size of aboriginal fish harvest in 1998-2002 and resident food fishery harvest in 2000-2002

5 ATLANTIC SALMON IN THE WEST GREENLAND COMMISSION

5.1 Catch and effort in 2002

At its annual meeting in June 2002 NASCO agreed to a revised *ad hoc* management programme for the 2002 fishery at West Greenland that as in the previous year incorporated the use of real-time data to allocate quota for the commercial fishery. The commercial fishery is defined as landings sold to processing plants and excludes reported private landings (not sold to plants) and unreported catch. The commission noted that the forecast pre-fishery abundance is considered to be highly uncertain, but also that there appears to be a relationship between the estimated pre-fishery abundance and catch per unit of effort in West Greenland, measured as average daily landings per licensed fisherman. Two harvest periods were implemented with quotas dependent on the observed average CPUE during the fishery in the first harvest period.

The initial quota for the first quota period of up to two weeks was set at 20 t, and additional quota was allocated for the subsequent harvest period of a maximum of five weeks based on catch per unit effort observed in the fishery. The maximum quota for the fishery as a whole would have depended on the observed average commercial CPUE during the first period of fishing, being 20, 38 and 55 t, respectively for three levels of CPUE.

Shortly before the opening date of the fishing season (August 12) the Organization of Fishermen and Hunters in Greenland and the North Atlantic Salmon Fund agreed to suspend the commercial fishery for salmon in 2003. The subsistence fishery was not affected by this agreement. As is the past, there was no quota limit set for the subsistence fishery. The authorities did not apply a closing date for the fishing season, i.e. the season was open till the end of the year.

By regulation, all catches including landings to local markets, privately purchased salmon, and salmon caught by food fishermen, are to be reported on a daily basis to the Fishery Licence Office. By the end of the year a total of 9 t of landed salmon was reported (Table 5.1.1.1). The geographical distribution of catches by Greenland vessels is given in Table 5.1.1.2 for the years 1977-2002. The unusually high proportion of catch observed in southern Greenland in 2000 and 2001 is not indicated for the 2002 season, being close to the average for the period 1995-1999.

Licences for the salmon fishery were issued to fishers fishing for factories, local markets, hotels, hospitals etc., while fishing for personal use was permitted without licence for residents of Greenland. The number of reporting fishers in the salmon fishery has decreased sharply since 1987, when a catch of more than 900 t was allowed and more than 500 licenses were active in the fishery. During the 2002 season 41 fishers reported catches, the lowest number on record.

Landing reports were received from August 15 until December 11. Due to a lesser incentive for a thorough and early reporting of catches many of the reports combined more than one landing of salmon. Some of the reports were probably also sent to the License Office with a considerable delay in relation to the time of fishing. Because of these changes in reporting, the Working Group was unable to estimate average CPUE values for that part of the fishery in 2002, which is comparable with the commercial fishery in preceding years. As a result, it was not possible to update the data series used to develop the *ad hoc* management programme used in the previous two years.

Due to the character of this fishery, which includes provisions for personal consumption, some unreported catch likely occurs. Unreported catch is primarily associated with personal consumption or subsistence fishing, which appears to have remained relatively stable through time. There is presently no quantitative approach for estimating the magnitude of unreported catch; however, based on local knowledge it is at the same level used for recent years (around 10 t).

5.1.1 Biological characteristics of the catches

Biological characteristics (length, weight, and age) were recorded from 1,297 fish in catches from NAFO Div. 1C, 1D and 1F (Figure 5.1.2.1) in 2002 and presented in Tables 5.1.2.1 to 5.1.2.3 together with corresponding data from sampling in Greenland since 1968.

The general downward trend in mean length and weight (unadjusted for sampling date) of both European and North American 1SW salmon observed from 1969–1995 reversed in 1996, when mean lengths and weights increased (Table 5.1.2.1, Section 5.2.3.1). In 2000, a decrease was observed, mainly in the North American component where the mean lengths and weights were among the lowest observed in the time series. In 2001 and 2002, mean lengths and mean weights increased again to a level close to the overall average for the recent decade.

Distribution of the catch by river age in 1968-2002 as determined from scale samples is shown in Table 5.1.2.2. The percentage of the European origin salmon that were river age-1 fish has been quite variable through the later years with relatively high values in 1998-2000, the 2000 value being the highest on record, but the percentage decreased thereafter to 10 % in 2002. A low percentage of this group suggests a low contribution from Southern European stocks. In 1998 and 1999 low percentages of 7.6 and 7.2 %, respectively, of river age-3 were observed, the lowest on record. In 2002, the percentage was 18 %, close to the overall mean of 16.9 %. The mean river age of the contribution from Southern European stocks reflects these changes in percentages, with the overall mean age of 2.0 years. The percentage of river age-2 salmon of North American origin declined somewhat from 1998, which was close to the overall mean value of 33.5 %, to 26.7 in 2002. In 2001 the lowest value on record was observed (15.2 %). The mean river age of the catch has varied throughout the last 10 years, but in 2002 is above age 3.0, the overall mean.

The sea-age composition of the samples collected from the West Greenland fishery showed no significant changes in the percentages in the North American component of fish from 1998 to 2002 (Table 5.1.2.3). The percentage of 1SW salmon in the European component has been very high since 1997 (99.3 %), and was 100 % from 1999 to 2000.

5.1.2 Origin of catches at West Greenland

5.1.2.1 Continent of Origin

An international sampling program requested by NASCO was instituted in 2001 to sample landings at West Greenland, and repeated in the 2002 fishing season. The sampling program included sampling teams from Greenland, United Kingdom, Ireland, United States and Canada. Teams were in place at the start of the fishery and continued to the end of September although landings continued until December. In total, 1,374 specimens, representing 44 % by number of the landings, were sampled for presence of tags, fork length, weight, scales, and tissue samples for DNA analysis. The limitation of the fishery to subsistence fishing caused severe practical problems for the sampling teams; however, the sampling program was successful in adequately sampling the Greenland catch temporally and spatially.

Tissue and biological samples were collected from the mixed population at West Greenland caught for local consumption in 2002. Samples were obtained from four landing sites, Qaqortoq and Narsaq (NAFO Div. 1F), Nuuk (NAFO Div. 1D) and Maniitsoq (NAFO Div. 1C). The sampled salmon were measured, scales were removed for ageing, tissue for analysis, and gutted weight recorded. No disease sampling was conducted in 2002 because of logistical difficulties, however, the Working Group recommends that it be done in 2003.

A total of 1,329 tissue samples were removed and preserved for DNA analysis. Funding was available to analyse about 500 tissue samples, so collected samples were subsampled to select samples for analysis that were representative of standard weeks and statistical areas where landings were prevalent. A total of 501 samples were genotyped at 11 microsatellite DNA loci for assignment to continent of origin. The maximum likelihood genetic distances between North American and European populations are used to generate continent of origin assignments that have been estimated to be virtually 100 % correct. Continent of origin assignments is based on 4,373 Atlantic salmon genotypes (individuals): 459 from Europe and 3,914 from North America with 600 of these from Canadian stocks. These genotypes of known origin were used to assign the 501 salmon to continent of origin using the Bayesian maximum likelihood algorithm. In total, 338 (67.5 %) of the salmon sampled from the 2002 fishery were of North American (NA) origin and 163 (32.5 %) fish were determined to be of European origin (Table 5.1.3.1).

The Working Group noted that the differences (see table below) among the continental percentages in the three NAFO divisions (Chi Square p <0.001) requires sampling catch from all to achieve the most accurate estimate of the contribution of fish from each continent to the mixed fishery.

NAFO division	North America		Europe	
	Number	%	Number	%
Div. 1C	102	69.9	44	30.1
Div. 1D	181	88.7	23	11.3
Div. 1F	55	36.4	96	63.3

Applying the continental percentages for reported catch by NAFO Division results in estimates of 6.4 t (2200 salmon) of North American origin and 2.6 t (900 salmon) of European origin fish landed in West Greenland in 2002. For divisions without samples the overall average weight and continent of origin splits were assumed. Quota reductions have resulted in an overall reduction in the numbers of both North American and European salmon landed at West Greenland until 1999. The number of North American salmon remained about the same in 1999 and 2000 (5-6,000 salmon), but increased in 2001. In 2002, the number of landed salmon decreased to the lowest number on record (Table 5.1.3.2, Fig. 5.1.3.1). A high percentage of European salmon in Div. 1F was observed in 2000-2002.

5.1.2.2 Origin of Atlantic salmon caught at West Greenland at a finer resolution than continent of origin

Within a mixed stock fishery, the identification of the origin and composition of the exploited resource is essential for the responsible management of the shared resource. This is especially true for stocks that are protected under various nation-specific Endangered species legislations. In addition, the NASCO Decision Structure requires that the stock composition of mixed stock fisheries be considered while developing management plans. As an example, the West Greenland Atlantic salmon fishery falls within this category.

Atlantic salmon is highly genetically structured compared to most fish species (Ward et al.1994). Enzyme variants (allozymes) show that approximately one third of the total genetic diversity of Atlantic salmon results from genetic differences between populations. Analyses of microsatellite DNA data from archived scales indicates that the local genetic structure of Atlantic salmon is temporally stable, even over several decades (Nielsen et al. 1999). A major genetic dichotomy exists between populations from either side of the North Atlantic Ocean and between European populations in Baltic and Atlantic drainages (Ståhl 1987). One microsatellite locus has shown almost perfect separation of North American and European Atlantic salmon (Taggart et al. 1995; Koljonen et al. 2002). Such hypervariable nuclear DNA marker types can in theory be used to distinguish any distinct population group from one another, provided that there is a demonstrated positive correlation between genetic and geographic distance and that a sufficient number of unlinked loci are studied. However, it remains to be seen how well these markers estimate finer scale composition within a mixed stock fishery where a large number of populations are contributing.

Data collected for continent of origin assignments for the West Greenland mixed stock fishery have been based on 4,373 Atlantic salmon genotypes (individuals): 459 from Europe and 3,914 from North America with 600 of these from Canadian stocks. These data have also been used to do preliminary assignments of countries, and thus stock complex within Europe, and between Canada and USA. What follows describes an approach for estimating the catch of fish from the USA Distinct Population Segment (DPS), eight rivers in Maine collectively listed as Endangered.

Probabilistic-based Genetic Assignment model (PGA)

The PGA is a probabilistic model that uses Monte Carlo sampling (using @RISK, an Excel add-on) to determine the continent of origin, country of origin or finer scales of resolution for a mixed stock fishery where genetic assignment data and the variability surrounding these data are available.

<u>Generalized approach:</u>

All genetically characterized individuals from the 2002 West Greenland fishery were assigned to continent of origin and country of origin (for NA assigned individuals only). Unanalysed individuals from the catch were assigned to continent of origin (COO) according to a binomial distribution from known (genetically analysed) COO assignments. Furthermore, all North American (NA) origin individuals were assigned to country of origin according to a binomial distribution from the country of origin assignments provided. The regional assignments within the USA were calculated according to the proportion of the 2SW adult returns to all Atlantic salmon rivers within the USA. For the DPS estimate, a Pert distribution, based on the mean estimate, 90% confidence intervals and a truncation of the minimum value (at 0) generated from the linear regression model was used to generate the estimate. Finally the regional assignments were adjusted for natural mortality to estimate the increase in returns that would have resulted with no commercial harvest.

It is estimated that the reference dataset correctly assigns continent of origin 100% of the time whereas the country of origin assignments (USA vs. Canada) are estimated to be 92.2% for assigning USA samples back to the USA and 88.0% for assigning Canadian samples back to Canada (Spidle et al. 2003). These accuracies reflect the high degree of genetic separation between continents and the much lower separation on the country scale (Figure 5.1.3.2). The composition of the reference dataset greatly affects its assignment accuracy, both in terms of the spatial coverage of samples within the dataset as compared with the unknown samples and the quantity of samples within these reference sets. If a reference dataset is used to classify unknown samples, but the reference dataset does not include known samples from the range of possible populations or there are a disproportionate number of samples from one known group or another, the misclassification rate can rise significantly above that recorded through cross validation procedures on the reference dataset. However, if the classification accuracies of the reference dataset are known, the misclassification rates can be accounted for and the tallies produced for the PGA can be adjusted.

While trying to identify USA origin fish in the 2002 West Greenland catch, biological inconsistencies were identified that confounded the model outputs. The cause of these inconsistencies appears to be related to the assignment accuracy of the reference dataset as determined by cross validation procedures. Whenever using genetic data to assign individuals to continent, country or region, external supporting data should be used to corroborate the assignments. Supporting evidence can come from past tagging studies or biological characteristics.

Classifying Southern and Northern European stock complexes in the West Greenland catch has direct applicability to the forecast of PFA. However, finer scale classification within continent will also be useful in evaluating the effects of other fisheries on salmon stocks.

Even finer resolution using genetic techniques is possible, but requires different techniques and more extensive datasets of known origin fish. In some cases, this level of genetic characterization is maintained for broodstock and consulted to reduce sibling mating at hatcheries managing endangered stocks. It is possible to determine the probable parents of an unknown juvenile if the suite of potential parents has been genetically characterized. This level of detail could be available for wild stocks on the verge of extirpation.

Within NEAC and NAC countries, the primary fisheries management unit is watershed. Managers are using differentiation of origin among tributaries for fish captured in mixed stocks fisheries within individual rivers to develop these plans. In UK (N. Ireland), analysis of genetic variation at microsatellite loci in baseline samples from river populations and from a mixed stock fishery in the Foyle area is being used to identify river populations contributing to the fishery. Preliminary analysis using genetic stock identification and assignment techniques is indicating that several areas of the overall Foyle catchment are driving the fishery, whereas other Foyle rivers are apparently under-represented. Results of this analysis may enable managers to regulate the fishery to achieve conservation in all stocks and take specific action to restore production in vulnerable stocks.

These examples show the need for the identification of country or region of origin for the management of mixed stock fisheries. Presently, the reference datasets used for these assignments lack adequate spatial and temporal sample coverage to consistently assign to finer scale with acceptable assignment accuracy. This is especially true for the European and Canadian stock complexes. Efforts need to be taken to bolster these reference datasets by collecting and analysing samples from additional populations over as wide a geographic scale as possible.

5.2 Status of the stocks in the West Greenland area

The salmon caught in the West Greenland fishery are mostly (>90%) non-maturing 1SW salmon, many of which would return to homewaters in Europe or North America as MSW fish if they survived the fishery. There are also 2SW salmon and repeat spawners, including salmon that had originally spawned for the first time after 1-sea-winter and 2-sea-winter. The most abundant European stocks in West Greenland are thought to originate from the UK and Ireland, although low numbers may originate from northern European rivers. Most MSW stocks in North America are thought to contribute to the fishery at West Greenland.

In European and North American areas, the overall status of stocks contributing to the West Greenland fishery is at the lowest level recorded, and as a result, the status of stocks within the West Greenland area is thought to be extremely low compared to historical levels. There has been no significant increase in survival index for the stock. Status of relevant stocks in the NEAC and NAC areas are summarized below, and detailed information can be found in Sections 3.4 and 4.2.

5.2.1 Southern European Stock

The main contributor to the abundance of the European component of the West Greenland stock complex is non-maturing 1SW salmon from southern Europe. The percentage of European fish in catches at West Greenland was around 30% in the early 1990's and the 2000's, but was below 20% from 1996 to 1999. A Run-Reconstruction Model was used to estimate the pre-fishery abundance of non-maturing 1SW salmon from 1971 to the present. These have declined since the 1970s, with the 2001 abundance of 546,939 being the 3rd lowest estimate on record (Figure 3.5.1.5). The contributions of countries within NEAC to this PFA, based on tagging data are: France, 2.7%; Ireland, 14.7%; UK (England &Wales), 14.9%; UK (Northern Ireland), <0.01%; UK (Scotland), 64.5%; and northern NEAC countries, 3.2%. Southern European MSW salmon stocks in the Southern NEAC area show a consistent decline over the past 10-15 years, and the estimated overall spawning escapement has been below conservation limits (S_{lim}) in four out of the past six years. Information from individual countries is summarized below:

France:

- MSW returns second lowest in the time series
- MSW spawners lowest in the time series

Ireland:

- MSW returns above the median value for the time series
- MSW spawners above the median value for the time series

- MSW numbers subject to considerable uncertainty as the sea age composition of the catch is not known accurately

UK (England & Wales):
- MSW returns 20% below the median value for the time series
- MSW spawners close to the median value for the time series

UK (Northern Ireland):
- Historical trends unclear as the sea age composition of the catch is unknown for most of the time series.

UK (Scotland):
MSW fish estimated to contribute between 40% & 70% of the spawning stock
MSW returns second lowest in the time series
MSW spawners second lowest in the time series

5.2.2 North American Stock

The North American Run-Reconstruction Model was used to update the estimates of pre-fishery abundance of non-maturing and maturing 1SW salmon from 1971-2001. The total population of 1SW and 2SW Atlantic salmon in the northwest Atlantic has declined since the 1970s, with the 2001 abundance of 428,300 being the lowest estimate (Figure 4.2.3.2). The percentage of North American salmon in the West Greenland catch was less than 70 % for all but one year until 1992, and then increased from 60% to 90% from 1995 to 1999, and has averaged approximately 67% from 2000 to 2002 (Table 5.1.3.1). In 2002, the overall conservation limit (S_{lim}) for 2SW salmon was not met in any area except Newfoundland. Specifically:

Newfoundland:
- 2SW and 3SW salmon are a relatively small component of this stock complex
- 2SW returns third lowest in the last 10 years
- 2SW spawners in 2002 at approximately 1.5 times the 2SW stock conservation limits (S_{lim})

Labrador:
- 2SW salmon historically an important part of this stock complex
- 2SW returns peaked in 1995, and decreased again in 1996 and 1997
- no estimate is given after 1997 from this area when the commercial fishery, the basis for the return and spawner model for Labrador, ended

Québec:
- 2SW and 3SW salmon an important part of this stock complex
- 2SW returns lowest in a 32-year time-series
- 2SW spawners in 2002 at 52% of 2SW conservation limit (S_{lim})

Gulf of St. Lawrence:
- 2SW salmon an important part of this stock complex
- 2SW returns second lowest in a 32-year time-series
- 2SW spawners in 2002 at 38% of 2SW conservation limit (S_{lim})

Scotia-Fundy:
- 2SW salmon historically an important part of this stock complex
- 2SW returns lowest in a 32-year time-series
- 2SW spawners in 2002 at 6% of 2SW conservation limit (S_{lim})
- inner Bay of Fundy stocks listed as Endangered by the Committee on the Status of Endangered Wildlife in Canada

United States:
- 2SW salmon historically an important part of this stock complex
- 2SW returns second lowest in a 32-year time-series
- 2SW returns in 2002 at 3% of 2SW conservation limit (S_{lim})
- stocks in 8 rivers listed as Endangered under the Endangered Species Act

5.2.3 Evaluating Atlantic salmon biological data for phase shifts

For the past two years the Working Group has noted that there is a potential problem of non-stationary relationships in spawners to PFA. In 2002, the report included regressions of CPUE (kg/reported landings) and North American and Southern European PFA, with residuals demonstrating a shift in the relationship following the 1992-1993 closure (ICES 2002/ACFM:14, Figure 5.1.2.1). This year the Working Group examined biological data from all three Commission areas for non-stationarity, specifically attempting to identify the transition year(s) where a phase shift was evident. It was hoped that this evaluation would inform the modeling process and facilitate change to integrate trends contained in the time-series of PFA and lagged spawner in NEAC and NAC.

North-East Atlantic Commission

Anon. (2003) provides a critical examination of selected NEAC stock and recruitment relationships Six rivers were considered: the R. Frome UK (England and Wales), the Girnock Burn and the R. North Esk UK (Scotland), the R. Bush and R. Burrishoole (Ireland) and the R. Ellidaar (Iceland). Stock (S) and recruits (R) were expressed in eggs. Recruitment was estimated from estimated returns of adult salmon back to the coast, prior to any homewater fishery. Preliminary examination of these SR series suggested a consistent drop in recruitment levels around the mid 1980s. Analysis of the 12 SR series (i.e. two periods for six rivers) was conducted using a Ricker model. Comparisons before and after the mid 1980s were made for two parameters: the slope at origin (a) and the maximum recruitment per m^2 of wetted area accessible to salmon (smax). Comparisons were based on the median of the posterior distribution of the parameters.

For all the six rivers analysed, there is an obvious drop in the recruitment process occurring in the mid 1980s (Figure 5.2.3.1). In four of the six instances, the productivity (Ricker α parameter - recruits produced per stock unit at low egg depositions) has also dropped significantly. Causes for this phenomenon are unclear although it certainly relates, at least partly, to changes in marine survival observed over the last three decades and to habitat changes (degradation of spawning areas or loss of specific spawning areas).

A non-parametric ratio test (NPRATIO) was used to investigate phase changes in time series of marine survival for salmon stocks in the southern part of the NEAC area (Rago 1993). The software generates the ratio of means from a baseline period compared to a treatment period (i.e the R_{crit} value). Random ratios are then generated from the time series and the number of times the R_{crit} is equal to, higher than or less than these random ratios is calculated. In the present analysis, a moving baseline period starting with the first year was initially compared to all other years in the series i.e. the treatment period. Each successive year was then removed from the treatment period and added to the baseline period with the analysis being repeated with each additional year. In this way, consistent differences in the ratio of the mean survival values of the baseline period and the treatment period could be tracked through each series. In order to provide significance levels at the 5% level, 1,000 random ratios were simulated for each comparison of baseline mean with treatment mean (Rago 2001).

Data for 1SW survival rates were available for five Irish stocks (Shannon hatchery, Screebe hatchery, Burrishoole hatchery, Corrib hatchery and wild), two UK (N. Ireland) stocks (Bush hatchery and wild) and one UK (Scotland) stock (N. Esk wild). These data extended through most of the period from 1980 through 2001 smolt migration years. Marine survival data were available for 2SW fish from four Irish stocks (Shannon hatchery, Burrishoole hatchery, Corrib Hatchery and Corrib wild), and one UK (Scotland) river (N. Eske wild). The time series extended from 1980 through 1998 smolt migration years.

Starting at the first baseline period for 1SW survival (i.e. 1980) compared to the treatment period of 1981-2001, the probability of observing an R_{crit} greater than the randomised ratios was 0.68 (680 of 1,000). Therefore, this R_{crit} value could have occurred by chance alone (Figure 5.2.3.2), indicating no significant difference in the survival in 1980 compared to the mean for the rest of the series. Similarly, for each successive addition of years to the baseline from the treatment period up to 1980/1984, the probability of the R_{crit} being less than the random ratio is less than 0.95, showing that the mean survival for the period 1980-84 was not significantly different to the post-1984 period. After the 1980/1984 period however, the successive removal of each years data from the treatment period and addition of this year to the baseline period indicates a significant difference in the means for each successive comparison up to the 1980-99 baseline and 2000-01 treatment period.

The first baseline period for 2SW survival is 1980, which is compared to the 1981-1998 treatment period. The probability of observing an R_{crit} greater than the randomised ratios was 0.36 (360 of 1,000) and therefore could have occurred by chance alone (Figure 5.2.3.3). For each successive comparison up to 1980/1989 the mean survivals are significantly higher in the earlier period compared to the later period ($p < 0.95$ in each case). After the 1980/1989 baseline period, the successive removal of each years data from the treatment period and addition of this year to the baseline period results in consistent period where the survival rates for the successive baseline/treatment comparisons are not significantly different.

These results provide some support of a phase change in marine survival consistent with other observed stock dynamic changes occurring in other stocks from the North East Atlantic and North America, particularly around the 1989/1990 period for 2SW stocks and possibly earlier for 1SW stocks. The percentage of Southern NEAC stock caught in the Greenland fishery has ranged from 10% to 66% and is estimated to be 33% presently. Therefore, the results of the 2SW analysis may be particularly pertinent to the identification of phase shifts affecting the dynamics of the Greenland fishery.

North American Commission
The relation between the returns of 1SW and MSW from a given smolt cohort was examined for three data sets from Québec for 1980 – 2001. The data were: estimates of total salmon returns in Québec and of returns from two index rivers. Returns were corrected based on estimates of captures made in home water, but not those in the distant fisheries. The regressions of 1SW to 2SW returns for a cohort were developed and residuals plotted against year (Figure 5.2.3.4). In each analysis the residuals for the regressions demonstrate two periods, namely from 1980 and 1990 and the period starting in 1991. A similar regression approach did not produce evidence for a shift in survial rate of hatchery 2SW returns to the Penobscot River. However, inverse weight estimates for North America show an increase in theoretical M in the second year over the last decade (Figure 2.3.1.2)

On the LaHave River, Nova Scotia, the natural log of recruits per spawner (survival index) determined at Morgans Falls had normal variance to 1986 but has been below replacement (zero line) ever since (Figure 5.2.3.5). The shift in population stability was not associated with an acute loss in freshwater productivity monitored by both juvenile densities and smolt emigration. However, the drop in the survival index (Ln(R/S)) in 1986 is associated with the decline in smolt age two-sea age two (age 2.2) and is equivalent to the 1990 PFA year.

Greenland Commission Area
The whole weight of 1SW North American salmon in the West Greenland fishery (uncorrected for sampling date) was examined in two independent tests. Mean 1SW salmon whole weights from 1969-2002 were regressed against year to determine when the relationship became significant by casting forward in groups of four years. There was a significant decline in weight from 1969 to 1992, followed by a significant increase in weights over time (1995-2002) (Figure 5.2.3.6), identifying the change in relationship in the early 1990's. These data were also analyzed using the randomization method described for Southern NEAC survival, identifying the break in the same time period (Figure 5.2.3.7). An analysis of river age distribution (%) for North America was begun, however, the analysis was confounded by changes in hatchery produced river age 1-fish over time and was abandoned.

Therefore the Working Group decided that the phase shift, detected in about 1990, needed to be considered when providing catch advice for the West Greenland fishery in 2003.

5.3 Evaluation of the effects on European and North American stocks of the West Greenland management measures

There have been the following significant changes in the management regime at West Greenland since 1993:

- First, NASCO adopted a new management model (Anon. 1993) based upon ICES assessment of the PFA of non-maturing 1SW North American salmon and the spawner escapement requirements for these stocks. This resulted in a substantial reduction in the TAC agreed to by NASCO from 840 t in 1991 to 258 t in 1992, and further reductions in subsequent years.
- The next change in management was the suspension of fishing in 1993 and 1994 following the agreement of compensation payments by the North Atlantic Salmon Fund. Due to the closure of the fishery in the two years no sampling could be carried out in Greenland, and no biological data were collected.
- In 1998, NASCO agreed on a subsistence fishery of 20 t, which in the past has been estimated for internal consumption at Greenland. In 1999, a multi-year management was agreed restricting the annual catch to that amount used for internal consumption.
- An *ad hoc* management arrangement for 2001 was agreed by NASCO, implementing an adaptive quota calculation, based upon three harvest periods. The resulting total quota for all harvest periods was 114 t.
- A revised *ad hoc* management arrangement for 2002 was agreed to by NASCO. In addition, an agreement was negotiated between the North Atlantic Salmon Fund and its partners, and the Greenland Association of Hunters and Fishers (KNAPK), to suspend the commercial part of the salmon fishery. The agreement is for a total of five years, and is automatically renewed annually unless one of the parties gives notice in advance of the fishing season of their intention to withdraw.

To calculate a possible TAC for those years according to the agreed quota allocation model (Anon. 1993) biological parameters from sampling in 1992 were used (Table 5.3.1). The variables in the table (percent of origin, mean weights, and percent of 1SW fish) are used in the analyses (Section 5.1).

The numbers of fish spared by the 1993-1994 closures are shown in Table 5.3.1. The potential catches in the years 1993 and 1994 of 89 and 137 t, respectively correspond to the TACs calculated in accordance with the quota allocation computation model that was agreed by NASCO at its annual meeting in 1993. For the successive years nominal catch figures are used. The table contains the number of salmon returning to home waters provided no fishing of the given magnitude took place in Greenland. The biological parameters given in the table represent the annual sampling data.

The mean number for 1993-2002 of potentially returning fish per ton caught at Greenland is calculated to 166 and 92 salmon for North America and Europe, respectively.

To estimate the number of salmon spared by the suspension of the fishery in 2002 the following assumptions are made:

- Excluding year 2000 the availability of salmon and the potential effort in 2002 is assumed to be close to average for the recent five years (1997-2001).
- The non-commercial landings in 2002 would have been close to average for the recent five years (as above) had there been a commercial fishery.

The average commercial catch for the period was 27,900 kg, and the non-commercial part was 4,800 kg. The difference between the reported non-commercial catch in 2002 and the five-year average is 4,200 kg, leaving 23,700 kg as a potential commercial landing in 2002. The corresponding number of salmon is 5,400 and 2,500 salmon of North American and European origin, respectively.

In the current analysis the effects of the management measures taken at West Greenland have been examined in terms of numbers of fish only. Thus it has been difficult to show direct benefits to home-water stocks from these measures. The Working Group recommends that other indices of change, i.e. changes in age composition, size at age and sea survival, should also be included in this evaluation.

Following on the above recommendation, the Working Group reviewed an analysis of the impacts of variations of the West Greenland fishery on expected returns to rivers. The analysis was based on an examination of the 1SW to 2SW relationship demonstrated for several stocks in eastern Canada and focused on the explanatory power of the West Greenland catches on the residuals of the relationship.

In the absence of fishing mortality, it was assumed that stocks would display an average 1SW to 2SW relationship albeit over a short time interval and with variation around the average relationship arising from several stock driven or environmentally driven factors. If fisheries mortality is proportional on both age groups, the relationship should be undistinguishable from the natural process. If a fishery exploits the 2SW age group but not the 1SW age group, then the 1SW to 2SW ratio should be unnaturally high. If fisheries exploit 1SW age group preferentially, then the 1SW to 2SW ratio would be unnaturally low. The absence of exploitation on one age group can be used to assess the relative impacts of the fishery on the other age group, especially if there have been changes in fisheries management affecting the age group of interest.

The fishery at West Greenland exploits predominantly 1SW salmon destined to mature and return as 2SW salmon the following year. Since 1992, essentially only 2SW salmon are presently exploited at West Greenland as a result of the progressive closures of the commercial fisheries in eastern Canada. It was assumed therefore that the 1SW salmon returning to rivers in eastern Canada and particularly so to the Maritimes have been filtered by natural survival only. Variations in 2SW returns to eastern Canada from the expectation of the 1SW to 2SW relationship may be exaggerated by variations in fisheries harvests at West Greenland.

This effect was examined using data from the following Maritime rivers:

- 1SW and 2SW returns of wild and hatchery origin salmon from the Saint John River at Mactaquac
- 1SW and 2SW wild and hatchery salmon from the LaHave River
- 1SW and 2SW wild salmon from the Miramichi River

The reference 1SW-2SW relationship for the Maritime rivers was considered to be 1992 to 2002. To assess whether there were any detectable effects on 2SW returns to rivers as harvests at Greenland varied, a covariance analysis was conducted. The model was:

$2SW_{i+1} = f\{1SW_{I,} GN1\}$

where 2SWi+1 = returns of 2SW salmon in the river in year I+1

1SWi = returns of 1SW salmon to the river in year I,

GN1 = harvest of North American 1SW salmon at West Greenland in year I

The returns data were log transformed before analysis therefore the model being adjusted was:

Ln(2SW returns in year I+1) = Ln(1SW returns in year I) + GN1

<u>1SW-2SW associations</u>

There are several strong associations between 1SW to 2SW salmon, particularly for the wild salmon. In both the LaHave and Southwest Miramichi relationships, the 2SW returns in 1993 are exceptionally low relative to the 1SW returns in 1992 (Fig. 2.4.3.8). There is a negative association between the level of harvest at West Greenland and the difference from expected (based on the 1SW / 2SW relationship) in the 2SW returns (Fig. 2.4.3.9). For all rivers and stocks (wild, hatchery) examined, the correlation coefficient of GN1 was consistently negative, meaning that as the harvests of 1SW nonmaturing salmon at West Greenland increased, the returns of 2SW salmon to these rivers, based on the expectation from the smolt cohort and returns of 1SW salmon the previous, were lower than expected. For the

Nashwaak River and the hatchery salmon from the Saint John River, consideration of the Greenland harvest did not contribute to describing the variations in 2SW returns corrected for variation in 1SW return the previous year (Fig. 2.4.3.9).

The analysis indicated that the variations in high seas exploitation at Greenland could be detected in the returns of 2SW salmon in home waters in the Maritimes, but only after correcting for the 1SW abundance of the same cohort. The benefits of reduced exploitation can only be appropriately evaluated if the variations in natural mortality are accounted for, as is the case for the 1SW-2SW associations. This also requires that the returns of one age group, in this case the 1SW age group, be exempt from exploitation, which has been the case for the 1SW maturing age group in North America since the closure of the commercial fisheries in 1992-1998. The reduced exploitations at West Greenland has benefited the rivers of the Maritimes although it is clear that fishing at West Greenland does not seem to be the major constraint on 2SW salmon in some areas of eastern Canada.

5.4 Age-Specific Stock Conservation Limits for All Stocks in the West Greenland Commission Area

Sampling of the fishery at West Greenland (Table 5.1.4.3) since 1985 has shown that both European and North American stocks harvested are primarily (greater than 90%) 1SW non-maturing salmon that would mature as either 2 or 3SW salmon, if surviving to spawn. Usually less than 3% of the harvest is composed of salmon that have previously spawned and a few percent are 2SW salmon that would mature as 3SW or older salmon. For this reason, conservation limits defined previously for North American stocks have been limited to this cohort (2SW salmon on their return to homewaters) that may have been at Greenland as 1SW non-maturing fish. These numbers have been documented previously by the Working Group and are in Section 4.4. The 2SW spawner limits of salmon stocks from North America total 152,548 fish, with 123,349 and 29,199 required in Canadian and USA rivers, respectively.

Conservation limits for the NEAC area have been split into 1SW and MSW components on the basis of the average age composition of catches in the past ten years. The stocks have also been partitioned into northern and southern stock complexes, and tagging information and biological sampling indicates that the majority of the European salmon caught at West Greenland originate from the southern stock complex. The current conservation limit estimate for southern European MSW stocks is approximately 263,000 fish (Table 3.4.3.1). There is still considerable uncertainty in the conservation limits for European stocks and estimates may change from year to year as the input of new data affects the 'quasi-stock-recruitment relationship'. The Working Group has previously noted that outputs from the national PFA model are only designed to provide a guide to the status of stocks in the NEAC area. Previously, the conservation limits for MSW salmon in the NEAC area have not been incorporated into the modeling of catch options for West Greenland.

5.5 Catch Options with Assessment of Risks Relative to the Objective of Achieving Conservation Limits

5.5.1 Overview of provision of catch advice

The Working Group was asked to advise on catch levels that would maintain spawning escapements sufficient to achieve conservation limits. Although advances have been made in our understanding of the population dynamics of Atlantic salmon and the exploitation occurring in the fisheries, the concerns about the implications of applying TACs to mixed-stock fisheries are of concern. In principle, adjustments to catches in mixed-stock fisheries provided by means of an annually adjusted TAC would reduce mortality on the contributing populations. However, benefits to particular stocks would be difficult to demonstrate, in the same way that damages to individual stocks are difficult to identify.

In 1993, the Working Group considered how the predictive measures of abundance could be used to give annual catch advice (ICES 1993/Assess:10; Sections 5.3 and 5.4). The aim of management is to regulate catches while achieving overall spawning escapement reflecting the spawner limits in individual North American and European rivers (when the latter have been defined). In order to achieve the desired level of exploitation for a given level of predicted abundance, a TAC could be fixed or some form of effort adjustment introduced. Such an assessment would also depend on a forecast of pre-fishery abundance for both North American and European salmon stocks.

To date, the advice for any given year has been dependent on obtaining a reliable predictor of the abundance of non-maturing 1SW North American stocks prior to the start of the fishery in Greenland. Gill net fisheries in Greenland harvest one-sea-winter (1SW) salmon about one year before they mature and return to spawn in North American rivers. This component was also harvested on their return as 2SW salmon in commercial fisheries in eastern Canada, angling and native fisheries throughout eastern Canada, and angling fisheries in the northeastern USA. The fishery in Greenland harvests salmon that would not mature until the following year, while the fishery in Labrador (closed in 1998) harvested a mix from the non-maturing component as well as maturing 1SW and MSW salmon. The commercial fisheries in Québec and the Maritime provinces of Canada harvested maturing 1SW and MSW salmon.

The Working Group had advocated models based on thermal habitat in the northwest Atlantic and spawning stock indices to forecast pre-fishery abundance and provide catch advice for the West Greenland fishery. While the approach had been consistent since 1993, the models themselves have varied slightly over the years. Changes have been made to these models in attempts to improve their predictive capabilities and add more biological reality. In particular, the models since 1996 have used a spawning stock surrogate variable (lagged spawners) in an attempt to describe the variations in parental stock size of the non-maturing 1SW component (PFA). The models of previous years included the following predictor variables: 1993 - thermal habitat in March; 1994 - thermal habitat in March; 1995 -thermal habitat in January, February, and March; and 1996-2001 - thermal habitat in February and lagged spawners from the Labrador, Newfoundland, Québec, and Scotia-Fundy regions of Canada. In 2000-2001, the model was based on the natural log of PFA relative to the natural log of spawners and habitat variables. In this way, the survival rate of salmon (PFA / Spawners) has a mean survival level that is modified by the habitat environmental variable.

The Working Group had previously noted that because the method of estimating spawning escapement for Labrador was based on commercial catches and exploitation rates which ended in 1997 following closure of the commercial fishery, lagged spawner values would have missing components in year 2003. Thus, an alternative index of salmon abundance is required and described below.

North American run-reconstruction model

The Working Group has used the North American run-reconstruction model to estimate pre-fishery abundance of 1SW non-maturing and maturing 2SW fish adjusted by natural mortality to the time prior to the West Greenland fishery (Section 4.2.3). Region-specific estimates of 2SW returns are listed in Table 4.2.2.2. Estimates of 2SW returns prior to 1998 in Labrador are derived from estimated 2SW catches in the fishery using a range of assumptions regarding exploitation rates and origin of the catch. With the closure of the Labrador fishery, 1998 to 2000 returns were estimated as a proportion of the total for other areas based on historical data (Section 4.2.3).

Update of thermal habitat

The Working Group has been using the relationship between marine habitat, an index of 2SW lagged spawners and estimated pre-fishery abundance to forecast pre-fishery abundance in the year of interest (ICES 1993/Assess:10; 1994/Assess:16; 1995/Assess:14; 1996/Assess:11, 1997/Assess:10; 1998/ACFM:15, 1999/ACFM:14; 2000/ACFM:13, and 2001/ACFM:15). Marine habitat is measured as a relative index of the area suitable for salmon at sea, termed thermal habitat, and was derived from sea surface temperature (SST) data obtained from the National Meteorological Center of the National Ocean & Atmospheric Administration and previously published catch rates for salmon from research vessels fishing in the northwest Atlantic (Reddin *et al*. 1993 and ICES 1995/Assess:14). The SST data were determined by optimally interpolating SSTs from ships of opportunity, earth observation satellites (AVHRR), and sea ice cover data. The area used to determine available salmon habitat encompassed the northwest Atlantic north of 41°N latitude and west of 29°W longitude and includes the Davis Strait, Labrador Sea, Irminger Sea, and the Grand Bank of Newfoundland.

Thermal habitat has been updated to include 2002 and January and February 2003 year data. Two periods of decline in the available habitat are identified (1980 to 1984 and 1988 to 1995) in the February index (Table 5.5.1.1 and Figure 5.5.1.1). Available habitat for February is unchanged from 2002. The 2003 February value is more than 10% higher than the long-term mean of 1,661.

Update of Lagged Spawners

The lagged spawner variable used in the model is an index of the 2SW parental stock of the PFA. It provides a means of examining the value in managing for spawning escapement and predicting recruitment in the extant seas fisheries. The calculation procedure is described in Section 4.2.4. Previous analyses indicated that the sum of lagged spawner components from Labrador, Newfoundland, Québec, and Scotia-Fundy, and excluding Gulf and U.S., was the strongest explanatory variable for the model. Inclusion of the Gulf spawning component reduced the explanatory power of the variable.

The Working Group recognized the problems inherent in this variable. The exclusion of a major component of the spawning stock contributing to the PFA was less than satisfactory. As well, spawning escapement estimates for Labrador are not available for the years 1998-2001. The previously formulated lagged spawner variable is therefore not available beyond 2002.

The Working Group investigated two approaches to resolve the issue: 1) estimating lagged spawners for Labrador using data from other areas to develop a relative spawner index, and 2) continue the lagged spawner index and exclude the Labrador time series.

A relative (time) index of spawners is sufficient to assess population dynamics or recruits per spawner. Covariance models can be used to derive relative indices and are used extensively in fisheries assessment for standardizing catch rates by vessel type or gear type or for season or area effects (Hilborn and Walters 1992; Gavaris 1980). An analysis using simulated series indicated that the covariance models could not account for missing components of index series when there are trends present. The ratio of Labrador spawners to the sum of the remaining region spawners fluctuated around 0.2 from 1978 to 1988, decreased and fluctuated around 0.1 from 1989 to 1999 and rose rapidly to over 0.4 in 2002. Such variation is difficult to capture in any model and the subsequent behaviour of the ratio beyond the measured year is unpredictable. If a ratio were used to fill in the missing years for Labrador, the Labrador spawner values would simply be adjusted as a fixed proportion of the trend in the sum of the spawners in the remaining regions, an assumption which cannot be tested with existing information or verified until alternative indices of spawner abundance for Labrador become available.

Patterns of standardized spawner indices (annual number/mean for period) without Labrador did not differ greatly from the sequence of spawner abundance with Labrador included. The trends in lagged spawners have fluctuations that demonstrate consistent patterns among adjacent areas. The trend is down since 1989 for USA and Scotia-Fundy spawners (Figure 4.2.4.4). There is a downward trend for Quebec spawners since the mid 1980s whereas Gulf spawners recovered quickly after the 1984 management plan, remained high through 1990 to 2000 and are declining into 2003. Newfoundland, like Labrador, has an increasing trend in spawner abundance since the mid-1990s, consistent with the management plan that increased escapement (Figure 4.2.4.4).

The variation in Labrador spawners has been much greater than the variation of the sum of the regions (Figure 5.5.1.2). The sum of the other region spawners declined from 1978 to 1988 and rose rapidly in 1989, directly as a response to the management plan of 1984 which imposed the closure of the commercial fishery and the mandatory release of large salmon in the Maritimes – the stepped increase in 1989 was driven by the Gulf stock. Subsequent to 1989, lagged spawners have been declining almost continually and most rapidly into 1992 (Figure 5.5.1.2). The exclusion of the Labrador time series in the North American spawner index is not ideal but is easier to defend in the context of the information available. Excluding the spawner series from Labrador is equivalent to assuming that the trend in Labrador is correlated with the trend of the remaining five regions.

In light of the analyses conducted, the Working Group developed a new lagged spawner index for North America, which consists of the sum of the lagged spawners from the five regions (US, Scotia-Fundy, Gulf, Quebec, Newfoundland) excluding Labrador (Table 5.5.1.1). Spawner estimates are available for these regions and are anticipated to continue into the future. The Working Group recognized however that this is not an ideal situation as this spawner index may not be an unbiased measure of the overall lagged spawner abundance from North America, particularly as the impression into the late 1990s was that spawning escapement in Labrador was estimated to have been rising rapidly. However the exclusion of Labrador did allow the lagged spawner series to be extended back in time one more year, the 1977 year of PFA (Section 4.2.4.2).

5.5.2 Forecast models for pre-fishery abundance of 2SW salmon

North American Forecast Model

The 2002 forecast of pre-fishery abundance was based on a modeling approach where habitat acts on PFA through survival rather than on absolute abundance. The model took the following form:

$$\text{PFA} = \text{Spawners}^{\gamma} * \exp^{-(\alpha + B*\text{Habitat} + \xi)}$$

This model relates directly to a survival relationship of the form: $N_t = N_0\, e^{-Z}$ .In the case of the PFA model, the survival rate of salmon (PFA / Spawners) has a mean survival level that is modified by the habitat variable. A linear form of the model fits the natural log of PFA relative to the natural log of spawners and habitat variables:

$$\text{Ln(PFA)} = \text{Ln(Spawners)} + \text{Habitat} + \text{intercept} + \xi$$

The basis for the model was the same two predictor variables as used from 1999 to 2001: thermal habitat for February (term H2) and lagged spawners (sum of lagged spawners from Labrador, Newfoundland, Scotia-Fundy, and Quebec, term SLNQ) (ICES 1996/Assess:11). This was justified on the basis of studies showing that salmon stocks over wide geographic areas tend to have synchronous survival rates and that the winter period may be the critical stage for post-smolt survival and maturation (Scarnecchia et al. 1989; Reddin and Shearer 1987; Friedland et al. 1993; Friedland et al. 1998).

With the development of an alternative lagged spawner index for 2003, the model was fitted with the new lagged index series and the February habitat index, as in previous years. Revised PFA values (based on updated information from previous years) were also used (Section 4.2.3). The data are summarized in Table 5.5.1.1 and Figure 5.5.1.1. The model was not significant ($p = 0.27$) with an r^2 value of 0.11.

The absence of a significant association between the PFA, lagged spawner index and habitat was expected given the analyses from previous years which indicated that the inclusion of Gulf Region lagged spawners resulted in a non-significant model. However, an analysis of the sequence of PFA and lagged spawner values revealed structure within the data set that had not appeared previously and that could not be accounted for by the model used in previous years. Specifically, when perceived over time, two states of Atlantic salmon production become evident with a transition state from 1988 to 1990 (Figure 5.5.2.1). Other indicators of a change in marine dynamics were presented in Section 5.2.3., and many were consistent with this time period. Average relative production, expressed as PFA / lagged spawner index, was 7.6 during 1977 to 1988 and averaged only 1.9 during the 1992 to 2001 period (Figure 5.5.2.1). This dynamic indicates that mortality of salmon between the spawner and PFA recruit stage has changed in the last 15 years. To capture this dynamic, a model that incorporated a break into two time periods, termed phases, was fitted to the data. The position of the change between the high production phase and the lower, more recent production phase was considered to be 1989 as this PFA year is the midpoint in the slide from a low spawner index and high PFA abundance to a high spawner index and unchanged PFA abundance (Figure 5.5.2.1).

The model fitted was similar to the previous year models with the addition of an indicator variable to capture the change between the phases.

$$PFA_{NA} = LS^{\gamma}_{NA}\, e^{(\alpha + \beta * Ph + \delta Hab + \xi)}$$

where PFA_{NA} = PFA for North America

LSNA = Lagged spawner index excluding Labrador (1977 to 2001)

Ph = Phase (indicator variable representing 2 time periods (1979-1988, 1990-2001)

Hab = Thermal habitat index for February

$\alpha, \beta, \gamma, \delta$ = coefficients of the variables and intercept

ξ = residual error, lognormal

The PFA_{NA} and LS_{NA} variables were natural log transformed before analysis. The linearized form of the model was:

$$Ln(PFA_{NA}) = \alpha + \beta * Ph + \delta\, Hab + \gamma * Ln(LS_{NA}) + \xi'$$

The year 1989 was considered transitional. It was alternatively placed in either the upper phase or lower phase in two runs of the model. The model was fittted initially using the annual mid-point values of PFA_{NA} and LS_{NA} (Table 5.5.1.1).

The thermal habitat variable was not a significant ($P > 0.50$) explanatory variable of PFA variability after accounting for the lagged spawners and the phase shift. Lagged spawner index and the phase shift were highly significant and accounted for more than 82% of the variance in Ln(PFA_{NA}) (Table 5.5.2.1). The year 1989, in either the first phase or the second phase, did not affect the overall explanatory power of the lagged spawner and phase shift variables. The model selected for generating the PFA_{NA} for 2003 and the catch advice included Ln(LS_{NA}) and a phase shift variable set around 1989 (Figure 5.5.2.2). The two phases share a common PFA_{NA}/LS_{NA} slope but with an intercept change which describes the large change in productivity between the two phases. The year 1989 is allocated to either phase using an uninformative prior.

Using the current model to estimate the 2002 pre-fishery abundance using the updated value for 2001 yields a PFA_{NA} prediction that is less than half of the previous year value (Figure 5.5.2.3). The impact of the change in the model and the hypothesis of the change in dynamic are evident in the PFA prediction.

For 2003, the PFA_{NA} forecast is among the lowest of the time series with a median value of 111,000 fish and about a 10% chance the abundance will be sufficient to meet the spawner reserve of 212,000 2SW salmon to North America (Figure 5.5.2.4).

Stochastic Analyses for North American PFA

Although the exact error bounds for the estimates of pre-fishery abundance (NN1(i)) are unknown, minimum and maximum values of component catch and return estimates have been estimated. Simulation methods, in the software package SAS (SAS Institute, 1996), were used to generate the probability density function of NN1(i) (PFA_{NA}) (Appendix 4). This was done in a seven-step procedure as follows:

Step 1: Annual values (1977–2001) of pre-fishery abundance (NN1) were generated assuming a uniform distribution of the minimum to maximum values of input parameters NC1, NC2, and NR2.

Step 2: Annual values (1977-2001) of the new lagged spawner index (LS_{NA}) were generated assuming a uniform distribution of the minimum to maximum values of LS_{NA}.

Step 3: The year 1989 is assigned randomly to the first phase (1977-1988) or the second phase (1990-2001) using an uninformative prior, draw from a uniform distribution with the criterion set at 0.5.

Step 4: The model incorporating LS_{NA} and a phase shift indicator variable, which estimates an intercept term for each phase is fitted using GLM procedure (SAS).

Step 5: A single pre-fishery forecast value for 2002 or 2003 was obtained by drawing at random from a normal distribution defined by the mean forecast value and the mean square error of the estimate (for a single prediction) from the regression statistics. The year 2002 or 2003 was assigned to one of the phases based on the likelihood of observing a change from PFA levels sufficient to move the stock to an alternate state (see following section). The normal distribution was used because the error structure of the regression (after log transformation) is assumed to be normal.

Step 6: Steps 1-5 are repeated 10,000 times to generate a vector of forecast values from variable model fits and predicted values. This resampling incorporates the uncertainty of the input parameters (steps 1 to 3) and the unexplained variance in pre-fishery abundance from the regression (steps 4 and 5).

Step 7: The probability profile of these stochastic realizations (in 5% intervals) of the pre-fishery abundance forecast was generated from the vector of pre-fishery abundance forecast values obtained in step 6.

These estimates were then used to develop the risk analysis and catch advice presented in Section 5.5.3. Managers may use this information to determine the relative risks borne by the stock (i.e., not meeting spawning limits S_{lim}) versus the fishery (e.g., reduced catches).

Determining the probability of 2003 being in one of the phases

When sequential observations are autocorrelated, previous states may provide a reasonable forecast of the immediate future. In the case of the phases described by the lagged spawner and PFA_{NA} model, it seems reasonable to expect that 2003 will be in the lower phase, as observed over the last ten years. However, to provide a PFA_{NA} for 2003, a quantification of the probability of being in either phase is required. The approach taken to estimate this probability was to examine the historical changes in PFA_{NA} from year t to year t+2. The two-year lag is used because current year PFA (i.e 2002) is not available due to its dependence upon 2SW returns in the next year. These historical observations are used to estimate the possible values of PFA_{NA} in the predicted year from the observed PFA_{NA} two years earlier under the assumption that the rate of change in PFA_{NA} is stationary over time (Figure 5.5.2.5). Application of these observed rates of change to last year's PFA_{NA} results in a distribution of potential PFA_{NA} values for the forecast year. These values are not used for catch advice, but rather to determine the probability of being in each phase of the two-phase regression. Using the mean square error from the fit model, the probability of any PFA value given a lagged spawner value can be calculated for each regression. Summing and standardizing these probabilities over all the potential PFA values for each regression and standardizing produces the probability of being in either phase (Table 5.5.2.2).

For the 2003 forecast of PFA_{NA}, the probability of being in the first phase (similar to 1977-1988 time period) is 4.8% and the probability of being in the lower productivity phase is 95.2% (Table 5.5.2.2). The predicted PFA_{NA} is then a modeled average distribution with random draws of a binomial distribution determining which intercept shift is applied to the lagged spawner variable in the year of interest. This selection is done at each iteration of step 5 above. This distribution can be thought of as a weighted combination of the two possible predicted PFA distributions from the two regressions, with weights determined by the probability of being in each phase.

5.5.3 Development and risk assessment of catch options for 2003

5.5.3.1 Development of catch advice

The provision of catch advice in a risk framework involves incorporating the uncertainty in all the factors used to develop the catch options. The ranges in the uncertainties of all the factors will result in assessments of differing levels of precision.

The analysis of risk involves four steps: 1) identifying the sources of uncertainty; 2) describing the precision or imprecision of the assessment; 3) defining a management strategy; and 4) evaluating the probability of an event (either desirable or undesirable) resulting from the fishery action. Atlantic salmon are managed with the objective of achieving spawning conservation limits. The undesirable event to be assessed is that the spawning escapement after fisheries will be below the conservation limit.

A composite spawning limit (S_{lim}) for the North American 2SW stock complex was developed by summing the spawning limits of Salmon Fishing Areas in Canada and river basins within the USA. Details on the methodology to estimate and update the spawner limits are provided in (ICES 1996/Assess:11) and in Section 4.4 of this report.

The fishery allocation for West Greenland is for fisheries on 1SW non-maturing salmon in 2003, whereas the allocation for North America can be harvested in fisheries on 1SW salmon in 2003 and/or in fisheries on 2SW salmon in 2004. To achieve spawner limits, a reserve of fish must be set aside prior to fishery allocation in order to meet spawner limits and allow for natural mortality in the intervening months between the fishery and return to river. The spawner limit for North America is 152,548 2SW fish. Thus, 212,189 pre-fishery abundance fish must be reserved ($152{,}548/\exp^{(-.03*11)}$) to equate to inriver S_{lim} because of natural mortality between Greenland and Canada.

Fisheries are managed for harvests of fish, not for escapes of fish. As such the development of catch advice in a risk analysis framework considers the consequences to the objective of meeting conservation limits in the rivers of North America of catching different quantities of fish. The risk consists of not having sufficient numbers of fish returning after the harvesting has taken place and the evaluation of the risk of not meeting the conservation limits depends upon the degree of uncertainty associated with the predicted number of salmon returning to the rivers to spawn.

The risk analysis of catch options for Atlantic salmon from North America incorporates the following input parameter uncertainties:

1) the uncertainty in attaining the conservation requirements simultaneously in different regions,
2) the uncertainty of the pre-fishery abundance forecast, and
3) the uncertainty in the biological parameters used to translate catches (weight) into numbers of North American origin salmon.

The risk analysis proceeds as illustrated in the flowchart of Figure 5.5.3.1. The three primary inputs are the PFA_{NA} forecast for the year of the fishery, the harvest level being considered (t of salmon), and the spawner requirements in the rivers of North America. The uncertainty in the PFA_{NA} is accounted for in the resampling approach described in Section 5.5.2. The number of fish of North American and European origin in a given catch (t) is conditioned by the continent of origin of the fish (propNA, propE), by the average weight of the fish in the fishery ($Wt1SW_{NA}$, $Wt1SW_{E}$) and a correction factor by weight for the other age groups in the fishery (ACF). These parameters define how many fish originating from the NAC and NEAC areas will be in the fishery. Since these parameters are not known, they must be borrowed from previous year values. For the 2003 fishery, it was assumed that the parameters for $Wt1SW_{NA}$, $Wt1SW_{E}$, propNA, and propE, and the ACF could vary uniformly within the values observed in the past five years (Tables 5.1.2.1, 5.1.3.2). After the fishery, fish returning to home waters are discounted for natural mortality from the time they leave West Greenland to the time they return to rivers, a total of 11 months at a rate of $M = 0.03$ (equates to 28.1% mortality). The fish that survive to homewaters are then distributed among the regions and the total fish escaping to each region is compared to the region's 2SW spawning requirements.

Harvest

For a level of fishery under consideration, the weight of the catch is converted to fish of each continent's origin and subtracted from one of the simulated forecast values of PFA_{NA}. The fish that escape the Greenland fishery are immediately discounted by the fixed sharing fraction (Fna) historically used in the negotiations of the West Greenland fishery. The sharing fraction chosen is the 4:6 West Greenland:North America split. Any sharing fraction can be considered and incorporated at this stage of the risk assessment.

Spawning Requirements

The spawning requirement risk profile for North America was described previously in ICES 1997/Assess:10. Briefly, North America is divided into six stock areas that correspond to the areas used to estimate returns and spawning escapements (Table 4.4.1). Under the assumption of equal production from all stock areas (i.e., recruitment in direct proportion to the spawner requirement) just over 172,000 fish should escape to North America as spawners to achieve the spawner requirement in all six stock areas at a 50% probability level. This value is higher than the point estimate for the North American stock complex (152,548 2SW salmon, Table 4.4.1) because it includes the annual variation in proportion female and the objective to have sufficient escapement in six stock areas simultaneously.

The Working Group had previously expressed concerns that the spawning requirement used for North America is for the continent as a whole and does not reflect the expected returns to the six regions, i.e. even if 172,000 2SW salmon reach the coast of North America, there will likely be severe under-escapement in some regions. Specifically, the 2SW returns to Scotia-Fundy, and USA have been below their corresponding conservation limits since 1985 (Figure 4.2.2.2). For the 1998 to 2002 PFA years, the most recent years when estimates of lagged spawners are available for all regions of North America, the Quebec and Gulf regions have accounted for a disproportionate number of lagged spawners relative to their 2SW requirements (Figure 5.5.3.2).

Based on past performance, there is no reason to expect the abundance of salmon in the North Atlantic to be proportional to the regional 2SW spawner requirements. Assuming that the abundance of Atlantic salmon in 2003 will be proportional to the abundance of lagged spawners in the last five years when lagged spawner estimates across regions were available, it is possible to calculate the number of salmon required to return to North America to achieve region-specific conservation requirements. For example, to achieve the Newfoundland 2SW requirement of 4,022 2SW salmon, a total of 72,062 fish would be required to leave West Greenland at the PFA_{NA} stage (Table 5.5.3.1). In the regions with lower stock performance, total PFA_{NA} abundance of about 454,000 fish would be required for the Scotia-Fundy region, and PFA_{NA} abundance of almost 1.9 million fish would be required for achieving the USA conservation requirements (Table 5.5.3.1).

There is a zero chance that the returns to USA rivers will meet or exceed the conservation limit, about 29,000 2SW salmon, in 2004 (Section 4.2.8). There is little chance of returns in 2004 being sufficient to meet the Scotia-Fundy requirement even in the absence of high seas fisheries. There would be a small chance that the PFA_{NA} abundance in 2003 would be sufficient to meet the conservation requirements based on the realized returns in recent years and the anticipated PFA of salmon in 2003 (Figure 5.5.2.4; Table 5.5.3.2).

Alternate Management Objectives
To guide the management, an alternative risk analysis was conducted. The Working Group recommends that fisheries managers attempt to meet the conservation limits simultaneously in the four northern regions of North America: Labrador, Newfoundland, Quebec, and Gulf. For the two southern regions, Scotia-Fundy and USA, an alternate objective to that of achieving the conservation requirement would be to achieve increases in returns relative to previous years with the intention that this will lead to the rebuilding of stocks, i.e. assess fisheries relative to the objective of achieving a minimally pre-agreed increase in returns relative to the realized returns of a previous time. Rates of improvement from previous years could be as low as 10% for those stocks that are approaching a stock status objective. A greater improvement as might be associated with more aggressive rebuilding rates might be to seek a 25% improvement over returns of a previous time period. These rates of increase refer to current stock size and not to percent of conservation limits. In Section 2.5, it was shown that stocks with low productivity such as these take a long time to rebuild to conservation limits. Both levels of spawner level improvements were quantified in the following risk analysis.

The final step in the risk analysis of the catch options involves combining the conservation requirement with the probability distribution of the returns to North America for different catch options. The returns to North America are partitioned into regional returns based on the regional proportions of lagged spawners for the 1998 to 2002 period. Estimated returns to each region are compared to the conservation objectives of Labrador, Newfoundland, Quebec, and Gulf. Estimated returns for Scotia-Fundy and US are compared to the objective of achieving at least a 10% increase or a 25% increase relative to average returns of the previous five years. The management objectives are shown in Table 5.5.3.1.

5.5.3.2 Catch Advice for the NAC

The pre-fishery abundance of salmon in 2003 is expected to be among the lowest on record (Figure 5.5.2.4; 5.5.3.3). Even in the absence of fisheries on the non-maturing 1SW salmon at West Greenland in 2003 and subsequently on the returning 2SW salmon to North America in 2004, there is only a 28% chance that the abundance of salmon will be sufficient to achieve the conservation requirements for 2SW salmon in the four northern regions. There is a better chance of realizing increases in returns to the southern North American stocks however at a fishery of 50 t in West Greenland in 2003, the chance of an improvement of 25% or more in both regions falls to less than 50% (Table 5.5.3.2). The Working Group indicated last year that a higher probability level than 50% should be used to evaluate catch options relative to the attainment of conservation limits. Using the 75% probability level, none of the management objectives would allow a fishery to take place.

The Working Group concludes that the North American stock complex of non-maturing salmon has declined to record levels and is in tenuous condition. Increased spawning escapements to rivers of some areas of eastern North America resulted in improved abundance of the juvenile life stages. Despite the closure of Newfoundland commercial fisheries in 1992 and subsequently in Labrador in 1998 and Québec in 2000, sea survival of adults returning to rivers has not improved and in some areas has declined further. The abundance of maturing 1SW salmon has also declined in many areas of eastern North America. Associations between 1SW returns in year i and 2SW returns in year i+1 observed in several rivers in eastern Canada suggest that abundance of 2SW salmon in 2003 in eastern Canada will be slightly improved from 2002 (Section 4.2.8). Smolt production in 2001 and 2002 in monitored rivers of eastern Canada were less than or similar to the average of the last five years and unless sea survival improves, the abundance of non-maturing 1SW salmon in the Northwest Atlantic is not expected to improve above the levels of the last five years.

The model presently describes two phases of salmon production in the Northwest Atlantic. The ability to detect a phase shift in recruitment per spawner in the northwest Atlantic during the last two decades was enhanced with the passage of time. The lower recruitment rates, which may not replace the spawners that generated them, are evident throughout eastern Canada and U.S., especially so in the southern regions. The reduced relative rate of recruitment does not suggest that the problem is entirely in the marine environment. The problem may be an integration of factors across all aquatic habitats of Atlantic salmon. Large areas of production have been lost or are severely impacted by anthropogenic factors. Given the presently described condition of salmon stocks, there is no evidence in the stock status from any of the regions in North America that there will be a turnaround in productivity in the ocean in 2003.

5.5.3.3 Catch advice for combined NAC and NEAC PFA

The Working Group considered a process for the provision of catch advice for West Greenland based on the combined PFA and CLs of the NAC and NEAC areas. A procedure for doing this is outlined in Figure 5.5.3.1 in which the PFA for NAC and NEAC are applied in parallel to the Greenland fishery and then combined at the end of the process into a single summary plot or catch advice table.

The parameters of the NAC risk analysis are described in Section 5.5.3.1.

For the NEAC evaluation, the following parameter inputs were used.

- The NEAC PFA prediction model for MSW salmon from southern Europe and the prediction of PFA_{NEAC} for 2003 are presented in Section 3.5.2. For 2003, the forecast for the southern Europe MSW salmon on January 1 of the first sea-winter year is 524,000 fish (95% C.I. 315,000 to 840,000).
- The PFA_{NEAC} for 2003 is adjusted for 8 months of natural mortality (0.03 per month) which equates to 79% survival to bring the fish to August of the fishery year at Greenland
- The sharing arrangement for the West Greenland fishery used in this example corresponds to the sharing arrangement used for the provision of catch advice for the NAC area. The sharing arrangement negotiated with one of the commission areas automatically determines the arrangement for the other area as the West Greenland fishery cannot selectively harvest fish on the basis of their continent of origin. Historically, the West Greenland share of the total NEAC MSW harvest was on average 40% from 1970 to 1993.
- The biological characteristics of the fish at West Greenland are simultaneously derived for fish from both continents
- The conservation limit for the NEAC MSW salmon is 262,935 fish (Table 3.4.3.1)

In the absence of any fishery at West Greenland, there is a less than 75% probability that the MSW conservation limit for southern Europe will be met (Table 5.5.3.3). The average biological characteristics of the previous five years in the fishery at West Greenland provide continental distributions of 78% NAC 1SW salmon in the fishery.

Using the 75% probability level, none of the management objectives in NAC or NEAC would allow a fishery to take place.

The Working Group also noted that the PFA of non-maturing 1SW salmon from Southern Europe has been declining steadily since the 1970s (Figure 3.5.1.5), and the preliminary quantitative prediction of PFA for this stock complex indicates that PFA will remain close to present low levels for each of the next two years (537,000 and 524,000 fish) (Figure 3.5.2.3). There is evidence from the prediction that PFA will decrease in the near future and the spawning escapement has not been significantly above the conservation limit for the last six years (Figure 3.5.1.6). The stock group is therefore thought to remain very close to safe biological limits, and the Working Group therefore considers that precautionary reductions in exploitation rates are required for as many stocks as possible, in order to ensure that conservation requirements are met for each river stock with high probability. The Working Group also notes that mixed stock fisheries present particular threats to conservation.

5.6 Updates to and Critical Assessment of the ‘Model’ Used to Provide Catch Advice

The following updates were made in the model to forecast PFA for the North American Commission Area. The portions of Section 5.5 that provide justification for the updates are noted in parentheses.

- Labrador was not included in the lagged spawners index due to lack of data (Section 5.5.1)
- Returns to Gulf and USA regions, excluded in previous years, were included in the lagged spawners index (Section 5.5.1)

- A two phase regression between PFA and lagged spawners was used (Section 5.5.2) to account for phases in productivity (Section 5.2.3)
- The habitat index did not provide a statistical improvement to the model and so was not included (Section 5.5.2)

Critical evaluations of updates to the model were documented during the process of developing catch advice. The portions of Section 5.5 that provide those critical evaluations are noted in parentheses.

- A comparison of the 2003 PFA estimates from the updated model to the configuration of the model used last year is not possible because the lagged spawner index for Labrador cannot be estimated. However, application of the updated model to estimate the 2002 PFA produced a lower estimate (median 135,000) than the estimate provided last year (median 325,000). (Figure 5.5.2.3, 5.5.3.3)
- The lagged spawner variable used in the model declines in 2003 to its lowest value and is used to predict PFA using relative spawner abundances that are outside the range of previously observed values. The uncertainty of associations increases as the predictor variable gets farther from the mean, which is the case for the 2003 projection.
- A jack-knife analysis of the two-phase regression model demonstrated that the model has better predictive capacity for the more recent years than for the earlier years. The 1989 value seems to fit better with the second phase than with the first phase (Figure 5.6.1 and Figure 5.6.2). However, residuals were positive for the years 1989 to 2001, demonstrating that the model underestimates subsequent PFA values.
- To compute the probability of achieving a given level of stock increase for the USA and Scotia-Fundy regions of North America, the Working Group used the recent a 5-year average of returns. The Working Group noted that if a moving average is used, and these stocks continue to decline, so will the baseline value. The Working Group draws attention of managers of the need to establish the range of years to define the baseline and the percentage increase from that baseline. This will provide the Working Group with the criteria to assess performance of the fisheries management.

5.7 Continuing Model Development

5.7.1 Juvenile Abundance Indices

The Working Group previously considered, juvenile abundance indices as an alternative to the lagged spawner variable. As surrogates of potential smolt production, a juvenile index model is conceptually more attractive because juveniles represent a life-stage closer to the PFA than the lagged spawner variable currently used. Consequently, some of the noise corresponding to the stochasticity in the recruitment process should be reduced, favoring a more direct link between the predictors and the PFA. Unfortunately, the Working Group has noted that alternate variables do not negate any of the assumptions within a model, and are also influenced by non-stationarity. Therefore the Working Group, suspended investigation of juvenile abundance indices to focus on issues of non-stationarity that may apply to any relationship between a predictive variable and PFA.

5.8 Data Deficiencies and Research Needs in the WGC area

Recommendations for the West Greenland Commission area are in Section 6.2.

Table 5.1.1.1. Nominal catches of salmon, West Greenland 1977-2002 (metric tons round fresh weight).

Year	Total	Quota
1977	1,420	1,191
1978	984	1,191

[1] CI – confidence interval calculated by method of Pella and Robertson (1979) for 1984 -86 and by binomial distribution for the others.

[2] During Fishery.

[3] Research samples after fishery closed.

[4] Determined by genetic analysis to be 100% correct

Table 5.1.3.2. The weighted proportions and numbers of North American and European Atlantic salmon caught at West Greenland 1982-1992 and 1995-2002. Numbers are rounded to the nearest hundred fish.

	Proportion weighted by catch in number		Numbers of Salmon caught	
Year	NA	E	NA	E
1982	57	43	192,200	143,800
1983	40	60	39,500	60,500
1984	54	46	48,800	41,200
1985	47	53	143,500	161,500
1986	59	41	188,300	131,900
1987	59	41	171,900	126,400
1988	43	57	125,500	168,800
1989	55	45	65,000	52,700
1990	74	26	62,400	21,700
1991	63	37	111,700	65,400
1992	45	55	46,900	38,500
1993	-	-	-	-
1994	-	-	-	-
1995	67	33	21,400	10,700
1996	73	27	22,400	9,700
1997	85	15	18,000	3,300
1998	79	21	3,100	900

Table 5.5.2.2. Assignment of probability of a given year of interest, for example 2003, being in one of the productivity states given the recent rate of change in PFA from previous years and the expected PFANA at the lagged spawner level if the productivity is in either state. The ratios for 2003 are combined with the probability distributions in Figure 5.5.2.5 to develop a weighted probability of 2003 being in each state. The probability of the 2003 productivity being in phase 1 = 0.048, and in phase 2 = 0.952.

YEAR	Lagged Spawner	PFA	Ratio for 2003 PFA (year) / PFA (year-2)	Possible levels of PFA in 2003 using ratio	Probability of phase state: 2003 in phase 2, 89 in phase 1	2003 in phase 2, 89 in phase 2	2003 in phase 1, 89 in phase 1	2003 in phase 1, 89 in phase 2

Table 5.5.3.1. A - Regional spawner requirement (2SW salmon), lagged spawners contributed by each region to PFA in last five years with available data, and the PFA number of fish required to meet region specific conservation limits if the returns to the regions are in proportion to the average lagged spawner distributions of 1998 to 2002. B - 2SW returns to the regions of North America, 1998 to 2002. C – Management objectives for the NAC area used to develop the risk analysis of catch options for the 2003 fishery.

A

Achieved lagged spawners by PFA year

Table 5.5.3.3. Probability profiles for the management objectives of achieving the 2SW conservation limits simultaneously in the four northern areas of North America (Labrador, Newfoundland, Quebec, Gulf), achieving increases in returns from the previous five-year average (examples: minimally 10% or minimally 25% increase in returns of 2SW salmon in 2003) in the two southern areas (Scotia-Fundy and USA), and achieving the MSW conservation limit for southern Europe relative to quota options for West Greenland. A sharing arrangement of 40:60 (Fna) of the salmon at West Greenland, regardless of continent of origin was assumed.

Figure 5.5.2.5. Relative change in PFA value in year relative to PFA in year-2 (upper panel) and predicted PFA distributions for 2003 (middle) and for 2002 (lower) based on allocating 1989 to either phase 1 or phase 2 and the 2003 or 2002 production levels being in phase 1 or phase 2. The probability profiles are the distributions of a single predicted value using the mid-points of PFA_{NA} and LS_{NA}.

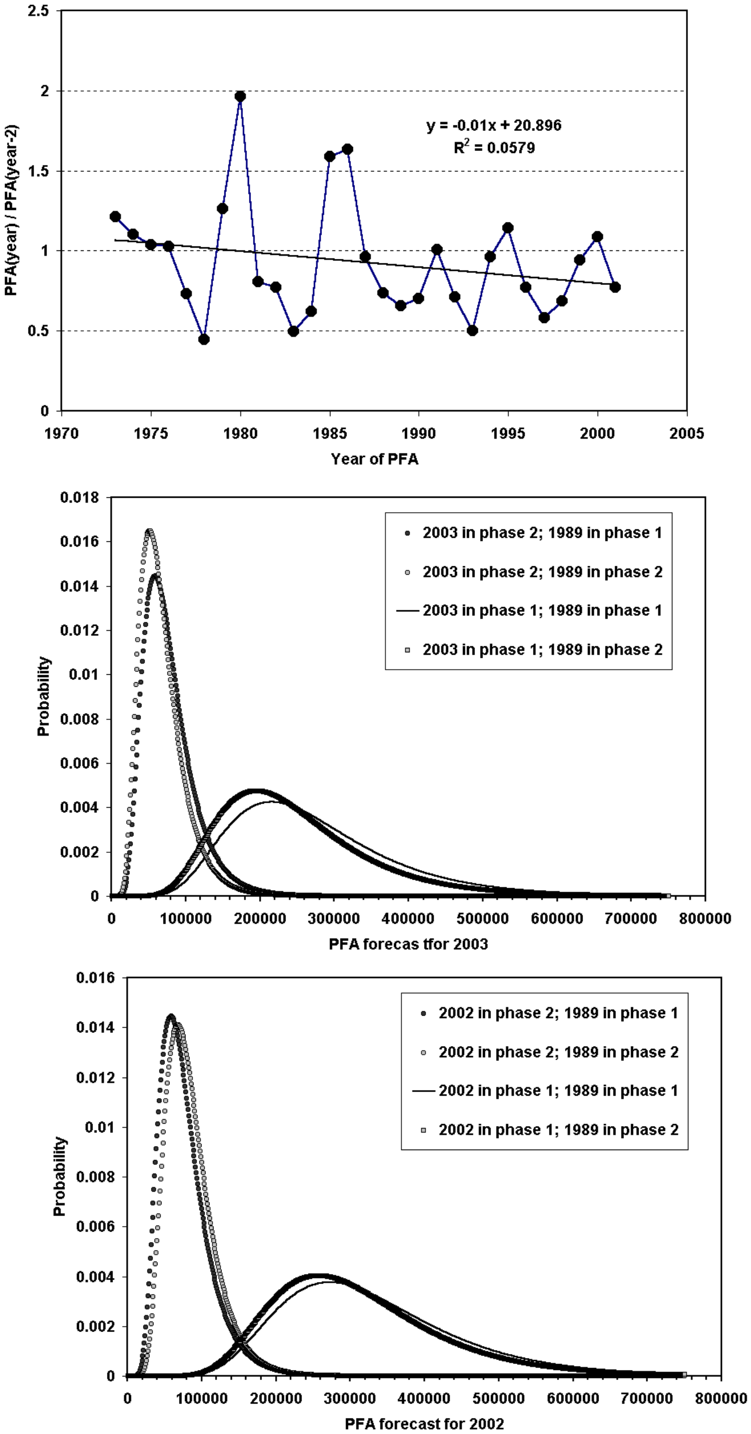

Figure 5.5.3.1. Flowchart of risk analysis of catch options at West Greenland using the PFA_{NA} and the PFA_{NEAC} predictions for the year of the fishery. Inputs with solid borders are considered known without error. Inputs with dashed borders are estimated, contain observation error which is incorporated in the analysis. Solid arrows are functions which introduce or transfer without error whereas dashed arrows transfer errors through the components.

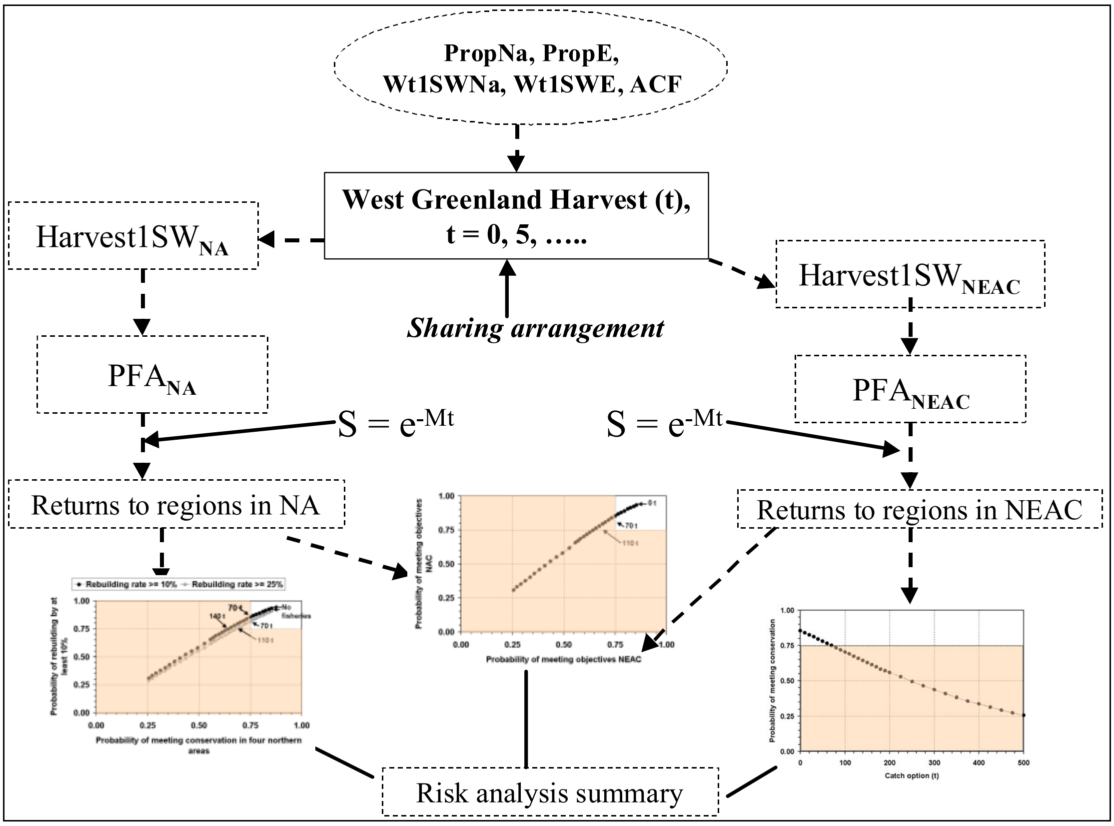

Figure 5.5.3.2. Average lagged spawners in the six regions of North America for the PFA years 1998 to 2002 and the 2SW spawner requirement in each region expressed as a proportion of the total for North America.

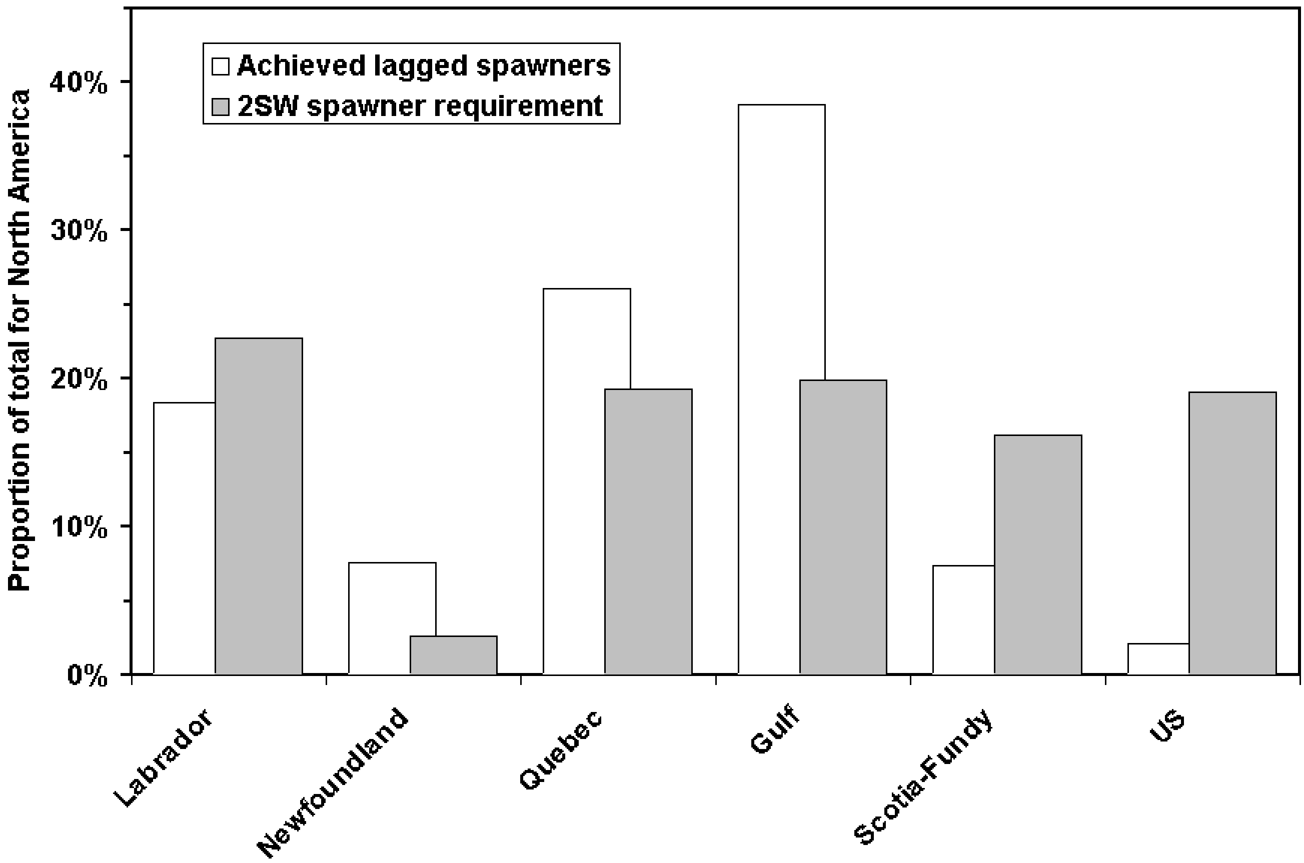

Figure 5.5.3.3. PFA_{NA} estimated for 1971 to 2001 and predicted PFA_{NA} for 2002 and 2003. There are two PFA_{NA} predictions for 2002. The open square is the value from the 2002 assessment using the lagged spawner variable, which included Labrador and excluded Gulf and US and the thermal habitat index. The dashed lines encompass the minimum to maximum range of the PFA estimated value. The shaded circles are the new model estimates for 2002 and 2003 using the revised lagged spawner index and a phase shift variable. The error bars on the predicted values describe the 5th to 95th percentile range.

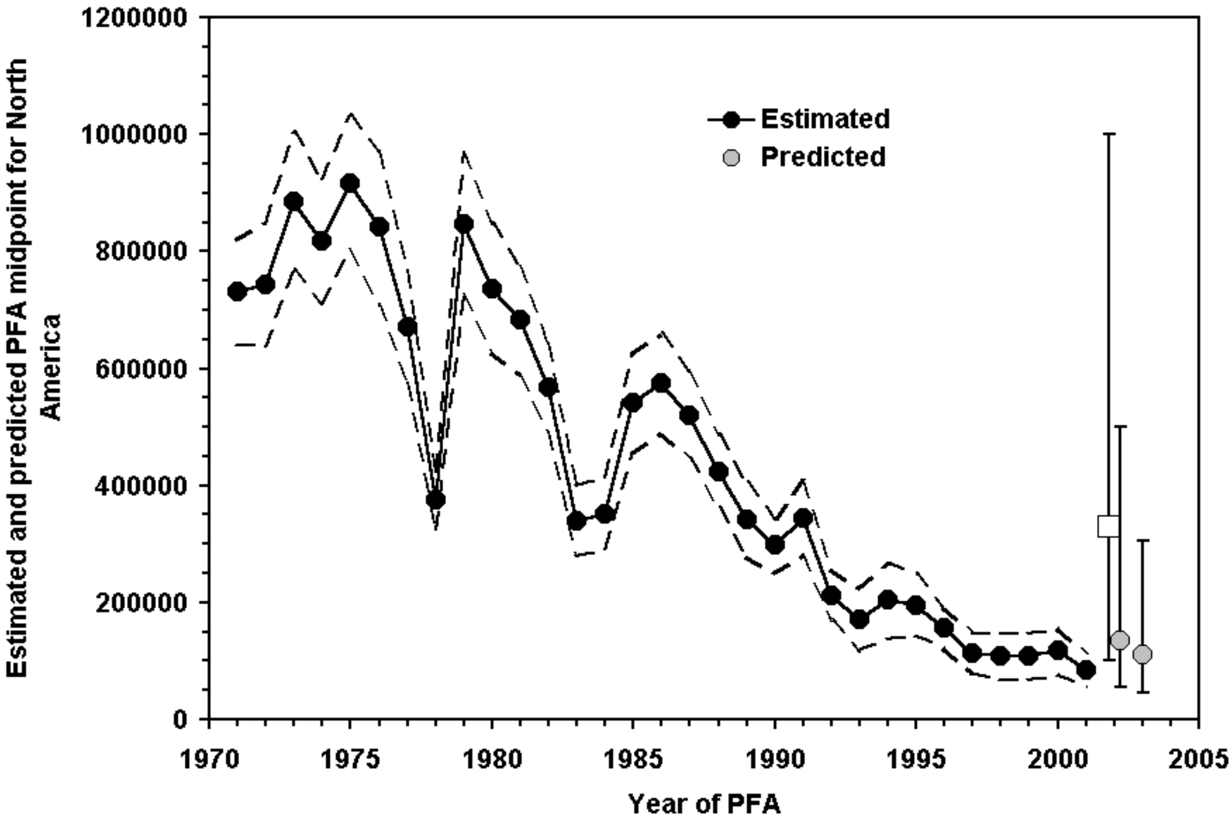

Figure 5.6.1. Observed estimates, jacknifed historical predictions, and simulated forecasts (Upper Panel A) of pre-fishery abundance from the multiplicative model with 1989 in Phase 1. The residual pattern from the jacknifed predictions is shown in the lower panel (Lower Panel B).

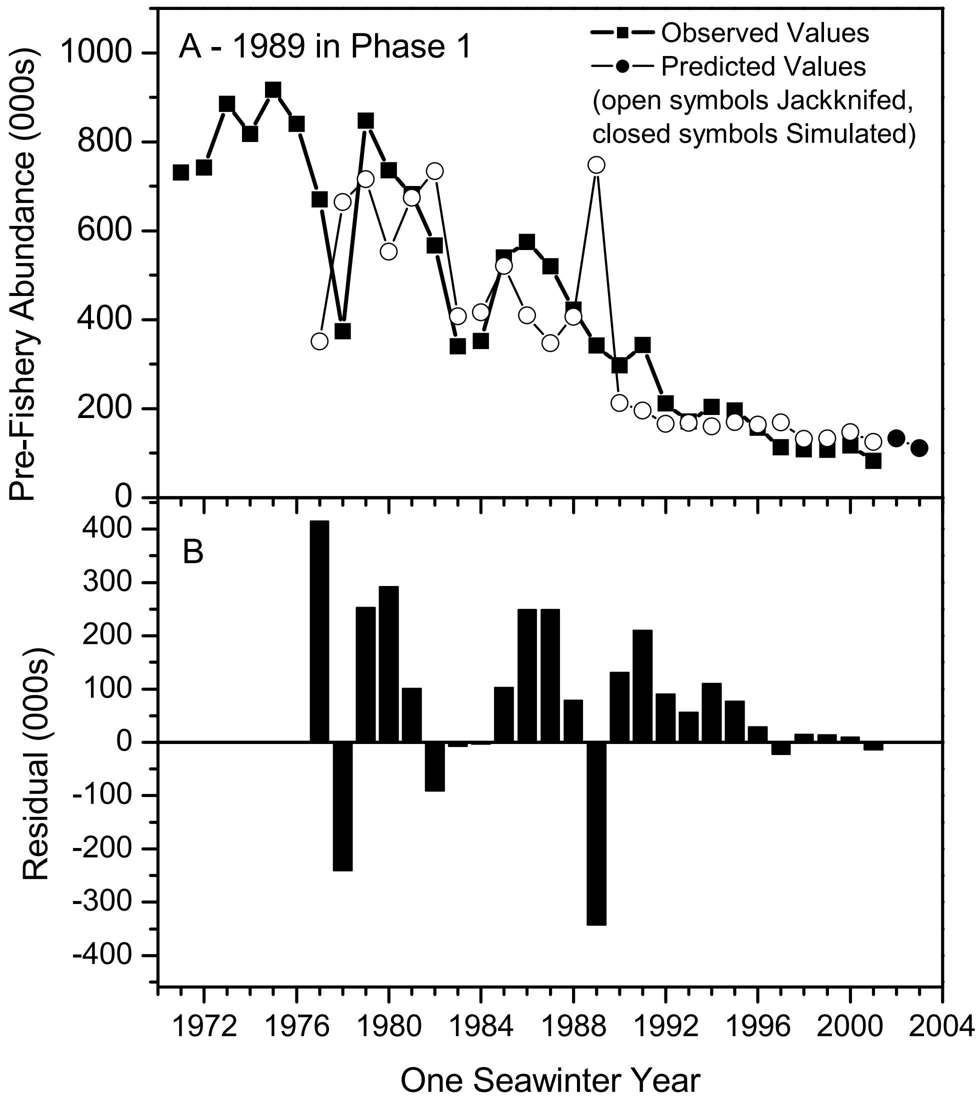

Figure 5.6.2. Observed estimates, jackknifed historical predictions, and simulated forecasts (Upper Panel A) of pre-fishery abundance from the multiplicative model with 1989 in Phase 2. The residual pattern from the jackknifed predictions is shown in the lower panel (Lower Panel B).

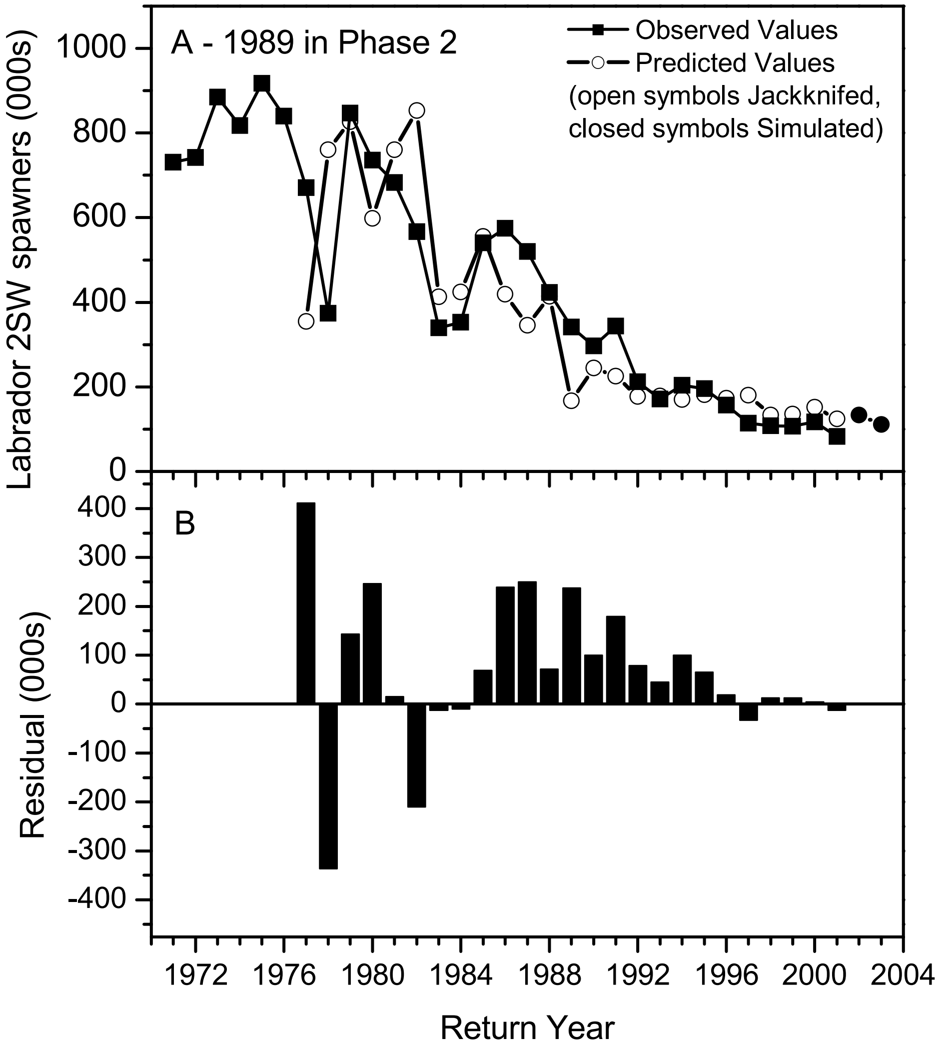

6 GENERAL RECOMMENDATIONS

The Working Group recommends that it should meet in 2004 to address questions posed by ACFM, including those posed by NASCO. An invitation to host the meeting was proposed to and agreed by the Working Group. Therefore, the Working Group intends to convene from the *29 th March – 8th April 2004* inclusive, in Halifax (Canada). It is strongly recommended by the Working Group that this period is adhered in order to provide sufficient time to adequately review and complete the report.

6.1 Data deficiencies and research needs.

Recommendations from Section 2- Atlantic salmon in the North Atlantic Area:

1. Given the importance of M in the provision of catch advice and in the understanding of the dynamics of Atlantic salmon in the ocean, and in order to refine the assessment of M with the maturity schedule method, hatchery stocking programs should attempt to confirm the sex ratio of the released smolts (Section 2.3.1).

2. The Working Group recommends that life history characteristics of salmon stocks including age structure, length at age, relative and absolute abundance of repeat spawners, run-timing and other such features be examined for Atlantic salmon stocks to ensure that conservation of salmon go beyond abundance (Section 2.4.3).

3. A coordinated tagging study should be designed and carried on to give information on migration, distribution, survival and growth of escaped farmed salmon from the NEAC countries (Sections 2.6.1 & 2.6.3).

4. The Working Group recommends that information on the application of tags to salmon placed in sea cages by commercial companies should be made available through State agencies and included in the tag compilation database (Section 2.7.1).

Recommendations from Section 3 - Fisheries and Stocks from the North East Atlantic Commission Area:

1. Further progress should be made in establishing a PFA predictive model using the PFA of maturing 1SW salmon, in addition to the spawner term, as a predictor variable for the PFA of non-maturing 1SW in the Southern NEAC area (Section 3.5).

2. Surveys should be extended to provide better temporal and spatial information on the distribution of post-smolts in relation to pelagic fisheries (Section 3.7).

3. Experimental trawling surveys should be conducted to evaluate the vertical distribution of post-smolts and older salmon in the sea, if possible in combination with tagging of post-smolt and salmon with depth and temperature recording tags (DSTs) (Section 3.7).

4. Studies on post-smolts and older salmon should be extended to elucidate behaviour patterns at sea and to investigate their behaviour in relation to different commercial gear types (e.g. pelagic trawls, purse seines) (Section 3.7).

5. Efforts should be made to inter-calibrate the CPUE for different trawling methods, in particular research gears against commercial trawls, to provide a better basis for assessing levels of by-catch (Section 3.7).

6. The Planning Group on Surveys on Pelagic Fish in the Norwegian Sea (PGSPFN) should consider intensive screenings of pelagic research hauls for the presence of post-smolts (small salmon in their 1st year at sea, generally < 45cm) and older salmon (Section 3.7).

7. The Working Group requests that ICES should make available data on the commercial catches of mackerel and herring in the Norwegian Sea (ICES Divisions IIa and Vb), Northern North Sea (Division IVa), and the west of Ireland and Scotland (Divisions VI a & b; VII b,c,j & k) by ICES Division and standard week. Further information on the number of vessels fishing, gear types and fishing techniques is also requested. (Section 3.7).

Recommendations from Section 4- Fisheries and Stocks from the North American Commission Area:

Some progress was made on research needs identified last year. The Working Group reiterates many of last year's recommendations and suggests some further ones.

1. Estimates of total returns to Labrador no longer exist. There is a critical need to develop alternate methods to derive estimates of salmon returns and develop habitat-based spawner requirements in Labrador, and to monitor salmon returns in the Ungava region of Québec (Sections 4.2.2 & 4.2.4).

2. There is a need to investigate changes in the biological characteristics (mean weight, sex ratio, sea-age and river-age composition) of returns to rivers, of smolt output, of spawning stocks of Canadian and US rivers, and the harvest in food fisheries in Labrador. These data and new information on measures of habitat and stock recruitment are necessary to re-evaluate existing estimates of spawner requirements in Canada and USA and for use in the run reconstruction model (Sections 4.2.2; 4.2.3 & 4.4).

3. There is a requirement for additional smolt-to-adult survival rates for wild salmon. As well, sea survival rates of wild salmon from rivers stocked with hatchery smolts should be examined to determine if hatchery return rates can be used as an index of sea survival of wild salmon elsewhere (Section 4.2.5).

4. Further basic research is needed on the spatial and temporal distribution of salmon and their predators at sea to assist in explaining variability in survival rates (Sections 4.2.3 & 4.2.5).

5. Return estimates for the few rivers (Annapolis, Cornwallis and Gaspereau) in SFA 22 that contribute to distant fisheries should be developed and when these are available, the SFA 22 spawning requirements for these rivers (476 fish) should be included in the total (Section 4.4).

6. A consistent approach to estimating returns is needed for instances in which offspring from broodstock are stocked back into the management area from which their parents originated (Section 4.1.3).

Recommendations from Section 5 - Atlantic Salmon in the West Greenland Commission Area:

1. Continued efforts should be made to improve the estimates of the annual catches of salmon taken for private sales and local consumption in Greenland (Section 5.1.1).

2. The mean weights, sea and freshwater ages and continent of origin are essential parameters to provide catch advice for the West Greenland fishery. The Working Group recommends that the sampling program be continued and closely coordinated with fishery harvest plan to be executed annually in West Greenland (Sections 5.1.2 , 5.1.3.1, 5.1.3.2 & 5.5.3).

3. Scale analysis of salmon captured at West Greenland indicated an infrequent appearance of escaped-farm salmon. To investigate this observation, farmed salmon need to be genetically characterized and included as baseline populations in continent of origin analyses of samples collected at West Greenland (Section 5.1.3.1).

4. Continue testing for ISAv and other diseases in Atlantic salmon caught in West Greenland (Section 5.1.3.1).

5. CPUE was not available in 2002 in West Greenland. Thus, there is a need to collect more refined data characterizing fishing effort to characterize availability of Atlantic salmon (Section 5.1.1).

6. Development of alternative in-season measures of abundance such as relationships between 1SW returns to rivers from the same cohort should be investigated as a future source of confirmatory information of abundance (Section 5.5.1).

7. Further basic research is needed on the spatial/temporal distribution and migration patterns of salmon and their predators at sea to assist in explaining variability in survival rates. Other indices of change, i.e. changes in age composition, size at age and sea survival, should also be included in this analyse (Section 5.2.3).

8. The Working Group endorses the continued development of genetic methods that will increase the precision and accuracy of the classification of stock complexes within and among continents, countries, and individual rivers, and recommends (Section 5.1.3.2):

    - to further evaluate the extent to which the genetics of stocks have been characterized within each country, and share that information at the Working Group meeting in 2004.
    -

- that all efforts be made to extend the spatial and temporal coverage of existing baseline genetic dataset for North Atlantic salmon stocks, especially those vulnerable to mixed stock fisheries, while making efforts to duplicate tissue sample representation across different laboratories.

- that an inventory of genetic material, particularly from historic scale samples and samples taken prior to significant management measures or ecological events, be assembled and that inter-laboratory calibration and standardization should be carried out to ensure optimal use of existing samples and samples to be taken in future.

SRR (Small returns to river) are the sum of Bay St. George small returns (Reddin & Mullins 1996) plus Humber R small returns (Mullins & Reddin 1996) plus small returns in SFAs 3-12 & 14A.
SSR (Small recruits) = SRR/(1-Exploitation rate commercial (ERC)) where ERC=0.5-0.7, 1969-91 & ERC=0, 1992-98.
SS (Small spawners) = SSR-(SC+(SR*0.1))
SC = small salmon catch retained
SR = small salmon catch released with assumed mortalities at 10%
RL (RATIO large:small) are from counting facilities in SFAs 3-11, 13 & 14A, angling catches in SFA 12.
LRR (Large returns to river) = SRR * RL
LR (Large recruits) = LRR*(1-Exploitation rate large (ERL)), where ERL=0.7-0.9, 1969-91; & ERL=0, 1992-98.
LS (Large spawners) = LRR-large catch retained (LC)-(0.1*large catch released)
2SW-RR (2SW returns to river)= LRR*proportion 2SW of 0.4-0.6 for SFAs 12-14A & 0.1-0.2 for SFAs 3-11.
2SW-S (2SW spawners) = LS * proportion 2SW of 0.4-0.6 for SFAs 12-14A & 0.1-0.2 for SFAs 3-11.
2SW-R (2SW recruits) = LR * proportion 2SW of 0.4-0.6 for SFAs 12-14A& 0.1-0.2 for SFAs 3-11.

Return and spawner estimates for SFA 15 are based on Restigouche River data, scaled up for SFA 15 using angling data.
Restigouche stock assessment is based on angling catch with assumed exploitation rates between 50% (min.) and 30% (max).
The proportion of 2SW in large salmon numbers is based on aged scale samples from angling, trapnets, and broodstock.
No scale samples were available for 1970-71, 1995-96: the mean value of 0.65 is used here.
Salmon in the Quebec portions of the Restigouche River were subtracted from the total for the watershed.
The returns and spawners estimates thus derived for the SFA 15 portion of the Restigouche were then multiplied by the minumum (1.117) and maximum (1.465) ratios of angling catch in SFA15:SFA 15 portion of Restigouche catch to obtain estimates for SFA 15.
For 2001, returns and spawners are based on previous five-year average, incomplete angling data were available.

Appendix 5(v)a. Returns of large salmon and 2SW salmon to SFA 16.

Returns to the Miramichi are from the assessment. Min. and max values are based on capture efficiencies of Millbank trapnet which gave a lower CI of -20% of estimate and upper CI of 33% of estimate.
For 1992 and 1993, lower and upper CI are based on estimate bounds of -18.5% to +18.5%.
For 1994 to 2002, min and max are 5th and 95th percentiles from the assessment.
Prop. 2SW are from scale ageing and have been corrected for 2001 from previous year's table.
Prop. 2SW for 2002 are based on scale ageing.
Miramichi makes up 91% of total rearing area of SFA 16.
Returns to SFA 16 are Miramichi returns / 0.91 or (Min., Max.) 2SW returns to Miramichi / 0.91

Appendix 5(v)b. Large salmon and 2SW salmon spawners to SFA 16. Same procedure as for returns (Appendix 5(v)a)

Same procedure for escapements as used to calculate returns.

Returns to the Miramichi are from the assessment. Min. and max values are based on capture efficiencies of Millb
trapnet which gave a lower CI of -20% of estimate and upper CI of 33% of estimate.
For 1992 and 1993, lower and upper CI are based on estimate bounds of -18.5% to +18.5%.
For 1994 to 2002, min and max are 5th and 95th percentiles from the assessment.
Prop. 1SW are from scale ageing. Proportions vary from 0.97 to 1.00. Ref. Moore et al. 1995.

Miramichi makes up 91% of total rearing area of SFA 16.
Returns to SFA 16 are Miramichi returns / 0.91 or (Min., Max.) 1SW returns to Miramichi / 0.91

Appendix 5(v)d. Small salmon and 1SW salmon spawners to SFA 16. Same procedure as for Appendix 5(v)c.

Same procedure for escapements as used to calculate returns.

	1SW Escape to SFA 16		Escapement to Miramichi			1SW Escape to Miramichi

Notes

Number of small retained salmon in 1993 was not recorded. The number given is the mean for 1986-1992

For 1970-1980, percent small is calculated from numbers of small and large salmon in the retained catch in each year. For 1981-1997, 1999, and 2002, percent small is calculated from numbers of small and large salmon taken at the Leard's Pond trap.

For 1998 and 2000-2001, percent small is taken from seining catches at Mooneys Pool.

Small recruits are calculated as small retained salmon/exploitation rate. Angler exploitation was calculated as 0.34, 0.347, and 0.264 of estimated returns in 1994, 1995, and 1996, respectively. For other years the mean of these values is used. The min and max max numbers of small recruits are calculated using exploitation + or - 0.1; e.g. 0.34 + or - 0.1 gives 0.24 and 0.44.

Small spawners = number of small recruits - number of small retained

Large recruits = (number of small recruits/(0.01*percent small))-number of small recruits

Large spawners = number of large recruits - number of large retained

It is asssumed that large salmon and 2SW salmon are equivalent

Appendix 5(vii). Total returns and spawners of small salmon and large salmon, and 2SW salmon returns and spawners to SFA 18.

SFAs 19, 20, 21: Returns, 1970-1997, estimated as run size (1SW recreational catch / expl. rate [0.2 t0 0.45]; where MIN and MAX selected as 5th and 95th percentile values from 1,000 monte carlo estimates) + estimated 1SW fish in commercial landings 1970-1983 (Cutting MS 1984). For 1998-2000, see "a" below.

SFA 22: Inner Fundy stocks and inner-Fundy SFA 23 (primarily 1SW fish) do not go to the North Atlantic.

SFA 23: For 1970-'97, similar to SFAs 19-21 except that estimated wild 1SW returns destined for Mactaquac Dam, Saint John River, replaced values for recreational catch and estimated proportions that production above Mactaquac is of the total (0.4-0.6) river replaced exploitataion rates (commercial harvest, bi-catch etc., incl. in estimated returns); hatchery returns attributed to above Mactaquac only; 1SW production in rest of SFA (outer Fundy) omitted.

"a"- Revision of method, SFA 23, 1993-2001, estimated returns to Nashwaak fence raised by proportion of area below Mactaquac (0.21-0.30) and added to total estimated returns originating upriver of Mactaquac (Marshall et al. 1998); MIN and MAX removals below Mactaquac based on Nashwaak losses, Mactaquac losses are a single value and together summed and removed from returns to establish estimate of spawners. SFAs 19-21, estimate of returns 1998-2000 based on regression of LaHave wild counts on MIN and MAX estimates of total SFA 19-21 returns, 1984-1997, because there was no (1998 and 2000) & little (1999) angling in SFAs 20-21.

Appendix 5(ixa). Total 2SW returns to SFAs 19, 20, 21 and 23, 1970-2002.

SFAs 19, 20, 21: Returns, 1970-'97 estimated as run size (MSW recreational catch * prop. 2SW [range of values]/ expl. rate [range of values]; where MIN and MAX selected as 5th and 95th percentile values from 1,000 monte carlo estimates) + estimated 2SW fish in commercial landings 1970-1983 (Cutting MS 1984). For 1998-2001 see "a" below.

SFA 22: Inner Fundy stocks do not go to north Atlantic.

SFA 23: For 1970-1997 Similar approach as for SFAs 19-21 except that estimated wild MSW returns destined for Mactaquac Dam, Saint John River, replaced values for recreational catch; and estimated proportions that production above Mactaquac is of the total river replaced exploitation rates (commercial harvest,bi-catch etc., incl. in estimated returns) + est. 0.85-0.95* MSW hatchery returns to Mactaquac; 2SW production in rest of SFA omitted.

"a": Revsion of method, SFA 23, 1993-2001, estimated MSW returns to Nashwaak fence raised by prop. of area below Mactaquac (0.21-0.30) * prop. 2SW (0.7 & 0.9) and added to estimated MSW hatchery and wild returns * (Marshall et al. MS 1998) (0.85-0.95; 2SW) originating upriver of Mactaquac. MIN & MAX removals below Mactaquac based on Nashwaak losses: Mactaquac losses were a single value and together summed and removed from MSW returns (prevously) to estimate spawners.
SFAs 19-21, estimate of 2SW returns for 1998-'02, based on regression of LaHave wild counts on MIN and MAX estimates of total SFA 19-21 MSW returns and 5th and 95th percentile values of MIN-MAX (0.5 & 0.9 2SW fish among MSW salmon).

Appendix 5(ixb). Total 2SW spawners in SFAs 19, 20, 21 and 23, 1970-2002.

Spawners = returns minus removals where: "returns" are from previous Appendix as are outlines of revisions to methods for SFAs 19-21, 1998-2000, and SFA 23, 1993-2000. "Removals" of 2SW fish in SFAs 19-21 have been few, largely illegal and unascribed since the catch-and-release angling regulations in 1985; removals in SFA 23, 1985-1997, had been in total, the assessed losses to stocks originating above Mactaquac. The revised method, 1993-2000, incorporates 5th and 95th percentile values for losses noted on the Nashwaak raised to the total production area downstream of Mactaquac as well as the previously assessed and used values for stocks upstream of Mactaquac.

pendix 5(x). Estimated numbers of salmon returns and spawners for Québec 1969-2002.
