PREFACE

Annual catch quotas and other regulations of the Barents Sea fisheries are set through negotiations between Norway and Russia. Assessment of the state of the stocks and quota advices are given by the International Council for the Exploration of the Sea (ICES). Their work is based on survey results and the international landings statistics. The results from this demersal fish winter survey in the Barents Sea are an important source of information for the annual stock assessment.

The survey started in the mid 1970-ies, focused on acoustic measurements of cod and haddock. Since 1981 it has been designed to produce both acoustic and swept area estimates of fish abundance. Some development has taken place since then, both in area coverage and in methodology. The development is described in detail by Jacobsen et al. (1997). At present the survey provides the main data input for a number of projects at the Institute of Marine Research, Bergen:

- monitoring abundance of the Barents Sea demersal stocks
- mapping fish distribution in relation to climate and prey abundance
- monitoring food consumption and growth
- estimating predation mortality caused by cod

This report presents the results from the survey in February-March 2005. The survey was performed with the Russian research vessel “Smolensk” and the Norwegian research vessels “G.O. Sars” and “Johan Hjort”. The total duration of the survey was from 31 January to 14 March. One scientist from PINRO, Murmansk, participated onboard ”G.O.Sars”.

SUMMARY

A combined acoustic and bottom trawl survey to obtain indices of abundance and estimates of length and weight at age has been carried out each winter (4-6 weeks in January- March) since 1981 in the Barents Sea. The target species are cod and haddock, but abundance indices have also been worked out for the redfish species since 1986 and Greenland halibut since 1990. Prior to 1993 a fixed standard area (ABCD in Fig. 2.1) was covered, but in 1993 the survey area was extended to the north and east in order to obtain a more complete coverage of the younger age groups of cod. In winter 1997 only the Norwegian part of the Barents Sea and a small part of the Svalbard area was covered, while in 1998 also a small part of the Russian EEZ was covered. In 1999 and 2000 the Norwegian vessels had full access to the Russian EEZ. In the years 2001-2005 a Russian research vessel covered the areas where the Norwegian vessels did not have access.

The main results in 2005 were:

- the abundance of the 2003 and 2001 year-classes of **cod** are well blow average, while the 2002 year and the 2000 year-classes are near average. The index for the 2004 year-class is well below average. This year-class was distributed outside the covered area and is therefore underestimated.
- The abundance of older cod (6 years and older) has decreased considerably compared to the results of the 2004 survey.
- lengths and weights at age have remained fairly stable in recent years.
- the survey mortality calculated from the swept area results show an increasing trend over the last three years for age 5 and older.
- for **haddock** the indices are above average for all age groups 1-7. The index for the 2004 year class is the highest in the time series.
- length and weight at age and weight increments show a decreasing trend since 2003.
- the abundance indices of the **redfish** species are among the lowest in the time series and there are no signs of improved recruitment
- compared to the 2004-results the abundance indices of **Greenland halibut** have increased for nearly all length groups.

1. INTRODUCTION

The Institute of Marine Research (IMR), Bergen, has performed acoustic measurements of demersal fish in the Barents Sea since 1976. Since 1981 a bottom trawl survey has been combined with the acoustic survey. The survey area was extended in 1993. Since then the typical effort of the combined survey has been 10-14 vessel-weeks, and about 350 bottom trawl hauls have been made each year. Most years 3 vessels have participated from about 1 February to 1 March.

The purpose of the investigations is:

- Obtain acoustic abundance indices by length and age for cod, haddock and redfish
- Obtain swept area abundance indices by length (and age) for cod haddock, redfish and Greenland halibut.
- Map the geographical distribution of those fish stocks
- Estimate length, weight and maturity at age for those stocks
- Collect and analyse stomach samples from cod, for estimating predation by cod

Onboard R/V “G. O. Sars” in 2005 zooplankton was sampled at all bottom trawl stations. The results are described in the Appendix.

Data and results from the survey are used both in the ICES stock assessments and by several research projects at IMR and PINRO.

From 1981 to 1992 the survey area was fixed (ABCD in Fig. 2.1). Due to improved climate and increasing stock size in the early 1990-ies, the cod distribution area increased. In 1993 the survey area therefore was increased towards east and north, and since then the survey has been aiming at covering the whole cod distribution area outside the ice-border. Since 1997 Norwegian research vessels have had limited access to the Russian EEZ. In 1997 and 1998 the vessels were not allowed to cover the Russian EEZ, and in 1999 the coverage was partly limited by a rather unusually wide ice-extension. Adjustments, associated with large uncertainties, are applied to the estimates in 1997 and 1998 to compensate for the lack of coverage. The results for those years may therefore not be comparable to the results for other years. Since 2000 Russian research vessels have participated in the survey and the coverage have been satisfactory.

2. METHODS

2.1 Acoustic measurements

The method is explained by Dalen and Smedstad (1979, 1983), Dalen and Nakken (1983), MacLennan and Simmonds (1991) and Jakobsen *et al*. (1997). The acoustic equipment has been continuously improved. Since the early 1990-ies Simrad EK500 echo sounder and Bergen Echo Integrator (BEI, Knudsen 1990) have been used. The Simrad ER60 echo sounder has replaced the EK500; on the new R/V "G.O. Sars" since the 2004 survey and on R/V "Johan Hjort" since the 2005 survey.

In the mid 1990-ies the echo sounder transducers were moved from the hull to a protrudable centreboard. This latter change has largely reduced the signal loss due to air bubbles in the close to surface layer.

Acoustic backscattering values (s_A) are stored at high resolution in the BEI-system. After scrutinizing and allocating the values to species or species groups, the values are stored with 10m vertical resolution and 1 nautical mile horizontal resolution. The procedure for allocation by species is based both on the composition in trawl catches (pelagic and demersal hauls), the appearance of the echo recordings, and inspection of target strength distributions.

For each trawl catch the relative s_A-contribution from each species is calculated (Korsbrekke 1996) and used as a guideline for the allocation. In these calculations the fish length dependent catching efficiency of cod and haddock in the bottom trawl (Aglen and Nakken 1997) is taken into account. If the trawl catch gives the true composition of the species contributing to the observed s_A value, those catch-based s_A -proportions could be used directly for the allocation. In the scrutinizing process the scientists have to evaluate to what extent these catch-based s_A -proportions are reasonable, or if they should be modified on the basis of knowledge about the fish behaviour and the catching performance of the gear.

Estimation procedures

The area is divided into rectangles of 1/2° latitude and 1° longitude. For each rectangle and each species an arithmetic mean s_A is calculated for the demersal zone (less than 10m above bottom)

and the pelagic zone (more than 10m above bottom). Each of those acoustic densities by rectangle are then converted to fish densities by the equation:

$$\overline{\rho}_A = \frac{\overline{s}_A}{\overline{\sigma}_A} \qquad (1)$$

$\overline{\rho}_A$ is average fish density (number of fish / square n.mile) by rectangle
$\overline{s}_A$ is average acoustic density (square m / square n.mile) by rectangle
$\overline{\sigma}_A$ is average backscattering cross-section (square m) by rectangle

For cod, haddock and redfish the backscattering cross-section (σ), target strength (TS) and fish length (L cm) is related by the equation (Foote, 1987):

$$\mathrm{TS} = 10 \cdot \log\left(\frac{\sigma}{4\pi}\right) = 20 \cdot \log(L) - 68 \qquad (2)$$

Indicies for the period 1981-1992 have been recalculated (Aglen and Nakken 1997) taking account of:

-changed target strength function

-changed bottom trawl gear (Godø and Sunnanå 1992)

-size dependant catching efficiency for cod and haddock (Dickson 1993a,b).

In 1999 some errors in the time series were discovered and corrected (Bogstad *et al.* 1999).

Combining equations 1and 2 gives:

$$\overline{\rho}_A = 5.021 \cdot 10^5 \cdot \overline{s}_A \,/\, \overline{L^2} \qquad (3)$$

$\overline{L^2}$ is average squared fish length by rectangle and by depth channels (i.e., pelagic and bottom)

As a basis for estimating $\overline{L^2}$ trawl catches considered to be representative for each rectangle and depth zone are selected. This is a partly subjective process, and in some cases catches from neighbouring rectangles are used. Only bottom trawl catches are used for the demersal zone, while both pelagic and bottom trawl catches are applied to the pelagic zone. Length frequency distributions by 1cm length groups form the basis for calculating mean squared length. The bottom trawl catches are normalised to 1 nautical mile towing distance and adjusted for length dependant fishing efficiency (Aglen and Nakken 1997, see below). Length distributions from pelagic catches are applied unmodified. Since 2001 the post processing program BEAM has been used for working out the acoustic estimates. This program provides an automatic allocation

of trawl samples to strata (rectangles). The automatic allocation is modified by the user when considered necessary.

Let f_i be the (adjusted) catch by length group *i* and let L_i be the midpoint (cm) of the length interval *i*. Then:

$$\overline{L}^2 = \frac{\sum_{i=i_{\min}}^{i_{\max}} f_i \cdot L_i^{\,2}}{\sum_{i=i_{\min}}^{i_{\max}} f_i} \qquad (4)$$

For each species the total density ($\overline{\rho}_A$) by rectangle and depth zone is now calculated by equation (3). This total density is then split on length groups according to the estimated length distribution. Next, these densities are converted to abundance by multiplying with the area of the rectangle. The abundance by rectangle is then summed for defined main areas (Figure 3.2). Estimates by length are converted to estimates by age using an age length key for each main area.

2.2 Swept area measurements

All vessels were equipped with the standard research bottom trawl Campelen 1800 shrimp trawl with 80 mm (stretched) mesh size in the front. Prior to 1994 a cod-end with 35-40 mm (stretched) mesh size and a cover net with 70 mm mesh size were used. Since this mesh size may lead to considerable escapement of 1 year old cod, the cod ends were in 1994 replaced by cod-ends with 22 mm mesh size. At present a cover net with 116 mm meshes is mostly used. The trawl is now equipped with a rockhopper ground gear. Until and including 1988 a bobbins gear was used, and the cod and haddock indices from the time period 1981-1988 have since been recalculated to 'rockhopper indices' and adjusted for length dependent fishing efficiency and/or sweep width (Godø and Sunnanå 1992, Aglen and Nakken 1997). The sweep wire length is 40 m, plus 12 m wire for connection to the doors. Vaco doors ($6m^2$, 1500kg), which are considered to be the best compromise when doing both pelagic and bottom trawling, have been used as standard trawldoors on board the Norwegian research vessels. On the Russian vessels and hired vessels V-type doors (ca 7 m^2) have been used. Since 2004, R/V "Johan Hjort" and R/V "G.O.Sars" also have used a V-type door ("Steinshamn W-9", $7.1m^2$, 2050kg), the same type as used on the Russian research vessels. In order to achieve constant sampling width of a trawl haul

independent of e.g. depth and wire length, a 10 m rope “locks” the distance between the trawl wires 150-180 m in front of the trawl doors. This is called “strapping”. The distance between the trawl doors is then in most hauls restricted to the range 48-52 m regardless of depth (Engås and Ona 1993, Engås 1995). Strapping was first attempted in the 1993 survey on board one vessel, in 1994 It was used on every third haul and in 1995-1997 on every second haul on all vessels. Since 1998 it has been used on all hauls when weather conditions permitted. Standard tow duration is 30 minutes (until 1985 the tow duration was 60 min.). Trawl performance is constantly monitored by Scanmar trawl sensors, i.e., distance between the doors, vertical opening of the trawl and bottom contact control.

The positions of the trawl stations are pre-defined. When the swept area investigations started in 1981 the survey area was divided into four main areas (A, B, C og D, Fig 3.2) and 35 strata.

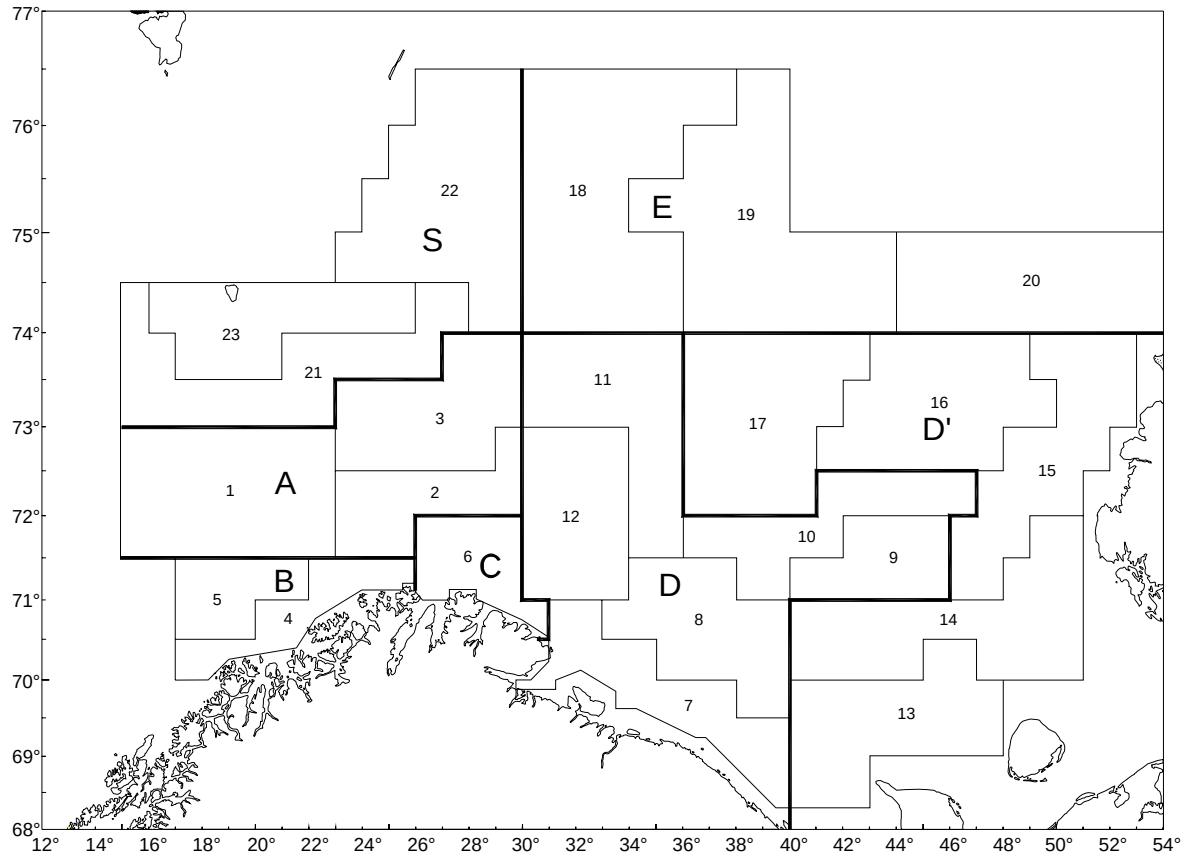

Figure 2.1 Strata (1-23) and Main Areas (A,B,C,D,D’,E and S) used for swept area estimations. The Main Areas are also used for acoustic estimation.

During the first years the number of trawl stations in each stratum was set based on expected fish distribution in order to reduce the variance, i.e., more hauls in strata where high and variable fish densities were expected to occur. During the 1990ies trawl stations have been spread out more evenly, yet the distance between stations in the most important cod strata is shorter (16 n.miles)

compared to the less important strata (24 or 36 n.miles). During the 1990s considerable amounts of young cod were distributed outside the initial four main areas, and in 1993 the investigated area was therefore enlarged by areas D', E, and the ice-free part of Svalbard (S) (Fig. 3.2 and Table 3.1); 28 strata altogether. In the 1993- and 1994 survey reports, the Svalbard area was included in A' and the western (west of 30°E) part of area E. Since 1996 a revised strata system with 23 strata has been used (Figure 2.1). The main reason for reducing the number of strata was the need for a sufficient number of trawl stations in each stratum to get reliable estimates of density and variance.

Swept area fish density estimation

Swept area fish density estimates ($\rho_{s,l}$) by species (s) and length (l) were estimated for each bottom trawl haul by the equation:

$$\rho_{s,l} = \frac{f_{s,l}}{a_{s,l}}$$

$\rho_{s,l}$ number of fish of length l per n.m.^{2} observed on trawl station s

$f_{s,l}$ estimated frequency of length l

$a_{s,l}$ swept area:

$$a_{s,l} = \frac{d_s \cdot EW_l}{1852}$$

d_s towed distance (n.mile)

EW_l length dependent effective fishing width:

$$EW_l = \alpha \cdot l^{\beta} \text{ for } l_{\min} < l < l_{\max}$$
$$EW_l = EW_{l_{\min}} = \alpha \cdot l_{\min}^{\beta} \text{ for } l \le l_{\min}$$
$$EW_l = EW_{l_{\max}} = \alpha \cdot l_{\max}^{\beta} \text{ for } l \ge l_{\max}$$

The parameters are given in the text table below:

Species	α	β	$l_{\min}$	$l_{\max}$
Cod	5.91	0.43	15 cm	62 cm
Haddock	2.08	0.75	15 cm	48 cm

The fishing width was previously fixed to 25 m = 0.0135 nm. Based on Dickson (1993a,b), length dependent effective fishing width for cod and haddock was included in the calculations in 1995 (Korsbrekke *et al*., 1995). Aglen and Nakken (1997) have adjusted both the acoustic and swept area time series back to 1981 for this length dependency based on mean-length-at-age

information. In 1999, the swept area 1983-1995 time series was recalculated for cod and haddock using the new area and strata divisions (Bogstad *et al.* 1999).

For redfish, Greenland halibut and other species, a fishing width of 25 m was applied, independent of fish length.

For each station, s, observations of fish density by length ($\rho_{s,l}$) is summed in 5 cm length-groups. Stratified indices by length-group and stratum will then be:

$$L_{p,l} = \frac{A_p}{S_p} \cdot \sum_{s \text{ in stratum } p} \rho_{s,l}$$

$L_{p,l}$ index, stratum *p*, length-group *l*
A_p area (n.m.^{2}) of stratum *p* (or the part of the stratum covered by the survey)
S_p number of trawl stations in stratum *p*

The coverage of the most northern and most eastern strata differs from year to year. The areas of these strata are therefore calculated according to the coverage each year. Indices are estimated for each stratum within the main areas A, B, C, D, D', E and S. Total number of fish in each 5 cm length group in each main area is estimated by adding the indices of all strata within the area. Total number of fish at age is estimated by using an age-length key constructed for each main area. Total indices on length and age are estimated adding the values for all main areas.

2.3 Sampling of catch and age-length keys

Sorting, weighing, measuring and sampling of the catch are done according to instructions given in Mjanger *et al*. (2005). Since 1999 all data except age are recorded electronically by Scantrol Fishmeter measuring board, connected to stabilized scales. The whole catch or a representative sub sample of most species was length measured on each station.

At each trawl station age (otoliths) and stomach were sampled from one cod per 5 cm length-group. All cod above 80 cm were sampled. The stomach samples were frozen and analysed after the survey. Haddock otoliths were sampled from one specimen per 5 cm length-group. Regarding the redfish species, *Sebastes marinus* and *S. mentella*, otoliths for age determination were sampled from two fish in every 5 cm length-group on every station. Greenland halibut were sorted by sex before length measurement and age (otolith) sampling. From this species otoliths

were collected from 5 fish per 5 cm length group for each sex on all stations. Table 3.2 gives an account of the sampled material.

An age-length key is constructed for each main area. All age samples are included and weighted according to:

$$w_{p,l} = \frac{L_{p,l}}{n_{p,l}}$$

$w_{p,l}$ - weighting factor
$L_{p,l}$ - swept area index of number fish in length-group *l* in stratum *p*
$n_{p,l}$ - number of age samples in length-group *l* and stratum *p*

Fractions are estimated according to:

$$P_a^{(l)} = \frac{\sum_p n_{p,a,l} \cdot w_{p,l}}{\sum_p n_{p,l} \cdot w_{p,l}}$$

$p_a^{(l)}$ - weighted fraction of age *a* in length-group *l* and stratum *p*
$n_{p,a,l}$ - number of age samples of age *a* in length-group *l* and stratum *p*

Number of fish by age is then estimated following the equation:

$$N_a = \sum_p \sum_l L_{p,l} \cdot P_a^{(l)}$$

Mean length and –weight by age is then estimated according to (only shown for weight):

$$W_a = \frac{\sum_p \sum_l \sum_j W_{a,p,l,j} \cdot w_{p,l}}{\sum_p \sum_l \sum_j w_{p,l}}$$

$W_{a,p,l,j}$ - weight of sample *j* in length-group *l*, stratum *p* and age *a*

3. SURVEY OPERATION

The survey in 2005 was conducted with R/V "G.O. Sars" 01.02-07.03 (IMR-BEI-survey no. 2005104, IMR-series no. 70301-70475), R/V "Johan Hjort" 01.02-14.03 (IMR-BEI-survey no. 2005203, IMR-series no. 70001-70203), and R/V “Smolensk” from PINRO 08.02-01.03. The catch data and biological samples from R/V “Smolensk” were converted to the IMR-format “Regfisk” (IMR-series no. 70701-70815). The acoustic data from R/V “Smolensk” was reported to IMR as allocated values by species at 5 n.mile intervals, split on a bottom layer (<10m from bottom) and a pelagic layer (>10m above bottom).

Fig. 3.1 shows survey tracks and trawl stations, and fig. 3.2 shows the trawl stations used for swept area estimation. Table 3.1 shows the area covered by the survey every year. In the 2005 survey 245 hydrographical (CTD) stations and 494 trawl stations were taken (fig. 3.1, table 3.2). 20 of the trawl stations were pelagic trawl hauls in order to get more samples and information to improve the echo scrutinizing by species and fish length. For the calculation of swept area indices, only the successful pre-defined bottom trawl stations within the defined strata system were used. Those added up to 373 stations.

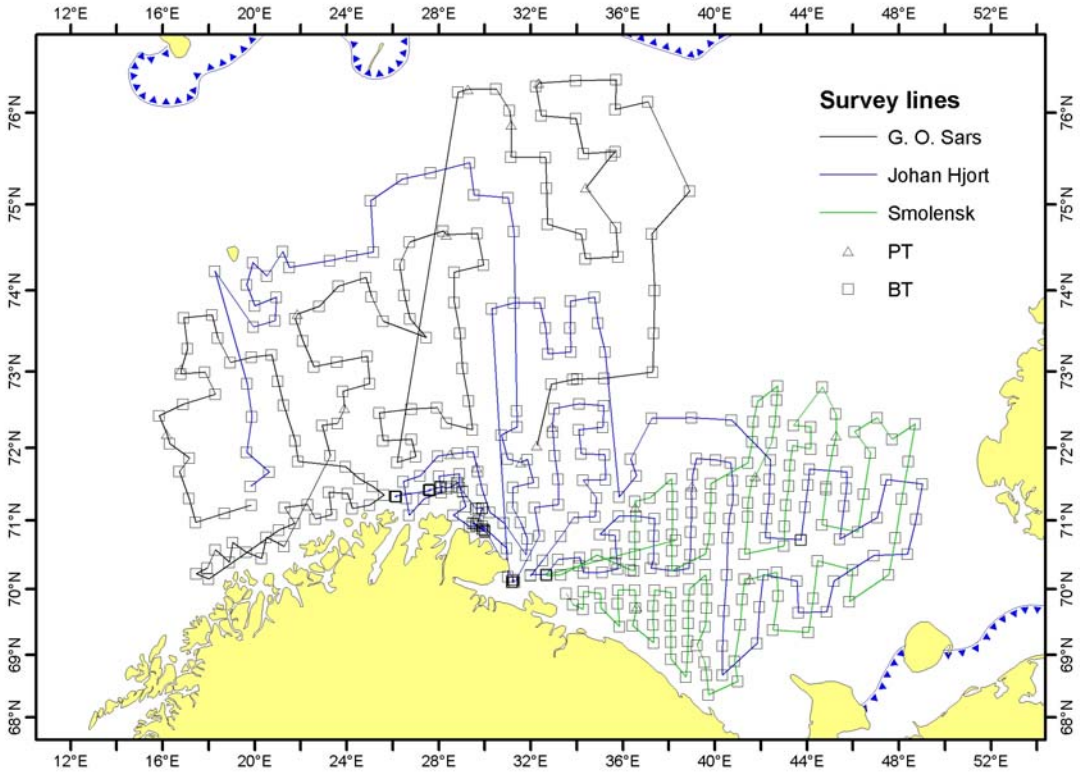

Figure 3.1. Survey tracks and trawl stations R/V "G.O. Sars" and R/V "Johan Hjort" and R/V ”Smolensk” 01.02-14.03.2005.

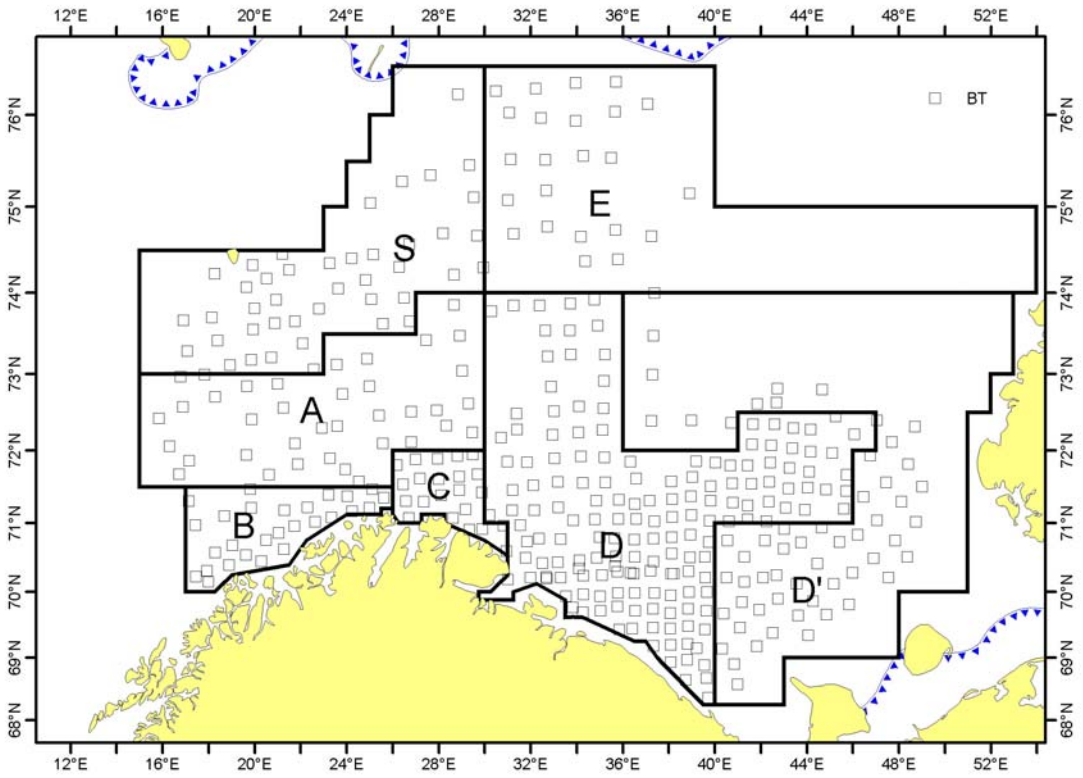

Figure 3.2. Bottom trawl stations used in the swept area estimation in 2005 and borders for the main areas.

Among the bottom trawl stations not used in the swept area calculation are; 91 stations taken for trawl comparisons, and 2 non-predefined hauls for identification of acoustic records. The rest were rejected due to damage or malfunction of the gear. Age sampling from these additional bottom trawl hauls and from pelagic hauls has been used in the calculations.

Table 3.2 gives an account of the sampled length- and age material from pre-defined bottom trawl hauls, other bottom hauls and pelagic hauls.

One zooplankton scientist from PINRO, Murmansk, participated onboard ”G.O. Sars”.

4. HYDROGRAPHY

The standard hydrographical sections ”Fugløya-Bjørnøya” and “Vardø-nord” taken during the last days of the survey. Figure 4.1 shows the observed mean temperature at 50-200 m depth, compared to the period 1999-2005. The Sem Islands section has not been taken since 2001. The value for Vardø-nord is the highest in the series and the value for Fugløya-Bjørnøya is the second highest in the series.

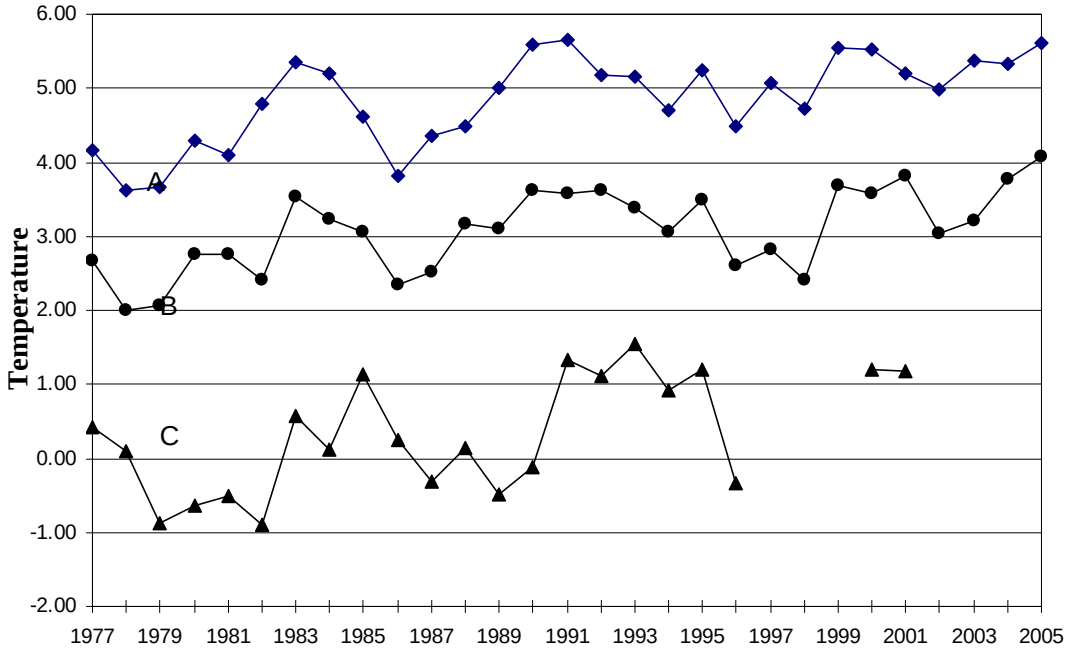

Fig.4.1. Mean temperatures in 50-200 m depth in 1977-2005. A) "Fugløya-Bjørnøya" in March, B) "Vardø-nord" in March, C) Sem Islands in January-February.

Horizontal temperature distribution is shown in figure 4.2 for 10m depth and in figure 4.3 near bottom. Rather high temperatures were observed over most of the area covered. Only at the most shallow stations near Bjørnøya and at the deepest stations near E 40 degrees temperatures below zero were observed. This is not very different from the situation in the 2-3 previous years, but warmer than most of the earlier years of the survey series.

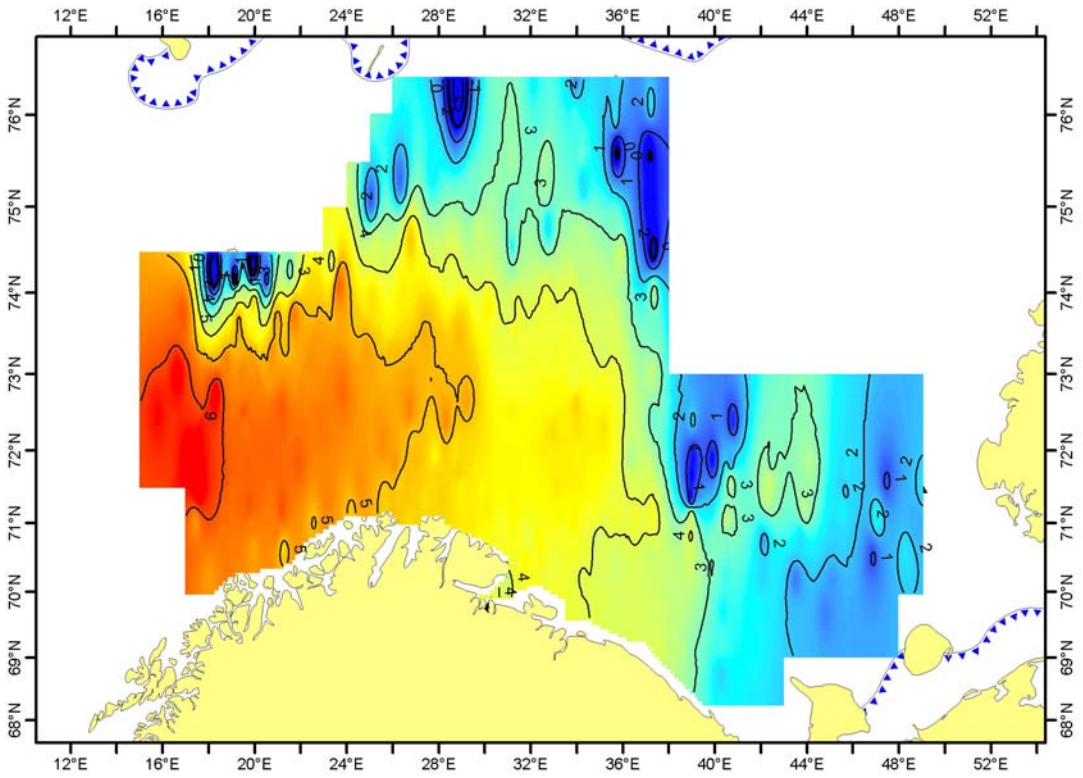

Figure 4.2. Temperature distribution February-March 2005 at 10m depth.

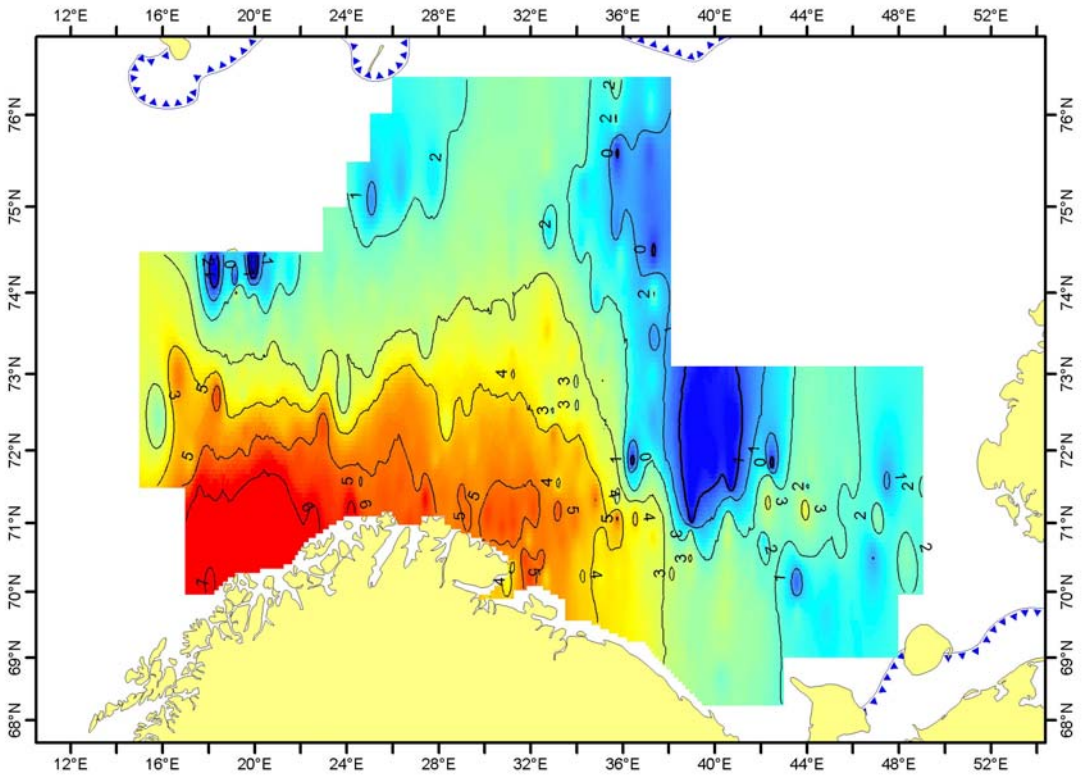

Figure 4.3. Temperature distribution February-March 2005 near bottom.

5. TOTAL ECHO ABUNDANCE OF COD AND HADDOCK

Table 5.1 presents the time series of total echo abundance of cod and haddock in the investigated areas. Since 1993 the acoustic values have been split between the two species. The 2005 value for cod is at a similar low level as in 2004. The 2005 value for haddock is rather high. Only 3 years in the 13 year time series show higher values. The fraction of the total echo abundance recorded in the bottom layer in 2005 was high (0.35 for cod and 0.33 for haddock) compared to most years in the series.

Table 5.2 shows the echo abundance (echo density multiplied by area) distributed on main areas as well as on pelagic versus bottom channels. For cod the values are distributed among the main areas in the same pattern as in 2004. For haddock the contribution from the northern main areas (E and S) were higher than in any earlier years.

Table 5.1. Cod and haddock. Total echo abundance and echo abundance in the 10 m layer above the bottom from acoustic surveys in the Barents Sea winter 1981-2005 (m^2 reflecting surface · 10^{-3}). 1981 - 1992 includes mainly areas A, B, C and D.

6. DISTRIBUTION AND ABUNDANCE OF COD

6.1 Acoustic estimation

Surveys in the Barents Sea at this time of the year mainly cover the immature part of the cod stock. Most of the mature cod (age 7 and older) have started on its spawning migration southwards out of the investigated area, and is therefore to a lesser extent covered. There are indications that a higher proportion than normal spawned along the Finnmark coast both in 2004 and 2005. Thereby a higher proportion of the spawners might have been covered by the survey these years.

Acoustic indices by length and age are given in table 6.1. Table 6.2 shows the acoustic indices for each age group by main areas, in the pelagic layer (P) and in the 10 m layer above the bottom (B). The time series (1981-2005) is presented in table 6.3. The estimates have fluctuated largely

in recent years and the high values observed in 2003 appear as overestimates compared to the results in 2002, 2004 and 2005.

* Indices raised to also represent the Russian EEZ.

6.2 Swept area estimation

Figs. 6.1-6.4 show the geographic distribution of bottom trawl catch rates (number of fish per 3 naut.mile, corresponding to 1 hours towing) for cod for each of the size groups < 20 cm, 20-34 cm, 35-49 cm and > 50 cm. As in previous years the greatest concentrations of the smallest cod (less than 35 cm) were found in the eastern part of the survey area within the Russian EEZ. In addition there were some concentrations near the northern borders of the area covered, indicating that these size groups might have been underestimated.

Table 6.4 presents the abundance indices by 5 cm length groups for each main area. Standard error and coefficient of variation (CV) are also given. Age-length distribution of the total swept area index as well as the distribution of the index by main area and age is given in tables 6.5 and 6.6, respectively. The swept area indices are somewhat higher than the acoustic indices (Table 6.3) for all age groups.

The time series (1981-2005) is shown in table 6.7. In the period 2000-2004 the abundance of 7 year and older fish has increased gradually, but decreased again in 2005. The latest survey confirms that the 2001 year-class is poor, and the 2003 year-class is also indicated to be low. The overall impression from table 6.7 is that survival has improved for most age groups since 1999, but the latest surveys again indicate reduced survival.

* Indices raised to also represent the Russian EEZ.

6.3 Growth

Table 6.8 and 6.10 show length and weight by age for each main area. In most years the largest fish at age has been observed in the south-western main areas (A, B and C). For age 8 there are few observations in main areas D' and E, and those mean lengths and weights are therefore more uncertain.

Tables 6.9 and 6.11 present the time series for mean length (1978-2005) and mean weight (1983-2005) at age for the entire investigated area. Weights and lengths at age were fairly low in the period 1995-2000, but increased somewhat in 2001. Since then there has been moderate fluctuations. The same pattern is reflected in the tabulated annual weight increments (Table 6.12).

Table 6.8. COD. Length (cm) at age in main areas of the Barents Sea winter 2005.

Area	Age (year-class)							
	1 (04)	2 (03)	3 (02)	4 (01)	5 (00)	6 (99)	7 (98)	8 (97)

6.4 Considerations and conclusion

When using the abundance indices for stock assessment it is important to be aware of all the technical changes introduced during the time series. Better acoustic equipment after 1990 has increased the quality of the indices for all age groups. The survey area was enlarged in 1993. This led to higher indices, especially for the youngest age groups, and the indices also became more accurate all over. The introduction of more fine meshed cod-ends in 1994 and fish length dependent fishing width of the trawl (the time series is adjusted for this) did also lead to more small fish relative to larger fish. Over the past 8-10 years the acoustic and swept are indices of cod have been in reasonable agreement and indicated a similar development. Over the most recent 5 year period the acoustic indices have fluctuated more than the swept area indices.

Table 6.13 gives the time series of survey based mortalities (log ratios between survey indices of the same year class in two successive years) since 1993. These mortalities are influenced by natural and fishing mortality, age reading errors, and the catchability at age for the survey. In the period 1993-1999 there was an increasing trend in the survey mortalities. The trend appears most consistent for the age groups 3-7 in the swept area estimates. The later surveys show lower mortalities, but the 2004 and 2005 surveys indicate a new increase. Presumably the mortality of

the youngest age groups (ages 1-3) is mainly caused by predation, while for the older age groups it is mainly caused by the fishery. Before 2001 the survey mortalities for age 4 and older were well above the mortalities estimated in the ICES assessment. Decreasing survey catchability at increasing age could be one reason for this. Another possible reason could be that the assessment does not include all sources of mortality, like discards, unreported catches, or poorly quantified predation.

The observed mortality rates in the acoustic investigations have been more variable. This is explained by changes in fish behaviour and how available the fish is for acoustic registration. During the winter survey 1998 the relative abundance of cod in the bottom channel was lower than the years before, and hence the fish were more available for acoustic registration. A similar situation is observed in 2000 compared with 1999. The negative mortalities observed from 2002 to 2003 are possibly caused by sampling errors; over-representation of dense near-shore concentrations in 2003.

7. DISTRIBUTION AND ABUNDANCE OF HADDOCK

7.1 Acoustic estimation

As for cod it is expected that the survey best covers the immature part of the stock. At this time of the year a large proportion of the mature haddock (age 6 and older) are on its spawning migration south-westwards out of the investigated area. In 2004 and 2005 concentrations of mature haddock have been observed pelagic rather far above bottom along the shelf edge. This concentrations are poorly covered by the bottom trawl sampling.

There are indications that the distribution of age groups 1 and 2 in some years are concentrated in coastal areas not well covered by the survey. This occurred in the late 90s. In the three latest surveys small haddock has been widely distributed, and haddock has been found unusually far to the north. This might be caused by rather favourably hydrographic conditions.

Table 7.1 shows the acoustic abundance indices by length and age, and table 7.2 presents the indices by age within the main areas for the pelagic layer and the bottom layer. As in most of the previous years the highest abundance was observed in main area D. The time series (1981-2005) is presented in table 7.3. The index of age 1 is the highest in the 25 year time series.

7.2 Swept area estimation

Figs. 7.1 - 7.4 show the geographic distribution of bottom trawl catch rates (number of fish per 3 n.mile, corresponding to 1 hours towing) for haddock for each of the size groups < 20 cm, 20-34 cm, 35-49 cm and > 50 cm. As in the two previous years, the distribution extends further to the north than usual, especially for the size groups <20 cm.

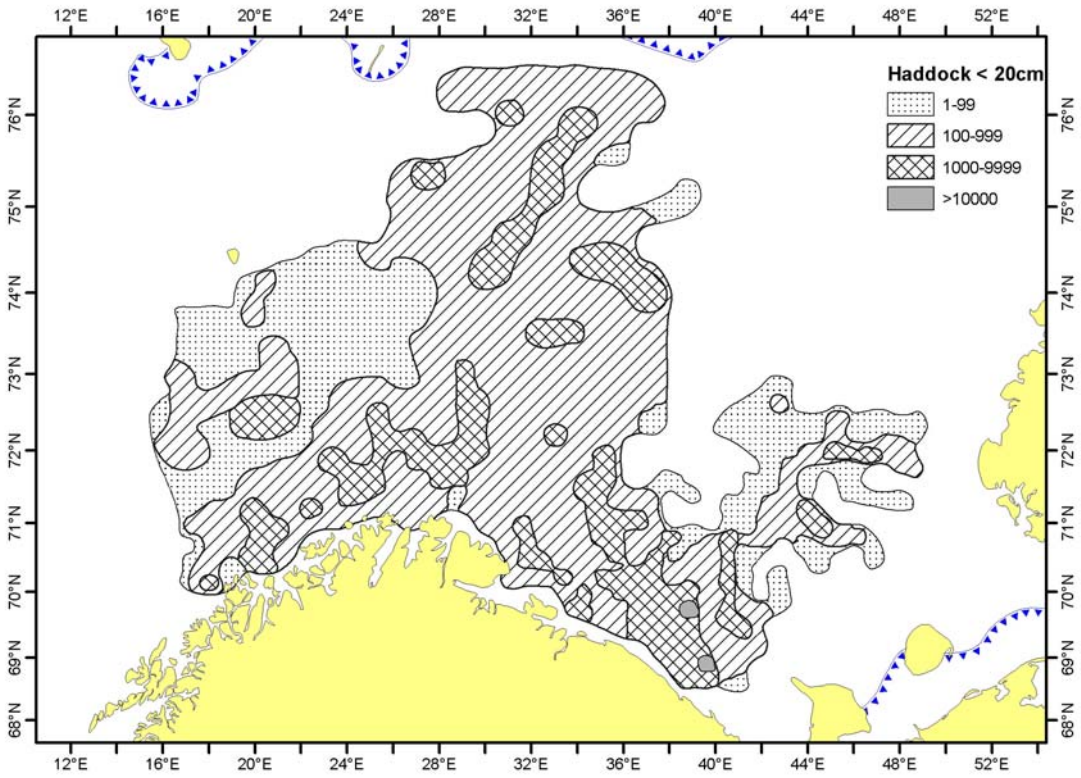

Figure 7.1. HADDOCK < 20 cm. Distribution in the trawl catches winter 2005 (number per hour trawling).

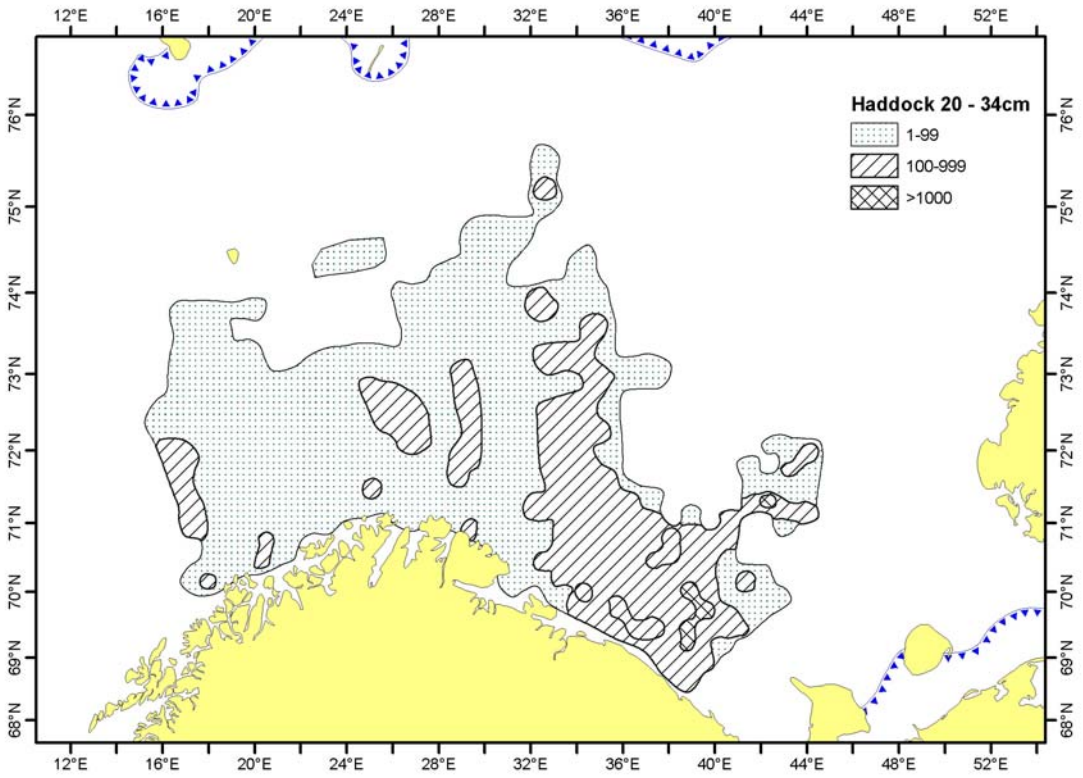

Figure 7.2. HADDOCK 20-34 cm. Distribution in the trawl catches winter 2005 (number per hour trawling).

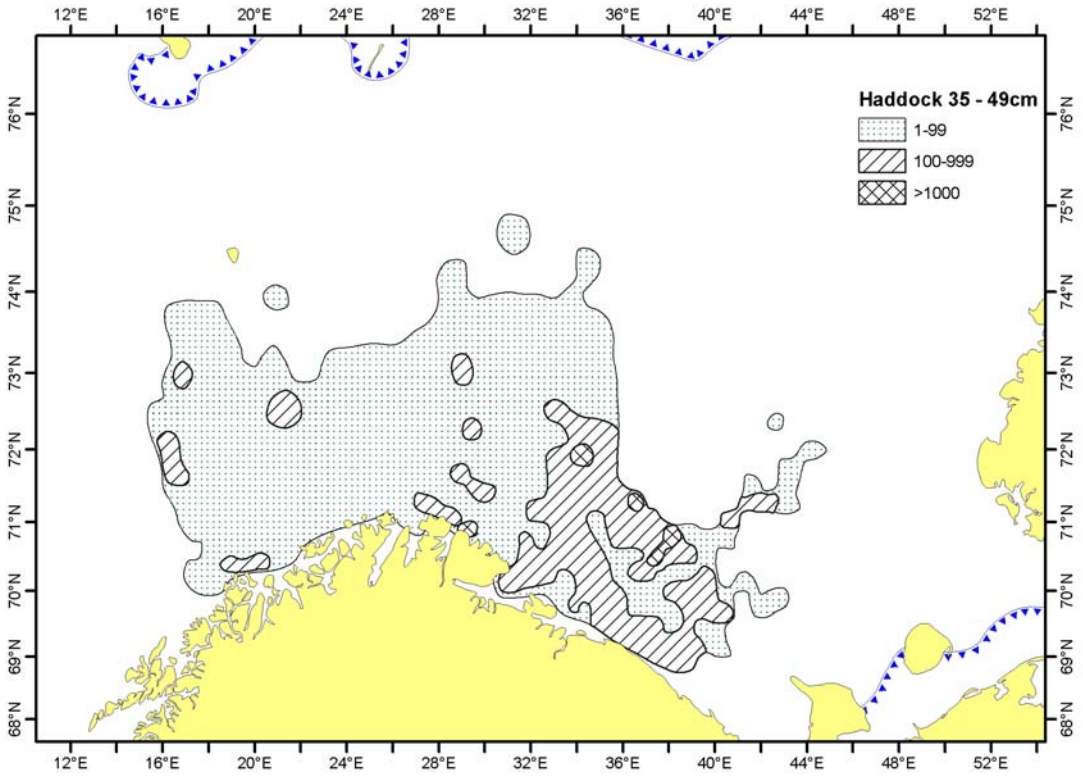

Figure 7.3. HADDOCK 35-49 cm. Distribution in the trawl catches winter 2005 (number per hour trawling).

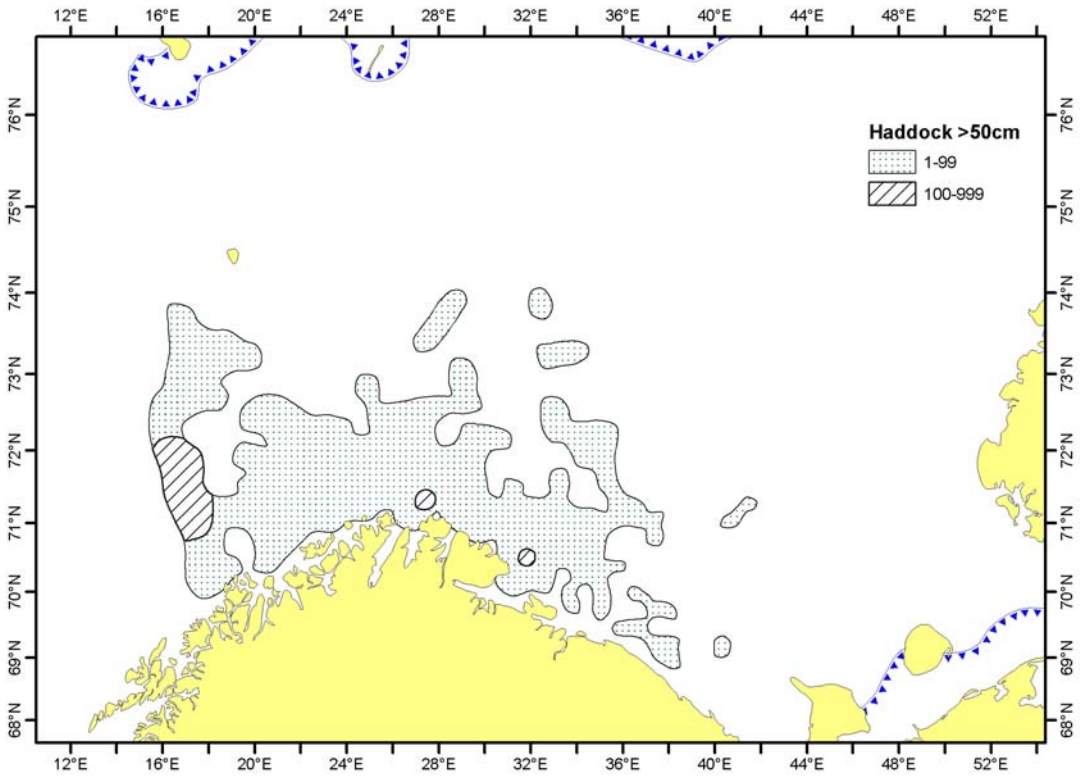

Figure 7.4. HADDOCK > 50 cm. Distribution in the trawl catches winter 2005 (number per hour trawling).

Table 7.4 presents the abundance indices by 5 cm length groups for each main area. Standard error and coefficient of variation (CV) are also given.

Table 7.5 shows the abundance indices by age- and length groups, and table 7.6 presents the indices for each age group by main areas. The time series (1981-2005) is shown in table 7.7. The indices for all the ages 1-7 are above the 1993-2004 average. The swept area index of ages 1 is the highest in the 25 year time series.

Table 7.4. HADDOCK. Abundance indices (I) at length with standard error of mean (S) from bottom trawl hauls for main areas of the Barents Sea winter 2005 (no. in mill).

[1)] Indices raised to also represent the Russian EEZ.

7.3 Growth

Mean length and weight at age for each main area in 2005 are shown in table 7.8 and 7.10. The time series (1983-2005) is shown in tables 7.9 and 7.11. Annual weight increments are shown in Table 7.12. Both lengths and weights show a decreasing trend since 2003.

7.4 Conclusion

Survey mortalities based on the acoustic indices (tables 7.13) have varied between years, and for most age groups there is no obvious trend. Mortalities based on the swept area indices show a decreasing trend since 1998 (table 7.13).

Table 7.13. Total mortality observed for haddock during the winter survey in the Barents Sea for the period 1993-2005.

8. DISTRIBUTION AND ABUNDANCE OF REDFISH

8.1 Acoustic estimation

Earlier reports from this survey has presented distribution maps and abundance indices based on acoustic observations of redfish. In recent years blue whiting has dominated the acoustic records in some of the main redfish areas. Due to incomplete pelagic trawl sampling the splitting of acoustic records between blue whiting and redfish has been very uncertain. The uncertainty relates mainly to the redfish, since it only make up a very minor proportion of the total value. This was also the case in 2003 and 2004, and the acoustic results for redfish are therefore not included in the report.

8.2 Swept area estimation

The swept area time series for redfish (tables 8.3 and 8.4) are based on catch data from trawls with bobbins gear until 1988 inclusive, and rockhopper gear since 1989. The time series has not been adjusted for this change.

Fig. 8.1 shows the geographical distribution of ***S. marinus*** based on the catch rates in bottom trawl. The distribution in 2005 is very similar to those observed in the two previous years. Table 8.1 presents swept area indices by 5 cm length groups with standard error for each main area in addition to the coefficient of variation for the total area.

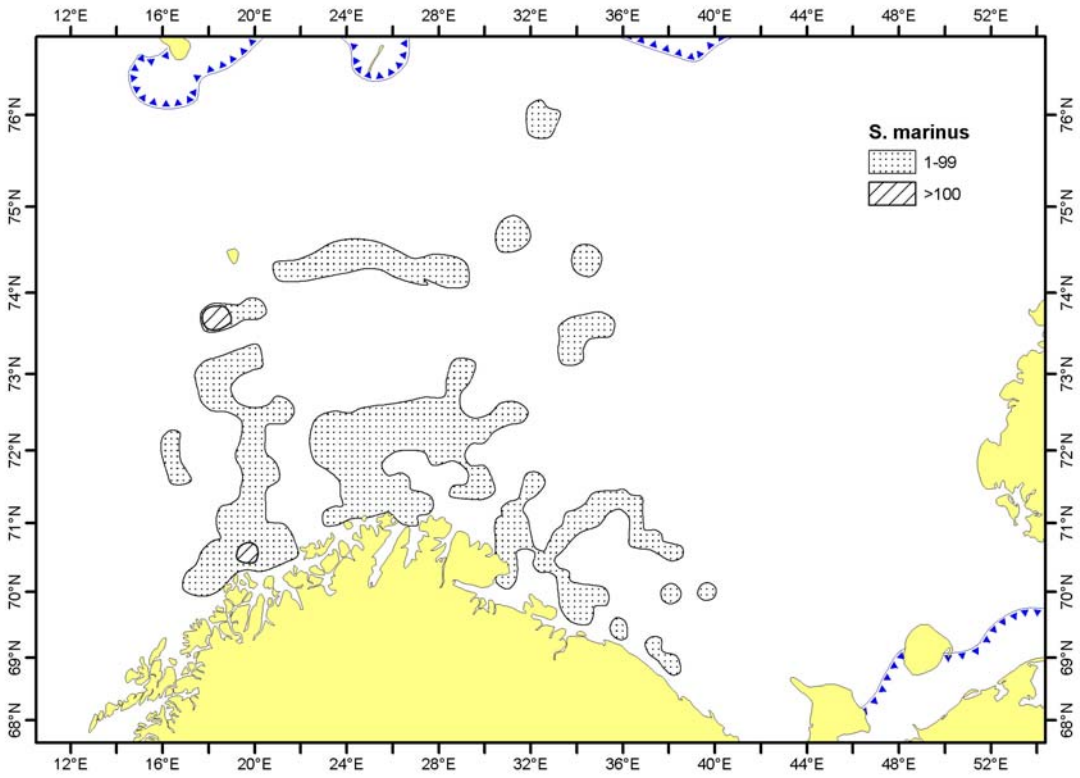

Figure 8.1. *Sebastes marinus*. Distribution in the trawl catches winter 2005 (no. per hour trawling).

The time series for 1986-2005 (table 8.3), shows historic low indices for all the length-groups below 30 cm. Thus, there are no signs of improved recruitment.

1) Indices raised to also represent the Russian EEZ.

The mapping of the distribution of ***S. mentella*** (fig. 8.2) is not complete in the north western part of the surveyed area due to this species' extensive distribution further north in the Svalbard area, west and north of Spitsbergen.

Table 8.2 presents the swept area indices by 5 cm length groups with corresponding standard errors for each main area in addition to the coefficient of variation for the total area.

The time series (1986-2005) of swept area indices for *S. mentella* is presented in table 8.4. The indices for fish less than 30 cm are very low. The future of the *S. mentella* stock is relying on the survival of the last good year classes born in 1989-1990 before the recruitment collapse in 1991. These year classes, at present above 30 cm, compose the bulk of the stock, and should be protected as much as possible to improve the recruitment to maintain a fishery on this resource in the future.

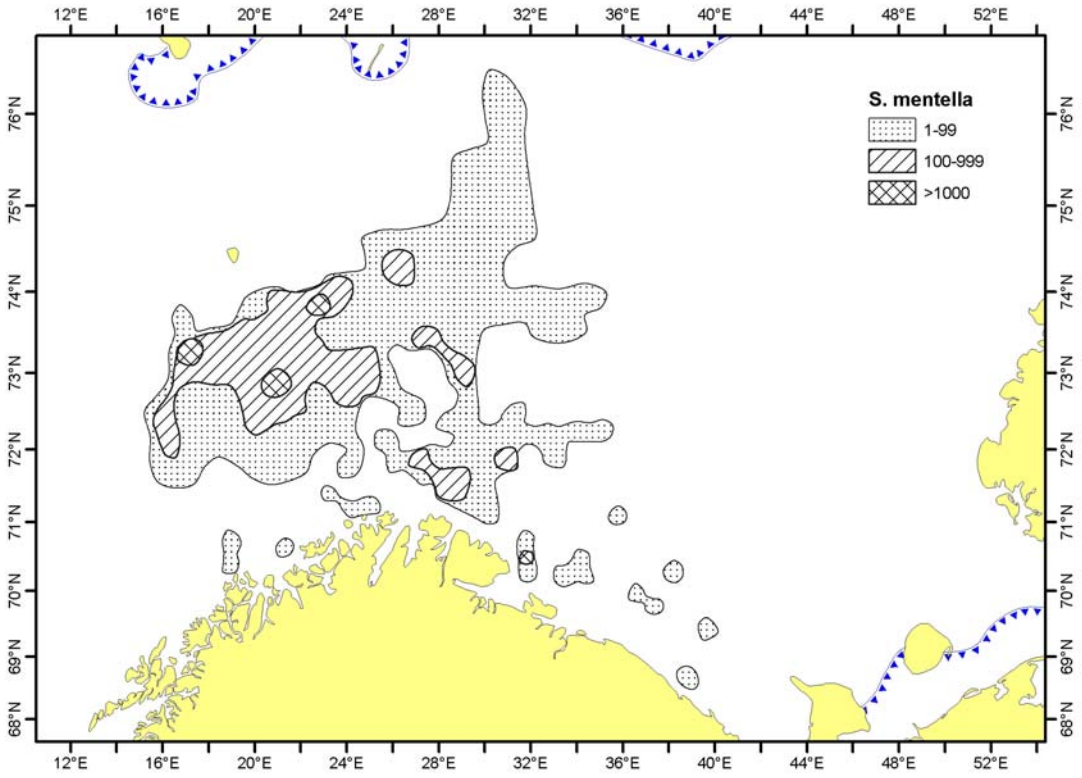

Figure 8.2. *Sebastes mentella*. Distribution in the trawl catches winter 2005 (no. per hour trawling).

Table 8.4. SEBASTES MENTELLA.[1] Abundance indices from bottom trawl surveys in the Barents Sea winter 1986-2005 (numbers in millions). 1986-1992 includes only main areas A. B. C and D.

1) Includes unidentified Sebastes specimens, mostly less than 15 cm.
2) Indices raised to also represent the Russian EEZ.

9. DISTRIBUTION AND ABUNDANCE OF OTHER SPECIES

9.1 Greenland halibut

Fig. 9.1 shows the distribution of bottom trawl catch rates of Greenland halibut. The most important distribution areas for the adult fish (depths between 500 and 1000 m along the western slope), are not covered by the survey. The observed distribution pattern was similar to those observed in previous years' surveys.

Table 9.1 presents the swept area indices by 5 cm length groups, with corresponding standard errors for each main area, in addition to the coefficient of variation for the total area. Most of the Greenland halibut was found in the main areas S and E. For most length groups the coefficient of variation is higher than for cod and haddock.

The time series for 1990-2005 is presented in table 9.2. Compared to the 2004 values the indices for nearly all size groups have increased.

9.2 Blue whiting

Since 2000 the blue whiting has shown a wider distribution than usual. The echo recordings in 2001 and 2002 indicated unusual high abundance in the Barents Sea, while in 2003 it had decreased considerably. In the 2004 survey the echo abundance increased again and remained high in 2005. Figure 9.2 shows the geographical distribution of the bottom trawl catch rates of blue whiting in 2005. This distribution is similar to the one observed in 2004. Since the fish was mainly found pelagic the bottom trawl do not reflect the real density distribution, but gives some indication of the distribution limits. For the same reason the swept area estimates shown in Table 9.3 are not considered to be a good indicator of abundance, but may reflect the size distribution of the fish. Compared to the three previous years the contribution from the size group 10-14 cm (age 1) has increased.

10. COMPARISONS BETWEEN RESEARCH VESSELS

In total “G.O.Sars” and “Johan Hjort” worked 80 experimental bottom trawl tows. About 60 of these were parallel tows. The reasons for these experimental hauls was to further optimise the use of the new type of trawl doors, and to test out a modified rigging to obtain more stable trawl performance on soft bottom. In addition it was tested for any differences in catch rates when using Thyborøn doors (135’’, 9 m^2) compared to using Steinshamn doors. No obvious differences were revealed. One important finding was that the use of angle sensors on the doors is an important tool for optimal adjustments of the warp lengths. The results will be given in a separate report.

Appendix. Zooplankton investigations

Results from macroplankton research
in the Barents Sea in autumn-winter 2004/05
by Natalia Zhukova

Summary
Regular macroplankton surveys have been conducted by PINRO in the Barents Sea since 1952. This research is carried out, most of all, with the purpose to study a relative abundance and distribution of euphausiids (krill), which represent one of the central rings in the trophic chain and serve as an important food component for many commercial fishes, such as capelin and cod. Macroplankton surveys involve annual monitoring of the abundance and distribution of crustaceans in the period of autumn-winter trawl-acoustic survey for demersal fishes. The trawl net (50 cm diameter of opening, sieve mesh size – 564 μm) attached to the upper headline of bottom trawl and taking macroplankton in 5-10 m layer from the bottom was used as a sampling gear. Since in winter krill are concentrated in the near-bottom layer and have no pronounced daily migrations, the results from the catches of euphausiids during autumn-winter survey are applied to estimate year-to-year dynamics of their abundance in the Barents Sea.

Material and methods
In the period of the cruise, 56 plankton samples have been collected. Samples were preserved in 10 % formaldehyde. The indices of euphausiids abundance expressed in ind./1000 m^3 are calculated by the results from euphausiids catches by trawl net. These indices are derived as an arithmetic mean from the sum of all the catches taken in some fishing areas corresponding to the scheme of the Barents Sea divisioning, adopted in PINRO (fig.1). The total length of krill was measured from the tip of rostrum to the end of telson. Some of krill samples were worked on board (specific and size composition of euphausiids). The rest of samples will be determined at IMR, Bergen, Norway.

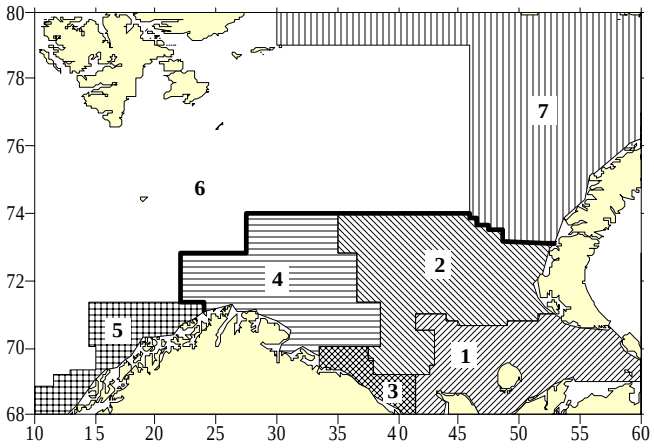

Fig.1. Local fishery areas in the Barents Sea (PINRO Proceedings, 1957, 10: 281).
1-Eastern areas; 2-Central areas; 3-Coastal areas; 4-Western areas; 5-Norwegian coast; 6-Northwestern areas; 7-Northeastern areas.
1, 2, 3, 4 – Southern part of the Barents Sea.

The received data on the cruise by the Norwegian R/V “G.O.Sars” have been incorporated with the data, which were received during trawl-acoustic survey for demersal fishes on the cruise by the Russian R/V “Fridjof Nansen”. For this study data from the 3 research vessels will be incorporated (fig.2).

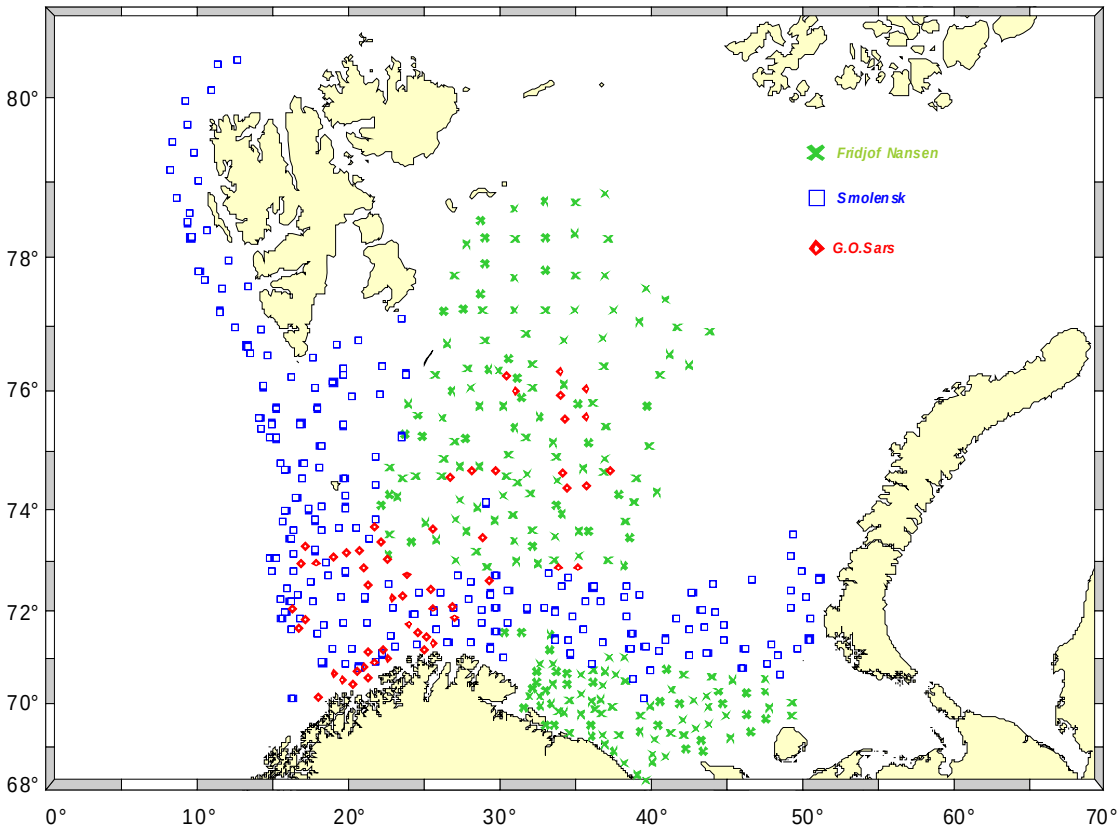

Fig.2. Map of the Barents Sea with the sampling stations where a net attached to the trawl was applied as a sampling gear during October-February 2004/05.
R/Vs “Fridjof Nansen” (13.10-28.12.04), “Smolensk” (14.10-29.12.04), “G.O.Sars” (06.02-07.03.05).

Results

By the results of the processing of samples collected in autumn-winter period of 2004/05, the mean annual indices of euphausiids abundance in the southern and northwestern sea exceeded the long-term mean in 1.3 and 1.1 times, respectively (Table 1). A slight decrease in krill abundance as compared to the previous year was noticed.

Table 1. Mean annual indices of krill abundance, ind./1000 m^3

Year	Mean annual indices of krill abundance	
	Areas 1, 2, 3, 4	Area 6
October-February 2003/04	689	689
October-February 2004/05	558	536
Mean for 1952-2002	411	464

However, a change in the distribution of krill in the Barents Sea was observed (fig.3). The decrease of euphausiids abundance was in the western and coastal areas, whereas in the eastern sea there was an increase in the number of euphausiids. Krill abundance was kept on the same level in the central areas as compared to 2003.

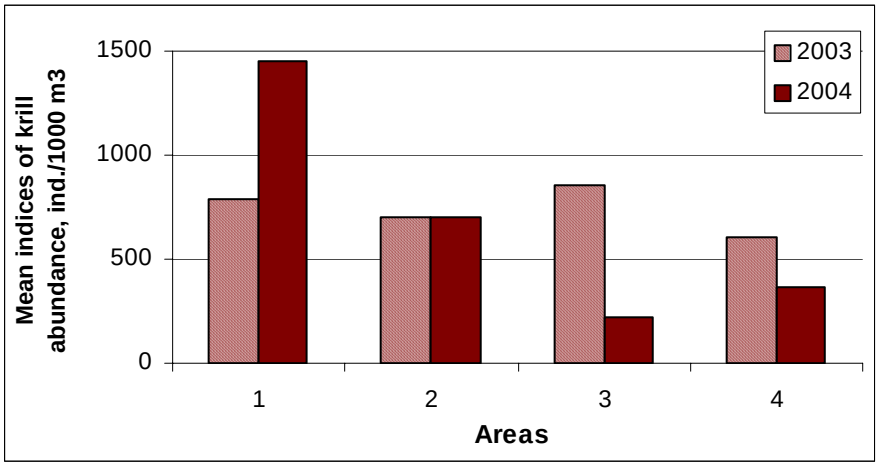

Fig.3. Mean indices of krill abundance in the separated areas of the Barents Sea, ind./1000 m^3.
1-Eastern areas; 2-Central areas; 3-Coastal areas; 4-Western areas.

The densest near-bottom concentrations of krill (> 5000 ind./1000 m^3) were registered in the northern and southeastern sea (Fig.4). They distributed in the limited area. The dense concentrations of euphausiids (1000-5000 ind./1000 m^3) were located in the northern, central and eastern Barents Sea. The near-bottom swarms of crustaceans with the mean density (500-1000 ind./1000 m^3) were registered in the wide area both in the southern and northern sea. The lowest near-bottom concentrations of krill were observed in the coastal areas.

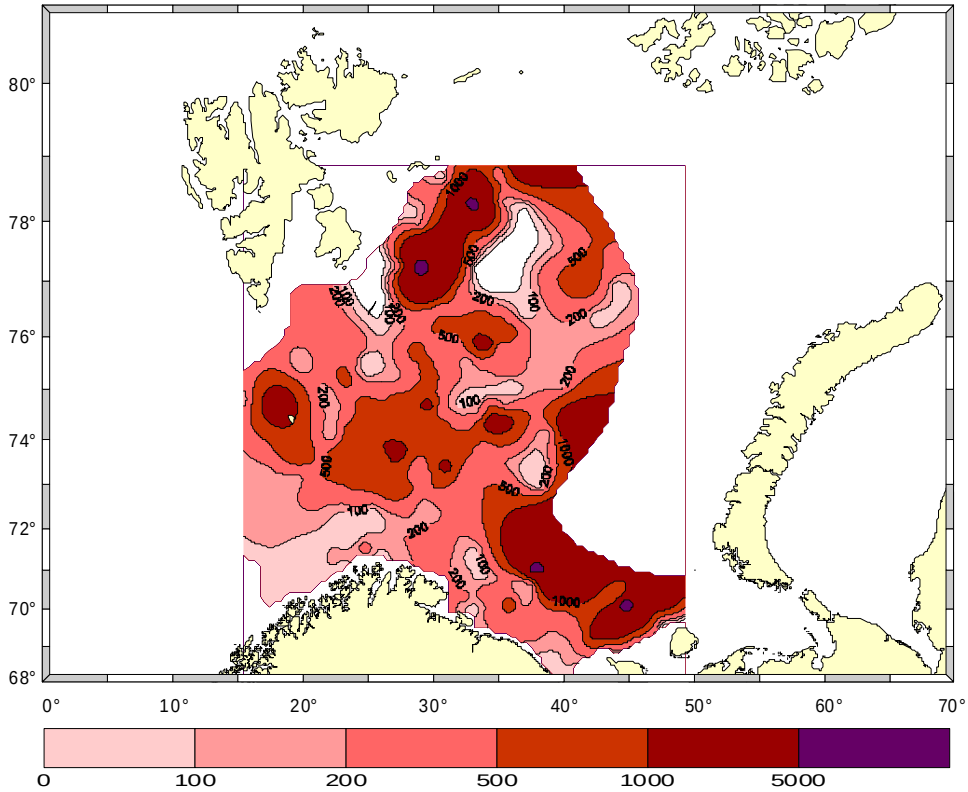

Fig.4. Winter distribution of krill in the near-bottom layer in October-February 2004/05, ind./1000 m^3 (based on data from the R/Vs "Fridjof Nansen" and "G.O.Sars").

Specific composition of euphausiids in February 2005 is given in Fig.5. In the samples *Thysanoessa inermis* prevailed and made up 81 %. The relative abundance of *T. longicaudata* was 13 %, of *Meganyctiphanes norvegica* – 4 % and of *T. raschii* – 2 %. Only single specimens of warm water euphausiid *Nematoscelis megalops* were found in the catches by trawl net in the western sea (0.32 % of the total abundance of euphausiids in samples).

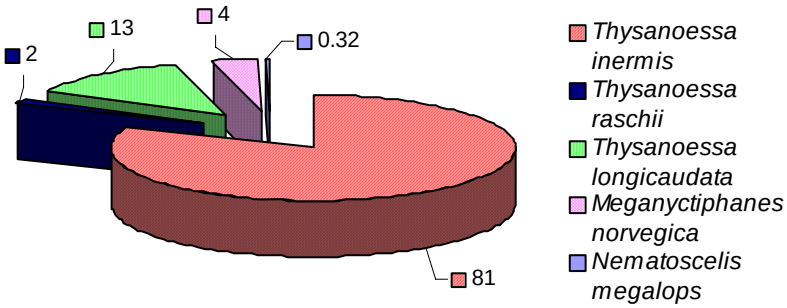

Fig.5. Relative amount of krill species in February 2005, % from the total number of krill in samples (based on data from "G.O.Sars").

Besides the euphausiids, the abundant representatives of macroplankton in the trawl net samples were hyperiids and arrowworms (fig.6 A, B). The indices of abundance of hyperiids fluctuated from 1 to 1128 ind./1000 m^3, the mean index of abundance of *Themisto spp.* amounted to 56 ind./1000 m^3. The indices of the arrowworms abundance varied from 6 to 5280 ind./1000 m^3. In the period of the cruise the mean index of abundance of *Sagitta spp*. was 626 ind./1000 m^3.

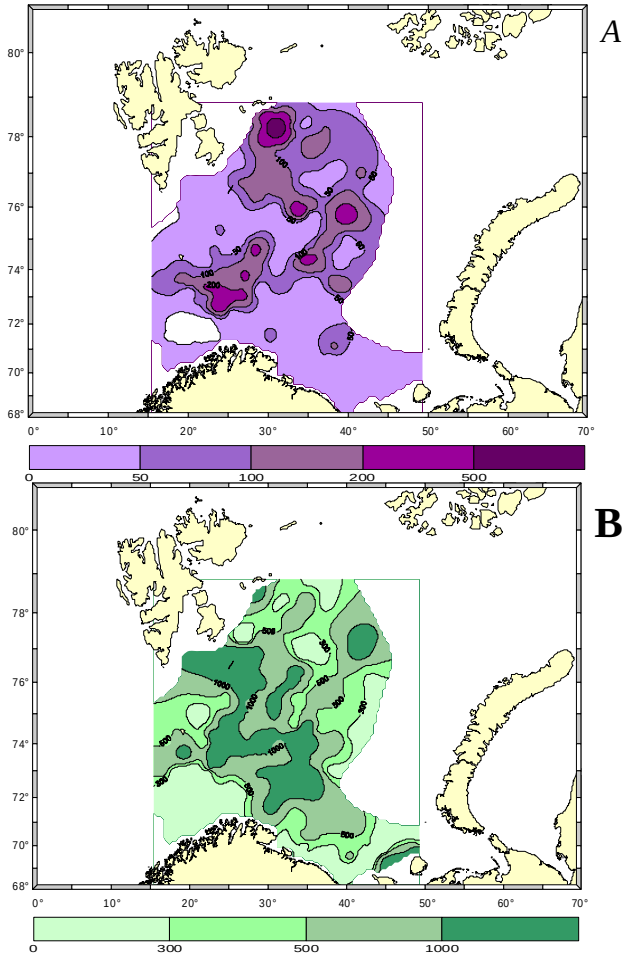

Fig.6. Winter distribution of hyperiids (A) and arrowworms (B) in the near-bottom layer in October-February 2004/05, ind./1000 m^3 (based on data from the R/Vs "Fridjof Nansen" and "G.O.Sars").
